The Value of Continuous Turbidity Monitoring and Particle Counting. From the foregoing discussion of effluent quality patterns, the value of providing continuous monitoring of filtrate quality for each individual filter becomes apparent. As noted earlier, it is useful to observe the length of the initial filtrate quality improvement period to guide the duration of filtering to waste. Continuous monitoring is also especially effective for detecting the onset of end-of-run breakthrough. This is especially important because research has shown that along with increased turbidity at breakthrough, even more significant passage of specific particulate contaminants occurs. Robeck et al. (1964) showed increases in filter effluent viruses at breakthrough, whereas Logsdon et al. (1981a) demonstrated this for asbestos fibers. In another study, Logsdon et al. (1985) showed that a threefold end-of-run change in turbidity for an alum-coagulated and settled surface water corresponded to a 30- to 40-fold change in the effluent concentration of *Giardia* cysts. Similarly, Huck et al. (2002) showed significantly decreased log removal of *C. parvum* oocysts at onset of breakthrough and breakthrough conditions.

Important fundamental differences between measurement of turbidity and optical blockage based particle counts are described in Chap. 3. Filter effluents with very low concentrations of greater than 2 μm size particles that can be detected by a particle counter typically have very low turbidity. Because hydraulic shear is more likely to cause detachment of particles of a few microns in size compared with submicron-sized particles, continuous particle count monitoring data frequently show earlier and more significant relative change indicating end-of-run breakthrough compared with turbidity data; a classic example of this is shown in Fig. 10-17, taken from the work of Huck et al. (2002). Early detection of breakthrough is especially significant in light of the associated increases in filter effluent pathogen levels found in the same study. In general, typical online particle counters can detect increases in concentrations of particles greater than 2 μm in size that may not be associated with significant increases in filtrate turbidity and so can provide plant operators with early warning of incipient turbidity breakthrough. This is especially true for low-turbidity waters below 0.1 ntu because the turbidity measurement is reaching its lower limit of detection. The monitoring of particle counts in filtered waters can improve understanding and control of the filtration process and especially the impacts of plant operation on filtered water quality.

The Critical Importance of Adequate Prefilter Coagulation

Because of the particle removal mechanisms in deep-bed filtration, continuous pretreatment that produces destabilized filter influent particles is absolutely essential to producing

FIGURE 10-17 Turbidity and particle counts during onset of breakthrough for a pilot filter. (Source: Huck et al., 2002.)

good-quality effluent from rapid media filters; this is expected based on fundamental filtration theory. Any interruption of good pretreatment (e.g., proper coagulation) results in an almost immediate deterioration of filtrate quality because particle attachment to filter media and previously deposited particles decreases. Long before the development of fundamental theories, Fuller’s famous work (1898) recognized this, as evidenced by this quotation from his 1898 report: “In all cases, experience showed that for successful filtration, the coagulation of the water as it enters the filter must be practically complete.”

Intermittent causes of inadequate coagulation include failure of coagulant chemical

FIGURE 10-18 Influence of loss of chemical feed on filter performance. (Source: Trussell et al., 1980.)

feed pumps and sudden changes in raw water quality without concomitant coagulant dosing changes. The latter case was documented in the Robeck et al. (1964) study at Gaffney, SC. Two filters at 5 and 25 m/h (2 and 5 gpm/ft²) were operating in parallel and producing about equal turbidity in the filtrate; however, when the quality of the source water suddenly worsened and coagulation was thereby upset, the effluent of both filters deteriorated sharply. The immediate detrimental impact of loss of coagulant dosing on filtrate quality during an in-line direct filtration pilot study was examined by Trussell et al. (1980), as shown in Fig. 10-18. In

this case, the coagulant feed was discontinued for 30 minutes, and filtrate turbidity rose sharply until the chemical feed was resumed.

Most importantly, a number of studies have demonstrated that proper coagulation is the most important factor for effective removal of protozoan pathogens by media filters. Logsdon et al. (1981b) found a 10- to 50-fold increase in effluent *Giardia* cyst concentrations when turbidity increased by only 0.1 to 0.3 ntu following coagulant feed interruption. Patania et al. (1995) showed poor removal of *Cryptosporidium* oocysts and *Giardia* cysts when no coagulant was added during pilot studies of GAC and anthracite/sand dual-media filters. The pilot study by Huck et al. (2002) examined impacts of suboptimal coagulation as well as no coagulation and found dramatic impacts on removal of *Cryptosporidium* oocysts by media filters. Thus all precautions must be taken to ensure that the chemical dosage is appropriate and that the feed is maintained reliably. This is even more critical in direct filtration because of the short detention time ahead of the filters; that is, there is less time to identify and correct a coagulation problem. As noted in Chap. 3, online monitoring of the streaming current after rapid mixing is an excellent method to immediately detect loss of chemical feed or sudden changes in raw water quality. Prefilter treatment processes that affect the size (flocculation) and amount (clarification) of particles in the filter influent also affect filter performance, but mostly with respect to head loss development and the length of a filter run, not the ability of the deep bed to remove particles adequately for some period of time.

Detrimental Effects of Rate Increases and Restarting Dirty Filters

If the rate of filtration is increased on a dirty filter, the equilibrium between the attachment forces holding the solids in the filter and the hydraulic shearing forces tending to dislodge those solids is disturbed. The result is a temporary flushing of solids deeper into the filter and into the filtrate; the effect is more significant if the rate change is sudden and for dirtier filters. The relative effect of rate changes is also affected by the nature of the removed solids, that is, weak floc versus stronger floc, use of filter aids, etc.

Cleasby et al. (1963) showed that the amount of material (iron floc) flushed through the filter was greater for sudden increases in filtration rate than for gradual increases in rate. Also, the amount of material released was greater for large increases than for small increases, but the amount was not affected by the duration of the maximum imposed rate of filtration. The detrimental impact of sudden rate increases on dirty filters also is evident in the work of Tuepker and Buescher (1968) and in the studies of DiBernardo and Cleasby (1980).

Again, the impacts of rate changes on pathogens in filter effluents are of most concern. The studies by Logsdon et al. (1981b) showed that when the filtration rate was increased suddenly from 11 to 27 m/h (4.5–11 gpm/ft²), the turbidity in the effluent increased 4-fold, whereas effluent concentrations of *G. muris* cysts increased 25-fold.

Significant detrimental filter effluent impacts can occur when starting up a dirty filter after brief idle periods. Trussell et al. (1980) demonstrated this based on particle counts, as shown in Fig. 10-19. In the investigation of the causes of a cryptosporidiosis outbreak in Georgia, Logsdon et al. (1990) reported that restarting dirty filters resulted in filtered water turbidities of 0.5 to 5 ntu that persisted for 1 to 1.5 hours. In contrast, filters operated continuously after backwashing had low turbidities of 0.1 to 0.2 ntu. As a result, it was recommended that dirty filters should not be restarted.

These results demonstrate that filtration rate increases on dirty filters should be avoided or minimized and made very gradually (e.g., over 10 minutes). Routine operation of treatment plants often results in undesired rate increases; overall plant design should seek to minimize the need for this to occur. A common situation is to maintain overall plant production during filter backwashing by increasing the HLR for in-service filters while one filter is taken out of service for backwash. Analysis of effluent turbidity and particle counts versus

FIGURE 10-19 Influence of stop-start on filter performance. (Source: Trussell et al., 1980.)

run time for the in-service filters frequently clearly show when other filters are backwashed by a sudden intermittent increase in these parameters; this is difficult to avoid despite careful rate change control. In some cases, the required filtration rate increase is made more severe if the source of backwash water is a clearwell that must remain at a certain level to meet disinfection requirements. Appropriate provision of storage, a separate backwash source, or allowance for decreased plant production during backwash should be used to minimize required flow rate increases for in-service media filters.

Head Loss Development During a Filter Run

The rate of increase in head loss during the filter run is roughly proportional to the rate of solids capture by the filter. Assuming essentially complete capture of incoming solids, the head loss develops in proportion to the filtration rate V and the influent suspended solids concentration C_0 . The rate of head loss development is reduced if the solids capture occurs over a greater depth of the bed rather than in a thin upper layer of the bed. A coarser grain size encourages greater penetration of solids into the bed and possibly different deposit morphology, thereby reducing the rate of head loss development per unit mass of solids captured. As noted earlier, particle size also can affect deposit morphology and density with subsequent impacts on head loss.

The most common head loss pattern encountered in rapid filtration is linear with respect to volume of filtrate or nearly linear, as shown by Cleasby and Baumann (1962) for three constant-rate 5 to 15 m/h (2–6 gpm/ft²) runs and one declining-rate run for the same filter. This linear head loss would be typical for most alum- or iron-coagulated waters. For

FIGURE 10-20 Head loss development for four pilot filters after alum coagulation; dissolved air flotation prior to filtration (see Table 10-5 for filter media descriptions).

constant-rate filtration, linear head loss increase with filter run time (thus filtrate volume) is typical.

Examples of head loss development for four different pilot filters operated at constant rate are shown in Fig. 10-20; these data correspond to the turbidity data in Fig. 10-16 and media specification in Table 10-5 [see Edzwald et al. (1999) for study details]. The data in Fig. 10-20 reflect the predicted effect of media size and bed depth on clean-bed head loss. The rates of head loss development versus time are almost the same for all four filters despite the two times higher HLR for the three coarser media filters compared with the lower rate for the finer dual-media filter (20 m/h or 8 gpm/ft² versus 10 m/h or 4 gpm/ft²); this means that the higher-rate filters remove twice the amount of suspended solids per unit time (and would have half the head loss rate per unit volume filtered). The reason for this result is the deeper penetration of solids for the coarser-media filters, as shown in the Fig. 10-21 plots of additional (or clogging) head loss development versus run time for different bed depths for the lower-rate, dual-media filter and the higher-rate, coarser-dual-media filter. A much greater fraction of the total head loss occurs in the upper section of the top-layer anthracite for the lower-rate, finer-media filter compared to the higher-rate, coarser-media filter.

An accelerating or exponentially increasing head loss versus unit filtrate volume pattern is observed less commonly. This pattern is caused by partial capture of solids in a surface cake and/or by heavy solids removal within a thin layer of the media at the top (Cleasby and Baumann, 1962). In this case, increasing the filtration rate reduces the exponential tendency by encouraging greater penetration of solids into the bed and increases the production to a given head loss. Quality of filtrate also must be observed, however, if such increases in filtration rate are being considered.

In the absence of plant- or pilot-scale data to assist in predicting development of head loss, experimental values of mass of solids captured per unit filter area per unit increase in head loss sometimes are used for prediction of clogging head loss. This is an admittedly simplistic

FIGURE 10-21 Clogging head loss development at several bed depths for two different pilot filters [data for filter runs in Figs 10-16 and 10-20 for low-rate (10 m/h) conventional dual media on the top and for high-rate (20 m/h) dual media on the bottom (see Table 10-5 for media descriptions)].

concept. The values used depend on the density of the solids, the ES of the media where flow enters the filter, and the filtration rate. Typical values range from 0.55 to 5.5 kg/m²/m (0.035–0.35 lb/ft²/ft) (Montgomery, 1985) and more commonly less than 1.6 kg/m²/m (0.1 lb/ft²/ft) for flocculent solids using typical potable water filter media and filtration rates. This approach can be applied only when a linear head loss versus time pattern is expected.

The Detrimental Effects of Negative Head

Some filter arrangements and operating practices can result in pressures below atmospheric pressure (i.e., negative head) in the filter bed during a filter cycle. This can occur in gravity filters when the total head loss at any depth in the filter bed exceeds the static head (i.e., water depth) at that depth; the schematic head profiles in Fig. 10-22 illustrate this concept. Negative head is more likely to occur if gravity filters are operated with low submergence of the media and if the filter effluent exits to the clearwell at an elevation below the top elevation of the filter bed.

FIGURE 10-22 Head profiles in media filtration; filtration time t_1 is less than time t_2 .

Negative head is undesirable because dissolved gases in the influent water may be released in the zone of negative pressure, causing gas bubbles to accumulate during the filter cycle (called *air binding*). Accumulations of gas causes more rapid development of head loss and poorer quality of filtrate because the flow velocity is higher around the gas pockets. Negative head can be avoided completely by terminating the filter run before the total head loss reaches the submergence depth of the media or by causing the effluent to exit at or above the surface of the filter bed.

FLOW CONTROL IN FILTRATION

Why Control Is Needed

The need for some method of filter flow control has been recognized since the early days of potable water filtration. If no attempt is made to control flow, the filters may not share the total plant flow in a reasonably equal manner, or sudden changes in flow rate may occur, both of which could cause filtrate quality to suffer. For these reasons, a number of papers presenting alternative flow control systems have been published (Aultman, 1959; Baylis, 1959b; Hudson, 1959; Cleasby, 1969a, 1981; Arboleda, 1974; Arboleda-Valencia et al., 1985; Cleasby and DiBernardo, 1980; Committee Report, 1984).

Rate Control Systems for Gravity Filters

Filter control systems currently in use can be divided into two categories—mechanical control systems and non-mechanical control systems that achieve control by the inherent hydraulics of the operating filters. Control systems also can be classified as equal-rate

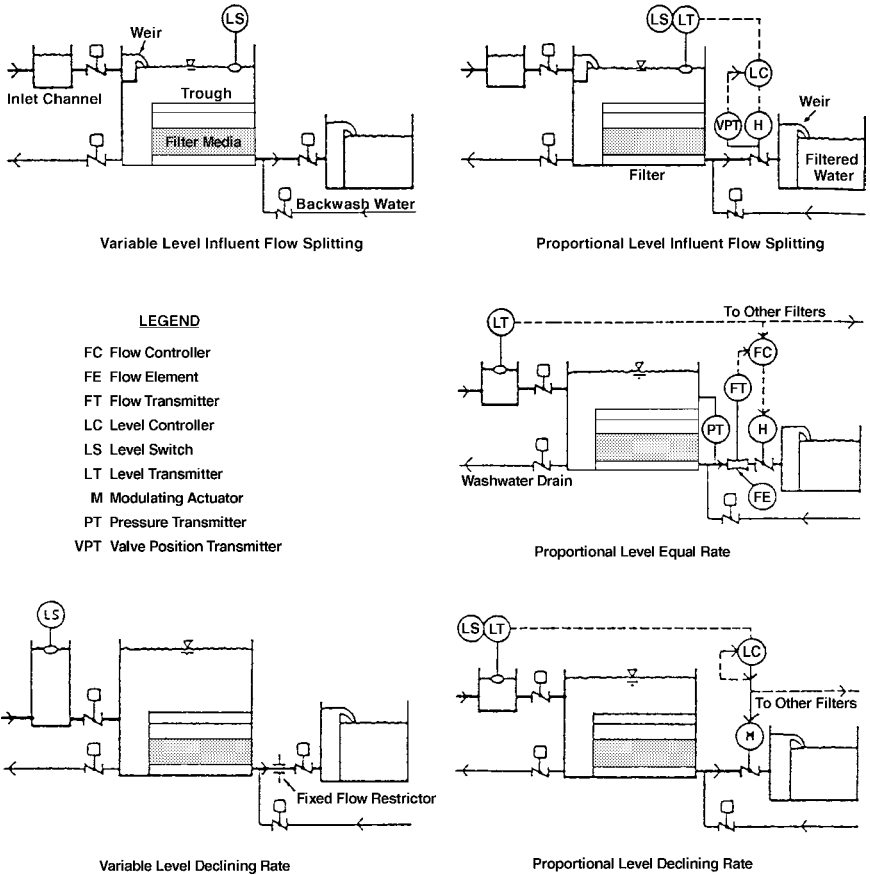

FIGURE 10-23 Schematic diagrams for common gravity filter flow control systems. (Source: From Browning, 1987, with permission of the Australian Water and Wastewater Association.)

systems or declining-rate systems, as was done by Browning (1987). Five control systems are shown in Fig. 10-23 using Browning’s classification system and nomenclature. They are for *equal-rate systems*, (1) variable-level influent flow splitting, (2) proportional-level influent flow splitting, and (3) proportional-level equal rate, and for *declining-rate systems*, (4) variable-level declining rate and (5) proportional-level declining rate.

It should be noted that none of the systems is called *constant-rate filtration*. True constant-rate filtration can occur only if the total plant flow rate is constant and the number of filters in service is constant. This is seldom the case. Plant flow rates are varied to meet variations in demand. Removing one filter from service for backwashing typically causes the other filters to pick up the load, thereby increasing the rate of filtration on the filters remaining in service. Thus, in most water plants, constant-rate filtration is not possible.

The key features of each of these systems are described briefly in the following paragraphs.

Variable-Level Influent Flow Splitting. This is an equal-rate nonmechanical system in which each filter receives an equal (or near-equal) portion of the total plant flow. This is

achieved by splitting the flow by means of an inlet weir box or orifice on each filter inlet above the maximum water level of the filter. The filter effluent discharges to the clearwell at a level above the surface of the filter bed. As solids accumulate in the filter pores, the water level rises in the filter box to provide the head required to drive the flow through the filter. The water level in each filter box is different and depends on the extent to which the filter pores are clogged. When the water level in a filter box rises to some selected maximum level, that filter must be backwashed. If the water level in the filter box is allowed to rise above the inlet weir box or orifice, flow in that filter becomes declining-rate flow.

No instrumentation is required for flow rate or head loss measurement on the individual filters. This is the simplest system for operators because the head loss is clearly evident merely from the water level in the filter box, and there is no control equipment or instrumentation to maintain.

Proportional-Level Influent Flow Splitting. This is an equal-rate mechanical system in which flow control occurs by inlet flow splitting, as in the prior system. A flow splitting weir or orifice at the inlet of each filter is located above the operating water level of the filter. However, each filter requires a level transmitter, a level controller, a modulating valve, and a head loss instrument. The modulating valve acts to control the water level in the associated filter, not as a flow rate controller. The effluent modulating valve for a filter is closed sufficiently to impart enough head loss to maintain the appropriate water level in the clean filter at the start of a filter run. The valve is gradually opened as clogging head loss increases during the filter run to continue to maintain the water level in its designated range.

Head loss is monitored for backwash initiation. No flow-measurement instrumentation is required for the individual filters.

Proportional-Level Equal Rate. This has been the most common equal-rate mechanical control system. It splits the total plant flow equally among the operating filters and maintains the water level in the influent channel within a preselected band. Each filter requires a flowmeter, a flow controller, a modulating control valve, and a head loss instrument. A single level transmitter in the inlet channel, serving a bank of several filters, sends an equal signal to the flow controller in each filter that is proportional to the water level within the band and represents the required flow. The flow controllers adjust the modulating valves to make measured flows match required flows.

When everything is working properly, flow rate through each filter is equal; however, equipment malfunction often results in unequal flow that often goes undetected. Head loss is monitored for backwash initiation.

Variable-Level Declining Rate. This is a declining-rate nonmechanical system. Flow enters the filter below the normal water level in each filter and discharges to the clearwell above the level of the filter bed. Because the inlet to the filters is below the normal water level in each filter, all filters connected by a common inlet channel or pipe operate at approximately the same water level and thus have the same total head loss available to the effluent weir level at any instant. Therefore, the cleanest filter operates at the highest filtration rate, and the dirtiest filter operates at the lowest filtration rate.

As solids accumulate in the filter media, the water level rises in all connected filters to provide the head required to drive the flow through the filter media. Water level is monitored at a single location for backwash initiation. In some plants, backwash is initiated when the filtration rate of the dirtiest filter drops to a preselected level or on a time-interval basis. The filtration rate of each filter declines in a stepwise fashion after each backwash. As a clean (backwashed) filter is returned to service, it assumes the highest rate of filtration.

A fixed flow restrictor (orifice plate or fixed-position valve) is provided for each filter to limit the starting rate on a clean filter. No instrumentation for flow rate or head loss measurement is required on individual filters; however, operating personnel prefer to have some flow rate indication to help them understand the system and for diagnostic purposes. Compared with other control systems, less total filter system head loss must be provided

because head consumed in turbulent head losses early in the filter run is reallocated to clogging head loss as the filtration rate declines (DiBernardo and Cleasby, 1980; Cornwell et al., 1991).

Proportional-Level Declining Rate. Browning (1987) suggested one additional flow control system combining the features of declining-rate with proportional-level control from the level in the filter inlet channel. As in the preceding system, submerged filter inlets result in a common water level in all filters. However, in this system, a modulating valve in the effluent of each filter is controlled by the water level in the inlet channel. All valves receive the same set point and are fully closed when water level in the channel is at the bottom of the band, and they are at their maximum opening when the water level is at the top of the band. This system functions like a variable declining-rate system but with filter water level controlled in a preselected bandwidth. Browning claimed that the depth of the filter box could be reduced with this system compared with the previous declining-rate system.

Common Elements of Filter Control Systems

Some common elements of the various rate control systems should be recognized. The total filter system head provided to operate the gravity filter is the vertical distance from the water level (hydraulic grade line) in the filter inlet conduit to the water level at the downstream control point. The downstream control point can be an overflow weir to the clearwell or an upturned elbow in the clearwell or the level in the clearwell if it is higher.

If the downstream control point is located above the top surface of the filter bed, no possibility of having pressures below atmospheric pressure (i.e., negative head) exists anywhere within the filter media or underdrain system because the static water level is above the surface of the media (consider Fig. 10-22). Also, no possibility of accidentally allowing the filter water level to drop below the top surface of the media (i.e., partially dewatering the filter bed) exists. These advantages are not obtained without cost, however, because all the needed head to operate the filter must be placed above the downstream control level, and this means a deeper filter box.

The three equal-rate systems have the common characteristic that the entire filter system operating head provided, which is essentially constant, is consumed throughout the filter run. The head that is not used by the dirty filter bed is wasted either in the modulating control valve of the mechanical systems or in free fall into the filter box for the influent flow splitting system. The declining-rate systems have a lower total filter system head requirement in the plant hydraulic profile because the total head is reallocated as the filter cycle proceeds, as described earlier.

The two non-mechanical systems (i.e., without proportional level control) have the inherent advantage that sudden changes in filtration rate cannot be imposed on the filter. If the total plant flow is increased or a filter is removed from service, the filters can pick up the load only by changing water level to generate the head needed to accommodate the increased flow. This changing of water level takes time so that the change in filtration can occur slowly and smoothly without mechanical devices.

Slow, smooth changes in filtration rate are also possible in properly designed proportional-level mechanical control systems, as well as in variable level influent flow splitting systems. The rate of change of the modulating control valve position should be proportional to the divergence of the measured variable (flow rate or level) from the desired value. The proportional-level control band should be substantial. The drive for the control valve should be an electric motor rather than a pneumatic or hydraulic valve because the latter two drives are prone to sticking and under- or overshooting (i.e., hunting, if repeated) problems as they age. No industry standards for filter control systems are available, so some systems do not have all the attributes just listed.

Choice of the Appropriate Control System

With the foregoing information at hand, some generalizations are possible about the five systems that may affect the choice of control system to meet the desired goals and needs of the utilities. Each system has a place, and a particular system should be used only when conditions are appropriate.

If full automation of the plant is desired, proportional-level systems are favored, although the two non-mechanical systems can be partially automated. If minimizing mechanical equipment and instrumentation is desired, nonmechanical systems are favored. This is especially important when equipment and future repair parts must be imported to a developing country that has scarce foreign exchange. In small, nonautomated plants with four or fewer filters and with unskilled operators, the variable-level influent flow splitting system is ideal because of its simplicity of understanding. In larger, nonautomated plants, the variable-level declining-rate method may be favored because it requires less total filter system head to generate equal filter cycle lengths and because it produces better filtrate quality in some cases (DiBernardo and Cleasby, 1980); however, this is not ensured in all cases (Hilmoe and Cleasby, 1986; Cornwell et al., 1991).

There is legitimate concern about poorer filtered water quality during the ripening phase at the beginning of the filter cycle. This concern is valid for all the control systems discussed earlier, and provision of filter-to-waste is the best available solution, as discussed elsewhere.

The design of variable-level declining-rate filters, including selection of the required total filter system head loss and prevention of excessive starting filtration rate for a clean declining-rate filter, has been presented by Cleasby (1993).

BACKWASHING AND MAINTENANCE OF FILTER MEDIA

Effective backwashing of rapid-rate media filters is essential to long-term successful service. The goal of the backwashing operation is to remove deposited solids and return the media to an acceptably clean condition so that no progressive evidence of the development of problems such as mudballs and filter cracks (discussed later) is seen in the filter bed.

Alternative Methods of Backwashing

The backwashing system is the most frequent cause of filter failure. Therefore, selection of the backwashing system and proper design, construction, and operation of that system are key elements in the success of a treatment plant. Two prominent systems of backwashing currently in use are compared in Table 10-6.

Upflow Wash With Full Fluidization. The traditional backwash system in the United States uses an upflow water wash with full bed fluidization. Backwash water is introduced into the bottom of the bed through the underdrain system. It should be turned on gradually over at least a 30 seconds to avoid disturbing gravel layers or subjecting the underdrain to sudden momentary pressure increases. The filter media gradually assume a fluidized state as the backwash flow rate is increased and the bed expands. The backwash flow is continued with full fluidization until the waste wash water is reasonably clear; a turbidity of about 10 ntu is sufficiently clear. Then the supply valve is shut off. Shutoff is not as crucial as the opening because no danger to the underdrain or gravel exists. A slow shutoff will result in a greater degree of re-stratification.

TABLE 10-6 Comparison of Two Backwash Alternatives for Granular Bed Filters

	Backwash method	
	With fluidization	Without fluidization
Applications	1. Fine sand 2. Dual media 3. Triple media	Coarse single-media sand or anthracite
Routines used	1. Water wash + surface wash 2. Water wash + air scour Air first, water second No air during overflow	Air scour + water wash Simultaneously during overflow (See text for precautions) Finish with water only wash
Fluidization	Yes, during water wash	No
Bed Expansion	15–30 percent	Negligible
Wash troughs	Usually used	Usually not used
Horizontal water travel to overflow	Up to 0.9 m (3 ft)	Up to 4 m (13 ft)
Vertical height to overflow	0.76–0.91 m (2.5–3 ft)	0.6 m (2 ft)

According to Baylis (1959c), backwash by water fluidization alone is a weak washing method. The reason for this weakness, discussed by Amirtharajah (1978), is attributed to a lack of abrasion occurring between the grains in a fluidized bed. For this reason, backwashing usually is assisted by an auxiliary scour system such as surface wash or air scour. The contrasts between the auxiliary scour systems are presented in Table 10-7 and in the following sections.

Surface Wash Plus Fluidized-Bed Backwash. Surface wash has been used extensively and successfully to improve the effectiveness of fluidized-bed backwashing. Surface wash systems inject jets of water from orifices located about 2.5 to 5 cm (1–2 in) above the surface of the fixed bed. Surface wash jets are operated for 1 to 2 minutes before the upflow wash and usually are continued during most of the upflow wash, during which time they are immersed in the fluidized filter media. Surface wash is terminated 2 or 3 minutes before the end of the upflow wash.

TABLE 10-7 Contrasts Between Backwash Alternatives

	With fluidization			Without fluidization
	Without auxiliary scour	With surface wash auxiliary	With air scour auxiliary	Simultaneous air + water backwash
Wash effectiveness	Weak	Fair	Fair	Good
Solids transport to overflow	Fair	Fair	Fair	Good
Compatible with fine media	Yes	Yes	Yes	No
Compatible with dual and triple media	Yes	Yes	Yes	No
Compatible with graded support gravel	Yes	Yes	Yes	No
Potential for media loss to overflow	Nil	Yes, mainly for coal	Yes, unless used properly	Major, unless used properly

Surface wash is accomplished either with a grid of fixed vertical pipes located above the granular media or with rotary water distribution arms containing orifices or nozzles that supply high-pressure jets of water. Orifice sizes typically are 2 to 3 mm diameter (3/32–1/8 in) and are directed downward 15 to 45 degrees below horizontal. Operating pressures typically are 350 to 520 kPa (50–75 psig). Fixed-nozzle systems deliver flows of 5 to 10 m³/m²/h (2–4 gpm/ft²), and rotary systems deliver 1.2 to 2.4 m³/m²/h (0.5–1 gpm/ft²).

The use of surface wash has a number of advantages and disadvantages (Cleasby et al., 1977). The advantages include the following: (1) It is relatively simple because only a source of high-pressure water is needed in conjunction with a system of distribution nozzles, and (2) it is accessible for maintenance and repair because it is located above the surface of the fixed bed. Some disadvantages of surface wash systems include the following: (1) Rotary-type washers sometimes stick in one position temporarily and do not rotate as intended, (2) if mudballs form in the bed and reach sufficient size and density, they can sink into the fluidized bed and no longer come under the action of the surface wash jets, (3) fixed-nozzle surface wash systems obstruct convenient access to the filter surface for maintenance and repair, and (4) in addition, nozzles are subject to becoming clogged (Logsdon et al., 2002).

Air Scour Assisted Backwash. Air scour systems supply air to the full filter area from orifices located under the filter media. Air scour is used to improve the effectiveness of the backwashing operation. If air scour is used during overflow, there is substantial danger of losing some of the media. Therefore, the system must be designed and operated properly to avoid such loss.

The air scour operating routines are different for finer filter media and for coarse sand media, as shown in Table 10-6. Operating sequences are listed below.

Air Scour Alone Before Water Backwash. This system can be used for fine-sand and dual- and triple-media systems.

- Lower the water level about 15 cm (6 in) below the edge of the backwash overflow.
- Turn on the air scour alone for 1 to 2 minutes.
- Turn off the air scour.
- Turn on water wash at a low rate to expel most of the air from the bed before overflow occurs.
- Increase the water wash rate to fluidize and re-stratify the bed, and wash until clean. Some additional air will be expelled.

Simultaneous Air Scour and Water Backwash During Rising Level Before Overflow. This system can be used for fine-sand, dual-media, triple-media, and coarse single-media anthracite systems.

- Lower the water level to just above the surface of the filter media.
- Turn on the air scour for 1 to 2 minutes.
- Add low-rate water wash at below half the minimum fluidization velocity as the water level rises.
- Shut off the air scour about 15 cm (6 in) below the overflow level while the water wash continues. Most air will be expelled before overflow.
- After overflow occurs, increase the water wash rate to fluidize and re-stratify the bed, and wash until clean. Some additional air will be expelled.

Simultaneous Air Scour and Water Backwash During Overflow. This system can be used for coarse (1.0 mm ES or larger) single-media sand or anthracite systems. However, for anthracite, special baffled overflow troughs are essential to prevent loss of anthracite.

- Turn on the air scour.
- Add water wash at below half the minimum fluidization velocity, and wash with simultaneous air plus water for about 10 minutes during overflow.
- Turn off the air scour, and continue the water wash until overflow is clean. The water wash rate is sometimes increased to hasten the cleanup, but usually below fluidization velocity.

For the simultaneous wash routine just outlined, the wash is very effective, even though the bed is never fluidized. A slow transport of the grains occurs, caused by the simultaneous air plus water flow that causes abrasion between the grains. The abrasion plus the high interstitial water velocities results in an effective backwash.

Several precautions are taken to prevent the loss of sand or anthracite when using simultaneous air plus water wash during overflow. The water and airflow rates are varied appropriately for the size of the filter media. For coarse sand, backwash troughs generally are not used, the dirty wash water exits over a horizontal concrete wall or central gullet, and the vertical distance from the surface of the sand to the wash water overflow is at least 0.5 m (1.6 ft). The top edge of the overflow wall(s) is sloped at 45 degrees downward toward the filter bed so that any sand grains that fall on the sloping wall during backwashing roll back into the filter bed (Degremont, 1973). Alternatively, if backwash troughs are used, specially shaped baffles can be located around each trough to prevent the loss of filter media (Dahab and Young, 1977). Such baffled troughs are especially important when using anthracite media.

Air Scour Delivery Systems. Air scour may be introduced to the filter through a pipe system that is completely separate from the backwash water system, or it may be through the use of a common system of nozzles (strainers) that distribute both the air and the water, either sequentially or simultaneously. In either method of distribution, if the air is introduced below graded support gravel, concern exists over movement of the finer gravel by the air, especially by air and water used concurrently by intention or by accident. This concern has led to the use of media-retaining strainers (Fig. 10-8) in some filters that eliminate the need for graded support gravel in the filter.

Backwash Water and Air Scour Flow Rates. Typical flow rates used in backwash practice are summarized in Table 10-8. Hewitt and Amirtharajah (1984) did an experimental study of the particular combinations of air and subfluidization water flow that caused the formation and collapse of air pockets within the bed, a condition they called *collapse-pulsing*. This condition was presumed to create the best abrasion between the grains and the optimal condition for air plus subfluidization water backwashing. An empirical equation relating airflow rate, fluidization velocity, and backwash water flow rate was presented. In a companion paper, Amirtharajah (1984) developed a theoretical equation for collapse-pulsing using concepts from soil mechanics and porous-media hydraulics. The resulting equation is

$$0.45Q_a^2 + 100(V/V_{mf}) = 41.9 \quad (10-18)$$

where Q_a is the airflow rate in standard cubic feet per minute per square foot, and V/V_{mf} is the ratio of superficial water velocity divided by the minimum fluidization velocity based on the d_{60} grain size of the media.

TABLE 10-8 Typical Water and Air Scour Flow Rates for Backwash Systems Employing Air Scour

Filter media	Backwash sequence	Air rate, m/h (scfm/sf)	Water rate, ^a m/h (gpm/sf)
Fine sand, 0.5-mm ES	Air first	37–55 (2–3)	37 (15)
	Water second		
Fine dual and triple media, 1.0-mm-ES anthracite	Air first	55–73 (3–4)	37–49 (15–20)
	Water second		
Coarse dual media, 1.5-mm-ES anthracite	Air first	73–91 (4–5)	
	Air+water on rising level	73–91 (4–5)	24 (10)
	Water third		61 (25)
Coarse sand, 1.0-mm ES	Air + water first simultaneously	55–73 (3–4)	15–17 (6–7)
	Water second		
Coarse sand, 1.0-mm ES	Air + water first simultaneously	110–146 (6–8)	24–29 (10–12)
	Water second		Same or double rate
Coarse anthracite, 1.5-mm ES	Air + water first simultaneously	55–91 (3–5)	20–24 (8–10)
	Water second		Same or double rate

^aWater rates for dual and triple media vary with water temperature and should fluidize the bed to achieve restratification of the media. See Eq. 10-20.

The empirical and theoretical equations give almost the same results over the range of airflow rates from 37 to 110 m/h (2–6 scfm/ft²). For a given airflow rate, both the equations predict somewhat higher water flow rates than the typical values presented in Table 10-8. The tabulated values should be used until future research reconciles these differences.

Some of the advantages of auxiliary air scour in contrast to surface wash systems follow (Cleasby et al., 1977): (1) Air scour covers the full area of rectangular filters and is adaptable to any filter dimensions, and (2) it agitates the entire filter depth, and therefore, it can agitate the interfaces in dual- and multiple-media beds and can reach mudballs that have sunk deep into the filter. Some disadvantages of the air scour auxiliary are (1) the need for a separate air blower and piping system, (2) the potential for loss of media, especially if air and water are used simultaneously during overflow, and (3) a greater possibility of moving the supporting gravel if air is delivered through the gravel concurrently with water; special gravel designs are required, as described earlier.

Backwash Troughs and Wash Water Required

If backwash troughs are used, they must be of adequate size and on appropriate spacing to take away the dirty backwash water without surcharging. Spacing is dictated by maximum horizontal travel of the water (see Table 10-6). At the maximum backwash rate, there should be a free fall of the water into the troughs, even at the upstream end. The top edges of the troughs all should be at the same elevation, and all should be level so that the flow is withdrawn evenly over the whole bed.

The volume of wash water required to wash a filter depends on the depth of the filter media and the vertical distance from the fixed-bed surface to the overflow level. The larger the depth of media, the larger is the water volume needed to flush detached particles out of the bed and into space above the filter. The larger the vertical distance from the surface of the media to the wash water overflow level, the larger is the volume needed to wash

detached particles out of the filter box. Typically, a wash takes about four displacement volumes for the void volume in the bed plus the water volume above the bed to the overflow level. Typical wash water volumes used per unit area per wash range from 4 to 8 m³/m²/wash (100–200 gal/ft²/wash); greater volumes (up to 12 m³/m²/wash or 300 gal/ft²/wash) may occur for very deep filters, greater than normal freeboard, flotation-over-filtration designs, and other special cases.

In filters with backwash troughs that are washed with full bed fluidization, the expanded media surface should be lower than the bottom of the troughs. If the expanded media rise up between the troughs, the effective vertical flow velocity is increased, and the danger of carrying the filter media into the troughs is increased.

The wash water volume required per wash to clean the filter could be reduced by decreasing the vertical distance from the fixed-bed surface up to the top edge of the troughs. The temptation to do this must be resisted, however, because the danger of loss of filter media would be increased. Loss of filter media is greater when anthracite or GAC is used. In this case, to minimize the loss of media, the vertical distance to the edge of the troughs should be increased above the traditional 0.75 to 0.9 m (2.5–3 ft) to 1.1 to 1.2 m (3.5–4 ft). This, in turn, requires a greater volume of wash water to complete the backwash.

Hydraulics of Fluidized Beds

Head Loss for a Fluidized Bed. The American practice of filter backwashing typically has used backwash flow velocities above the minimum fluidization velocity of the filter media. Therefore, some fluidization fundamentals are essential to proper understanding of this backwashing practice.

Fluidization can best be described as the upward flow of a fluid (gas or liquid) through a granular bed at sufficient velocity to suspend the grains in the fluid. During upward flow, the energy loss (pressure drop) across the fixed bed is a linear function of flow rate at low superficial velocities when flow is laminar. For coarser or heavier grains, it may become an exponential function at higher flow rates if the Reynolds number (Re) enters the transitional regime, $Re > 6$. As the flow rate is increased further, the resistance equals the gravitational force, and the particles become suspended in the fluid. Any further increase in flow rate causes the bed to expand and accommodate to the increased flow while effectively maintaining a constant pressure drop (equal to the buoyant weight of the media). Two typical curves for real filter media fluidized by water are shown in Fig. 10-24 (Cleasby and Fan, 1981).

The pressure drop Δp after fluidization is equal to the buoyant weight of the grains and can be calculated from the following equation:

$$\Delta p = h\rho g = L(\rho_s - \rho)g(1 - \epsilon) \quad (10-19)$$

in which ρ_s is the mass density of the grains and other terms are as defined previously.

Point of Incipient Fluidization. The point of incipient fluidization, or minimum fluidizing velocity V_{mf} , is the superficial fluid velocity required for the onset of fluidization. It can be defined by the intersection of the fixed-bed and fluidized-bed head loss curves, the points labeled V_{mf} on Fig. 10-24.

The calculation of minimum fluidization velocity is important in determining minimum backwash flow-rate requirements. The rational approach to the calculation is based on the fixed bed head loss being equal to the constant head loss of the fluidized bed at the point of incipient fluidization. Thus the Ergun equation (Eq. 10-16) can be equated to the constant-head loss equation (Eq. 10-19) and solved for the velocity, that is, V_{mf} . The accuracy of the result depends on using realistic values for sphericity ψ and fixed bed porosity ϵ . Such data

FIGURE 10-24 Head loss versus superficial velocity for 10- to 12-mesh sand at 25°C, $L_0 = 37.9$ cm and $\epsilon_0 = 0.466$, and for 5- to 6-mesh anthracite at 25°C, $L_0 = 19.8$ cm and $\epsilon_0 = 0.581$. (Source: Cleasby and Fan, 1981.)

for actual media may not be available, making the result uncertain. By using an approximate relation between sphericity and porosity, Wen and Yu (1966) developed a simplified equation for the calculation of V_{mf} . The resulting equation is

$$V_{mf} = \frac{\mu}{\rho d_{eq}} (33.7^2 + 0.0408Ga)^{0.5} - \frac{33.7\mu}{\rho d_{eq}} \tag{10-20}$$

where Ga is the Galileo number:

$$Ga = d_{eq}^3 \frac{\rho(\rho_s - \rho)g}{\mu^2} \tag{10-21}$$

For a bed containing a gradation in particle sizes, the minimum fluidization velocity is not the same for all particles. Smaller grains become fluidized at a lower superficial velocity than larger grains. Therefore, a gradual change from the fixed bed to the totally fluidized state occurs. In applying Eq. 10-20 to a filter bed with grains graded in size, calculating V_{mf} for the coarser grains in the bed is necessary to ensure that the entire bed is fluidized. The d_{90} sieve size would be a practical diameter choice in this calculation. Generally, the d_{eq} is not conveniently available, and the d_{90} diameter from the sieve analysis may be used as an acceptable approximation.

Furthermore, the minimum backwash rate selected must be higher than V_{mf} for the d_{90} sieve size (V_{mf90}) to allow free movement of these coarse grains during backwashing. A backwash rate equal to $1.3V_{mf90}$ has been suggested to ensure adequate free movement of the grains (Cleasby and Fan, 1981); however, a rate closer to V_{mf} may be better to avoid movement of graded gravel support layers.

Hemmings and Fitzpatrick (1997) measured minimum fluidization velocities for water only and combined air-water backwashing and reported on a pressure-signal technique to

measure the onset of the collapsed pulse condition. The measured result for water only agreed well with results from Eq. 10-20.

For filter media that has a very wide range of grain sizes, the use of V_{mf} for the d_{90} size during backwashing potentially could expand the finest grains so much that they could be lost to overflow. This is never a problem with the uniformity coefficients commonly specified for filter media ($UC < 1.7$, often < 1.5). Calculation of the minimum fluidization velocity is shown in Example 10-2.

Example 10-2 Minimum Fluidization Velocity

Calculate the minimum fluidization velocity for the anthracite shown in Fig. 10-4 at a water temperature of 20°C using an anthracite density of 1600 kg/m³ estimated from Table 10-2.

Solution Calculate the fluidization velocity V_{mf} for the d_{90} size of the anthracite as suggested in the text. The d_{90} size from Fig. 10-4 is 2.9 mm. Use Eq. 10-20:

$$V_{mf} = \frac{\mu}{\rho d_{eq}} (33.7^2 + 0.0408 Ga)^{0.5} - \frac{33.7\mu}{\rho d_{eq}}$$

And the Galileo number (Eq. 10-21) is

$$Ga = d_{eq}^3 \frac{\rho(\rho_s - \rho)g}{\mu^2}$$

Selecting values of physical water properties from Appendix D of this book and solving in SI units, we get

$$\mu = 1.002 \times 10^{-3} \text{ N} \cdot \text{s/m}^2$$

$$\rho = 998.21 \text{ kg/m}^3$$

$$g = 9.81 \text{ m/s}^2$$

$$d_{eq} \text{ (use } d_{90}) = 2.9 \text{ mm} = 2.9 \times 10^{-3} \text{ m}$$

$$Ga = (2.9 \times 10^{-3})^3 \frac{998(1600 - 998)9.81}{(1.002 \times 10^{-3})^2} = 143,170 \text{ (dimensionless)}$$

$$V_{mf} = \frac{1.002 \times 10^{-3}}{998(2.9 \times 10^{-3})} (33.7^2 + 0.0408 \times 143,170)^{0.5} - \frac{33.7(1.002 \times 10^{-3})}{998(2.9 \times 10^{-3})}$$

$$= 0.01725 \text{ m/s}$$

The recommended backwash rate would be up to 30 percent higher, as discussed in the text:

$$\text{Backwash rate} = 1.3 \times 0.01725 = 0.0223 \text{ m/s} = 80.1 \text{ m/h (32.8 gpm/ft}^2\text{)}$$

This is a higher than the normal backwash rate because of the very coarse anthracite grain size, the rather warm water, and the choice of 30 percent factor above V_{mf} . Without this factor applied, the rate would be 61.6 m/h (25.2 gpm/ft²). ▲

Expansion of Filter Media During Backwashing. When using upflow wash with full fluidization, the filter bed expands about 15 to 30 percent above its fixed bed depth. The degree of expansion is affected by many variables associated with the filter media and the water. Filter media variables include the size and size gradation and grain shape and

density. Water variables include viscosity and density. The ability to predict expansion is important, for example, in determining whether the expanded media will rise too high, possibly above the bottom of the troughs.

The following model for predicting expanded-bed porosity during backwashing was developed by extending a Reynolds number versus porosity function that had been used for fixed beds into the expanded-bed region (Dharmarajah and Cleasby, 1986). The modified Reynolds number (Re_1) uses interstitial velocity V/ϵ for the characteristic velocity and a term approximating the mean hydraulic radius of the flow channel, $\epsilon/[S_v(1 - \epsilon)]$, for the characteristic length.

$$Re_1 = \frac{V}{\epsilon} \frac{\epsilon}{S_v(1-\epsilon)\mu} \frac{\rho}{S_v(1-\epsilon)\mu} = \frac{V\rho}{S_v(1-\epsilon)\mu} \tag{10-22}$$

where S_v is the specific surface of the grains ($6/d$ for spheres and $6/\psi d_{eq}$ for nonspheres). The porosity function used previously to correlate fixed-bed pressure drop data to Re_1 was modified by combining it with the constant-head loss equation for a fluidized bed (Eq. 10-19), resulting in a new dimensionless porosity function for fluidized beds (A_1).

$$A_1 = \frac{\epsilon^3}{(1-\epsilon)^2} \frac{\rho(\rho_s - \rho)g}{S_v^3 \mu^2} \tag{10-23}$$

Using data for many different sizes and types of filter media, $\log A_1$ was correlated with $\log Re_1$ using a stepwise regression analysis and resulting in the following expansion correlation (Dharmarajah and Cleasby, 1986):

$$\log A_1 = 0.56543 + 1.09348 \log Re_1 + 0.17971(\log Re_1)^2 - 0.00392(\log Re_1)^4 - 1.5(\log \psi)^2 \tag{10-24}$$

This equation can be used to predict the expanded porosity ϵ of filter media of any uniform size (i.e., S_v = specific surface) at any desired backwash rate V . Because both A_1 and Re_1 are functions of ϵ , the solution is trial and error and is best solved numerically. When applying the equation to real filter media with size gradations, the bed must be divided into several segments of approximately uniform size using the sieve analysis data, and the expanded porosity of each size segment must be calculated. The expanded depth of each segment then can be calculated from the following equation that is based on the total grain volume remaining unchanged as the bed expands (Cleasby and Fan, 1981):

$$\frac{L}{L_0} = \frac{1-\epsilon_0}{1-\epsilon} \tag{10-25}$$

in which L/L_0 is the ratio of expanded depth L to fixed-bed depth L_0 , ϵ is the expanded porosity, and ϵ_0 is the fixed loose-bed porosity. Typical values of ϵ_0 were presented earlier in Table 10-2.

Example 10-3 Filter Bed Expansion

Calculate the expansion for the d_{50} size anthracite shown in Fig. 10-4 at 20°C and at the backwash rate of 80.1 m/h (32.8 gpm/ft²) calculated in Example 10-2. Use a sphericity of 0.55 and a density of 1600 kg/m³ estimated from Table 10-2.

Solution in SI Units Use Equation 10-22:

$$Re_1 = \frac{V\rho}{S_v(1-\epsilon)\mu}$$

Values from Example 10-2 and used here are $V = 0.0223$ m/s, $\rho = 998.21$ kg/m³, and $\mu = 1.002 \times 10^{-3}$ N · s/m². From Appendix D, $\mu/\rho = \nu = 1.004 \times 10^{-6}$ m²/s.

$$d_{50} = 2.2 \text{ mm or } 2.0 \times 10^{-3} \text{ m (Fig. 10-4)}$$

$$S_v = 6/\psi d = 6/(0.55 \cdot 2.0 \times 10^{-3}) = 5454 \text{ m}^{-1}$$

$$\text{Re}_1 = \frac{0.0223}{5454(1-\varepsilon)1.004 \times 10^{-6}} = \frac{4.073}{1-\varepsilon} \quad (\text{dimensionless})$$

where ε is the desired expanded porosity. Then use Eq. 10-23:

$$A_1 = \frac{\varepsilon^3}{(1-\varepsilon)^2} \frac{\rho(\rho_s - \rho)g}{S_v^3 \mu^2}$$

$$A_1 = \frac{\varepsilon^3}{(1-\varepsilon)^2} \frac{998(1600 - 998)9.81}{(5454)^3 (1.002 \times 10^{-3})^2} = \frac{36.184\varepsilon^3}{(1-\varepsilon)^2}$$

Insert these Re_1 and A_1 values into Eq. 10-24 as follows:

$$\begin{aligned} \log \left[36.184 \frac{\varepsilon^3}{(1-\varepsilon)^2} \right] &= 0.56543 + 1.09348 \log \left[\frac{4.073}{(1-\varepsilon)} \right] + 0.17971 \left[\log \frac{4.073}{(1-\varepsilon)} \right]^2 \\ &\quad - 0.00392 \left[\log \frac{4.073}{(1-\varepsilon)} \right]^4 - 1.5(\log 0.55)^2 \end{aligned}$$

Note that the only unknown in the preceding equation is ε , but it appears on both sides of the equation. A trial-and-error solution is necessary. The solution to Eq. 10-24 yields $\varepsilon = 0.616$

The expansion of this size anthracite can be calculated from Eq. 10-25, assuming an initial porosity of 0.56 from Table 10-2. Thus

$$\frac{L}{L_0} = \frac{1-\varepsilon_0}{1-\varepsilon}$$

$$\frac{L}{L_0} = \frac{1-0.56}{1-0.616} = 1.15$$

Therefore, this midsize material would be expanded 15 percent. To obtain the expansion of the entire bed, the bed must be divided into about five sizes and the expanded depth of each layer calculated and totaled. To obtain the expansion of dual- or triple-media beds, the expansion of each layer is calculated and totaled without regard to any intermixing at the interfaces between layers. ▲

Stratification and Intermixing During Backwashing

The related phenomena of stratification and intermixing are important issues in filter construction and backwashing. These are discussed below.

Stratification and Skimming. In the case of a single-media type of filter such as a sand filter, during backwash with fluidization, the grains tend to stratify by size, with the finer grains on top and the coarser grains on the bottom. The tendency to stratify at a given backwash rate (above fluidization velocity) is driven by bulk density differences between

the fluidized grains of different sizes. Smaller grains expand more and have a lower bulk density (grains plus fluidizing water) and thus rise to the top of the bed. The concept of bulk density is discussed further in the next section on intermixing of adjacent layers. This stratification is upset to varying extents by nonuniform upflow of the backwash water that creates localized regions of above-average upflow velocity. Larger grains are transported upward rapidly into the upper bed, whereas in adjacent regions the sand will be moving downward carrying finer grains down into the bed. These regions of excessive upflow are referred to as *sand boils* or *jet action* in the water filtration literature and as *gulf streaming* in some fluidization literature.

The tendency to stratify is used beneficially during construction of a filter to remove unwanted fine grains from the bed. The filter is washed above fluidization velocity, and the fine grains accumulate at the upper surface. After the backwash is completed, the fine grains are skimmed from the surface to avoid leaving a blinding layer of fines on top.

Better stratification is achieved at lower upflow rates, just barely above the minimum fluidization velocity of the bed. Therefore, in preparing for skimming, the bed first should be fully fluidized, and then the upflow wash rate should be reduced slowly over several minutes to bring to the surface as many of the fine grains as possible. The fluidization and skimming process may be repeated two or three times for maximum effectiveness.

During the installation of dual- or triple-media filter beds, skimming each layer as it is completed is common. The same concepts and procedures described earlier are equally appropriate for each layer. If the very fine grains are not removed from the lower layers, they may rise high in the next upper layer, partially negating the desired benefit of the coarse upper layer (Cleasby et al., 1984a).

Intermixing of Adjacent Layers. Intermixing tends to occur between adjacent layers of dual- and triple-media filters. For example, the upper finer sand grains of a dual-media bed move up into the lower coarser grains of the anthracite bed that lies above. The tendency to intermix between two adjacent layers of filter media can be estimated by comparing the bulk density of the two media calculated independently at any particular backwash flow rate and temperature. The *bulk density* is the mixed density of the grains and fluidizing water calculated as follows (Cleasby and Woods, 1975):

$$\rho_b = (1 - \epsilon) \rho_s + \rho \epsilon \quad (10-26)$$

in which ρ_b is the bulk density. The first term on the right-hand side is the density contributed by the solid fraction, and the second term is the density contributed by the water fraction.

The tendency to intermix increases with the backwash flow rate because the bulk densities tend to converge at higher flow rates. Intermixing actually begins before the bulk densities become equal because of uneven flow distribution and mixing and circulation patterns that exist in the fluidized layers. Mixing was observed to occur when the bulk densities converged to within 50 to 130 kg/m³ (3–8 lb/ft³) (Cleasby and Woods, 1975). Similarly, as the backwash rate is decreased slowly, the bulk densities of the adjacent layers diverge, and intermixing decreases.

The bulk density model would predict that inversion of layers should occur at very high wash rates, and such inversion was observed experimentally (Cleasby and Woods, 1975). Wash rates, however, were far higher than rates used in practice.

The tendency for sand and anthracite to intermix during backwashing is much less than for silica and garnet sand in the usual backwash flow range. This is so because the differences in bulk density are greater for the usual sand and anthracite sizes used in current practice.

Movement of Gravel During Backwashing

Many filters have layers of graded gravel to support the filter media. The conventional gravel layers are graded from coarse on the bottom to fine at the top, according to appropriate size guidelines presented earlier. With this conventional gravel arrangement, some cases of mounding of the gravel caused by lateral movement of the fine gravel have been reported. In severe cases, the finest gravel layer may be completely removed from some areas of the filter bed. This can lead to leakage of the filter media into the underdrain system and ultimately to the need to clean the underdrain and rebuild the filter gravel and media. Mechanisms contributing to movement of gravel have been discussed exhaustively by Baylis (1959a; AWWA, 1971), and those discussions related to fluidized-bed backwashing of sand beds are summarized here.

As backwashing begins, sand grains do not move apart quickly and uniformly throughout the bed. Time is required for the sand to equilibrate at its expanded spacing in the upward flow of wash water. If the backwash is turned on suddenly, it lifts the sand bed bodily above the gravel layer, forming an open space between the sand and gravel. The sand bed then breaks at one or more points, as shown in Fig. 10-25, causing sand boils and subsequent upsetting of the supporting gravel layers. This then requires frequent rebuilding of the graded gravel.

FIGURE 10-25 Sand boil at beginning of wash.

Opening the backwash valve slowly is essential. The time from start to full backwash flow should be at least 30 seconds and perhaps longer and should be restricted by devices built into the plant. The most destructive filter washing blunder is to turn the backwash water on quickly when the bed has been drained. Gross disturbance of the gravel results, and rupture of the filter underdrain system has resulted in many cases.

The upward flow from the gravel is never completely uniform. As a result, in some parts of the expanded sand bed the water and sand travel upward at rates higher than the average backwash velocity, and at other places the sand actually travels downward. This leads to jet action at the sand-gravel junction, as illustrated in Fig. 10-26. In some cases, the jet velocity is so great that it will move grains of small gravel several diameters larger than the sand grains adjacent to the gravel. The problem of gravel movement is greater at wash rates above 37 m/h (15 gpm/ft²).

The importance of sand in generating the movement of gravel is illustrated by the observation that an upward flow through a graded gravel bed at backwash rates exceeding 61 m/h

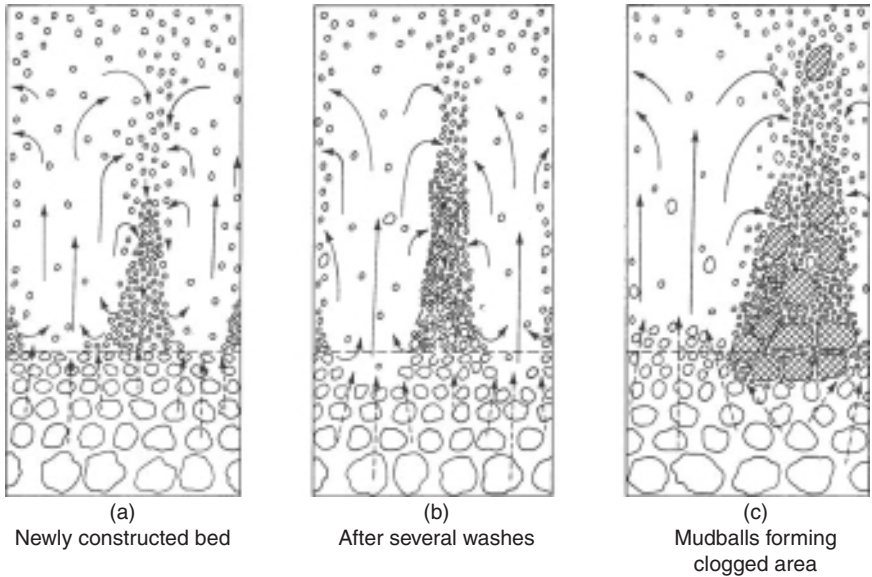

FIGURE 10-26 Jet action at the sand-gravel interface.

(25 gpm/ft²) will not move any of the gravel unless sand is present on top of the gravel (Baylis, 1959a). The presence of the sand greatly increases the mobility of the gravel.

Movement of the gravel also can occur when air scour and water backwash are used simultaneously. Provisions being used to avoid movement of gravel are the use of double-reverse graded gravel or the use of media retaining underdrains that require no gravel, as discussed earlier.

Three methods are used to determine whether the upper surface of the gravel has moved: (1) push a 6 mm (0.2 in) metal rod gently down to the gravel surface of a newly backwashed filter while the filter is at rest, (2) lower a probe with a flat plate on the end through the expanded filter media during the fluidized-bed backwash, and (3) drain the filter to the gravel, insert a thin-walled pipe of about 2.5 cm (1 in) in diameter into the media, and remove the media in segments until the top layer of gravel is reached in successive probings. Each method has advantages and disadvantages. The first method is quick, but distinguishing the fine gravel from the bottom filter media is difficult. The second method requires a long period of fluidized backwash. The third method is the most positive but also the most time-consuming and labor-intensive. Numerous measurements made on a gridiron pattern will reveal the contour of the top surface of the gravel.

Underdrain Failures

The filter underdrain is a vitally important component of the rapid-rate media filter. It serves to collect the filtered water, support the filter gravel (if used) and filter media, and distribute backwash water.

The most serious failures of rapid-rate filters are usually related to problems with the underdrain. Proper design and construction of the underdrain are essential. Any underdrain system, if designed improperly, can lead to uneven distribution of the backwash water. This,

in turn, can lead to problems such as dirty areas of the filter and migration of gravel if gravel is used to support the media.

False-floor underdrains with nozzles and plastic block underdrains with caps have occasionally failed by several modes. If the nozzles or caps have fine openings to retain the fine filter media, the openings may become clogged with debris from construction of the underdrain or from solids in the backwash water or because of mineral deposits. If steel filter vessels are allowed to corrode, the rust can clog backwash nozzles. If the clogging becomes excessive, the backwash flow rate may be diminished, and the pressure drop across the floor may cause excessive uplift during backwashing. The problem can be repaired by removing the filter media and cleaning the nozzles or caps. If not corrected, excessive pressure drop can result in an uplift structural failure of the false floor or filter blocks. An open pressure-relief pipe is often provided that projects an appropriate length above the backwashing water level. Excessive pressure in the underdrain is evident when this pipe starts to flow during the backwash operation.

Some modern plastic nozzles are not strong enough to accept the abuse of construction during or after installation. They may be weakened during construction, and the nozzle heads may break off during future backwashing operations. The result is leakage of media into the underdrain plenum.

The manifold and lateral type of underdrain is not subject to uplift failure. It can fail to function properly, however, if the distribution orifices are reduced in size because of mineral deposits or enlarged in size because of corrosion or erosion.

Vitrified clay block underdrains have proven quite successful if installed properly and if precautions are taken to prevent air from entering the backwash system. The manufacturers' recommendations for installation and grouting must be followed explicitly to obtain a good installation. Careless workmanship can lead to grout in the water-carrying channels. This can lead to maldistribution of wash water and in severe cases to excessive backwash pressures and uplift failure. Some plastic block underdrains eliminate the danger of grout intrusion by the use of O-ring gaskets or other positive exclusion systems.

Dirty Filter Media and Mineral Deposits

So-called dirty filters result from inadequate backwashing of the filter, including the absence or improper operation of auxiliary scour systems. Typical manifestations of inadequate backwashing include filter cracks and mudballs. Inadequate cleaning leaves a thin layer of compressible matter around each media grain. As pressure drop across the filter bed increases during the subsequent filter run, the grains are squeezed together, and cracks form in the surface of the media, usually along the walls first. In severe cases, cracks may develop at other locations as well. The AWWA has published a guidance manual for evaluation of granular media (Nix and Taylor, 2003).

The heavier deposits of solids near the top surface of the media break into pieces during backwashing, resulting in spherical/oblong-shaped accretions referred to as *mudballs*. Mudballs are composed of the filter grains and the solids removed by the filter and range from pea size to 2.5 to 5 cm (1–2 in) or more. The formation of mudballs is accentuated by the use of polymers as coagulant aids or as filter aids that form stronger attachments between the filter grains and the removed solids. If mudballs are small enough and of low enough density, they float on the surface of the fluidized media. If larger or heavier, they may sink into the filter to the bottom or to the coal-sand interface in dual-media filters. Subsurface accumulations can lead to solidified inactive regions of the filter bed that are not remedied in normal backwashing. This, in turn, increases the filtration rate through the remaining active portions of the bed with potential detriment to the quality of the filtrate and shorter filter cycles.

Surface mudballs can be removed manually by (1) lifting them from the surface with a large strainer while the backwash water is running at a low rate, (2) breaking them up with rakes, or (3) breaking them up with a high-pressure hose jet. Subsurface mudballs and agglomerations can be reduced by (1) probing the bed with lances delivering jets of high-pressure water, (2) pumping the media through an ejector, (3) washing the filter and using chemical additions (described below), or (4) digging out the hard spots and removing, cleaning, or replacing the media.

Solid surfaces in water greatly increase the rate of solid-phase formation via precipitation from dissolved species; this often occurs subsequent to solute adsorption and, in some cases, oxidation. Thus strongly attached mineral deposits or coatings can develop on the grains of the filter media, causing them to change size, shape, and density. Calcium carbonate deposits are common in many lime–soda ash softening plants if recarbonation is not sufficient to deliver a stable water to the filters. Such deposits also may occur in surface water plants if lime is added ahead of filtration for corrosion control. The deposition of calcium carbonate can be minimized by adding a low dosage of polyphosphate ahead of the filters. Surface deposition of calcium carbonate is not surprising because one effective softening method involves fluidized beds of granular $\text{CaCO}_3(s)$ (or pellets) for calcium removal.

Iron oxides and manganese oxides are common deposits on the filter media of iron- and manganese-removal plants. Aluminum oxide or iron oxide deposits can occur in surface water plants that use alum or iron salts for coagulation. In general, Al, Fe(III), and Mn(IV) are very insoluble, and essentially all precipitation occurs as suspended particles that are removed subsequently by clarification and filtration. Sorption of reduced Fe(II) or Mn(II) to media surfaces and subsequent oxidation can result in strongly attached coatings of insoluble Fe or Mn oxides.

The occurrence (and desirability) of manganese oxide (MnO_x) coatings on standard anthracite and sand filter media is of special importance. It has long been recognized that sorption of Mn(II) by MnO_x surfaces catalyzes oxidation of the sorbed reduced Mn(II) to Mn(IV), thus creating new sites for more Mn(II) uptake (Morgan and Stumm, 1964). Extensive work by Knocke and co-workers rediscovered the importance and mechanisms of Mn(II) removal by MnO_x coatings on anthracite and sand media in filters that are continuously exposed to free chlorine because of the application of prefilter chlorination, the so-called natural greensand effect (e.g., Knocke et al., 1988, 1990, 1991). This process is intentionally used by many utilities for Mn removal (see Chap. 7); MnO_x coatings also can develop unintentionally by removal of low levels of Mn added with iron coagulants. Process changes that eliminate prefilter chlorination, for example, a change to prefilter ozonation and operation of biologically active filters, but do not replace the MnO_x -coated media can result in unintended and undesirable release of Mn from the media (e.g., Gabelich et al., 2006). Results of earlier work by Knocke and a more recent study (Tobiason et al., 2008) show extractable Mn levels of 0.1 to 100 mg Mn/g media depending on Mn loading, years in service, location in the media, and other factors. In general, media size is not significantly affected by typical Mn coating levels, but extensive coatings on smaller media can increase size. These studies also showed appreciable levels of other metals (Al, Fe, Cu, etc.) associated with the extractable Mn coatings.

In general, mineral deposits are subject to later leaching into the filtered water if the pH is changed in a direction to increase solubility. Also, in the case of iron and manganese coatings, the occurrence of reducing conditions, possibly mediated by biofilms, can result in release of the more soluble reduced forms of these metals. In some cases, the increased size of the grains caused by mineral deposits results in an increase in bed depth and can impair filtration efficiency. Thus, cleaning the deposits from the grains or replacing the media may become necessary.

Dirty filters usually can be corrected by proper use of the auxiliary scour devices such as surface washers or air scour. Where auxiliary scour is not successful, use of chemicals may

be necessary in some cases to attempt to clean the filter media in place. Various chemicals have been used, including chlorine, copper sulfate, acids, and alkalis (Babbitt et al., 1962). Chlorine may be used where the material to be removed includes living and dead organisms or their metabolites. Copper sulfate is effective in killing algae growing on filter walls or media. Carrying a chlorine residual in the filter influent aids in the control of microorganisms in the filter. Acidifying the water to a pH of about 4 aids in dissolving deposits of calcium carbonate and the oxides of iron, aluminum, and manganese. Sulfuric acid and hydrochloric acid have been used, but care must be taken to prevent high local concentrations to prevent damage to concrete filter walls. Citric acid has been used in the St Louis, MO, softening plant, as well as diluted, food-grade glacial acetic acid at the lime softening plant at Decatur, IL (Mayhugh et al., 1996). These organic acids are less dangerous to handle. Caustic soda has been used at the rate of 5 to 15 kg/m² (1–3 lb/ft²) for removing deposits resulting from the use of alum and for deposits of organic material. Chemical solutions are generally left in contact with the filter media for 1 to 2 days, and the filter then is washed thoroughly and returned to service.

If a filter can be removed from service for an extended period, deposits of calcium carbonate can be removed by feeding at a low flow rate a water acidified with carbon dioxide. The flow rate is selected so that the water leaves the filter with the CO₂ fully consumed at a pH of about 8.

Backwash of GAC Media

The properties of GAC are sufficiently different from conventional anthracite or sand media that some special precautions are required related to backwashing of GAC media filters (Graese et al., 1987). The lower density of GAC means that lower backwash rates are required to fluidize the common size gradations being used. Lower wash rates mean lower hydraulic shear and less effective upflow wash. Mudballs have been a common problem in GAC filters. Therefore, surface wash or auxiliary air scour is essential for GAC backwashing.

The higher UC of gradations of GAC often being used results in a greater percent expansion and better size stratification if the full bed is fluidized. There is greater potential for loss of GAC into the backwash troughs. In retrofitting existing filters with GAC media, raising the backwash troughs may be necessary to reduce the loss of GAC.

GAC is abrasive and corrosive to many metals. Therefore, all metals in contact with GAC should be resistant to abrasion and corrosion. Metals can be coated with corrosion-resistant substances.

Special precautions are important when preparing a new GAC media filter for service. The filter box should be disinfected before installing the GAC. After installation of the GAC, it must be submerged and soaked for at least a day to allow water to penetrate the pores of the GAC. Then backwashing must be done at a very low rate initially to be sure that all air is out of the bed to avoid loss of GAC. When all air is removed, the backwash rate can be increased to wash out undesirable fines from the bed. Release of additional air and fines may be observed during the first week of normal backwashing operation. See Chap. 14 for further information on the backwashing of GAC adsorbers.

Waste Backwash Water Management

Sections of Chap. 22 on management of water treatment plant residuals describe the treatment and recycle of waste (or spent) filter backwash water (FBW). A brief discussion is included here for completeness and because of the importance of the subject. Waste FBW is produced at a high flow rate for a relatively short time period (i.e., 15–30 minutes per

backwash), yielding a rather large volume of water with low solids content. The volume is typically 2 to 5 percent of total plant production or, as noted previously, in the range of 4 to 12 m³/m²/run (100–300 gal/ft²/run). Typical management options include discharge to a receiving water (requiring a National Pollutant Discharge Elimination System permit and water quality control), discharge to a sanitary sewer (often not available or feasible), and recycle to the head of the treatment plant, with or without treatment (for direct filtration, solids must be removed from recycled waste FBW). In nearly all cases, flow equalization via storage and controlled discharge or recycle is practiced. As noted in studies conducted prior to the 2001 USEPA Filter Backwash Recycling Rule (FBRR) (USEPA, 2001), recycle of waste FBW is a common practice because of the benefits of recovering the large water volume and the challenges associated with other options.

The impact of the recycle of waste FBW on treatment performance and plant effluent quality needs to be carefully considered; potential and actual effects are quite case-specific. Raw water quality, performance of clarification prior to filtration, backwash water chemistry, waste FBW treatment performance, other recycle streams, and rate of recycle all can affect the impact of recycle.

Concerns about recycling of *Giardia* cysts and *Cryptosporidium* oocysts had significant impact on the language in the 1996 SDWA Amendments that led to the USEPA FBRR. This was logical because when media filters remove cysts or oocysts, their concentration in the untreated waste FBW should be 20 to 50 times higher than in the filter influent water. The significance of this depends very much on levels of pathogens in raw water and the performance of prefilter clarification for removal of pathogens. Mass-balance modeling of recycle impacts can show the detrimental impacts of recycle (Cornwell and Lee, 1994), and it also can show that good clarifier performance greatly decreases or eliminates the possibility for waste FBW recycle to negatively affect plant influent (raw plus recycle) pathogen levels (Edzwald et al., 2001, 2003). Pilot studies with spiking of inactivated oocysts showed no negative impact of waste FBW recycle on clarification performance (Cornwell and MacPhee, 2001; Edzwald et al., 2003). A study of well-equalized recycle of untreated waste FBW at several plants for one utility (Tobiason et al., 2003b) showed no detrimental impacts on clarification (DAF or plate settling) or media filtration performance with respect to turbidity; the utility routinely had no detection of protozoan pathogens in its source waters. A companion pilot study showed that high levels of recycle of waste FBW with altered water chemistry (high pH) can have significant negative impacts on clarifier performance and some limited impact on filtration performance (Tobiason et al., 2003a).

As noted in Chap. 22, other water quality concerns associated with waste FBW recycle include organic matter (DBP precursors) and suspended solids and metals. Design of facilities for management of waste FBW and operation of recycle should be based on careful and rational consideration of the risk and impacts on treatment performance. Utilities should regularly monitor recycle stream quality and assess impacts on plant influent quality and process performance.

Wash Water versus Filtered Water Chemistry

The chemistry of the water used to backwash a filter may be significantly different from the chemistry of the filter influent and effluent waters and thus may affect aspects of filter performance and the management of waste backwash water. This is most likely to occur if the wash water source is the plant effluent clearwell and chemicals for disinfection and corrosion control have been added to the media filter effluent; common examples are free chlorine, chloramines, acid or base for pH alteration, a phosphorus-based corrosion inhibitor, and fluoride.

Backwashing with wash water of different chemistry than the filter effluent may have impacts on the stability of particles in backwash remnant water and thus affect particle

removal on filter startup; oxidation by disinfectants, surface-charge change due to pH change, and adsorption of corrosion inhibitors may be important. The actual impact is likely to depend on the extent of difference in water chemistry and the relative volume of wash water versus filter influent in the filter on startup; filter to waste may be useful in mitigating potential negative impacts on filtered water quality.

The presence of oxidants such as free chlorine in wash water when not typically present in filter influent or effluent may affect biological activity (Emelko et al., 2006) and may provide minimal regeneration of sorption sites for reduced manganese (Tobiason et al., 2008). Detrimental impacts of chlorine on GAC filter media are also possible.

As noted earlier, the chemistry of wash water may affect the quality of waste FBW and thus the quality of recycle streams. Changes in pH and oxidants relative to filtration conditions may result in dissolution of precipitated particles and/or desorption of material such as NOM. Also, free chlorine could interact with NOM in waste FBW and create additional DBPs that could be recycled. Impacts are site-specific and may or may not be of significance.

DIRECT FILTRATION

Process Description, Advantages, and Disadvantages

Direct filtration is a surface water treatment process that includes addition of coagulant, rapid mixing, flocculation, and filtration. In some cases, the flocculation tank is omitted, and the process is referred to as *in-line* or *contact filtration*. The most significant feature of direct filtration is the elimination of a separate clarification process prior to filtration. There are advantages and disadvantages to selection of direct filtration as well as limitations and special issues.

The advantage of direct filtration over conventional treatment is the potential for reduced costs. Capital and operating costs are lower because of elimination of a clarification process. If the clarification process was sedimentation, then lower capital costs for flocculation can be realized because the detention time for producing a “pinpoint” size filterable floc is much lower than the time required to produce a large settleable floc (e.g., 10–15 minutes versus 30–40 minutes). In some cases, lower coagulant dosages may be used in direct filtration if the comparison is against the use of excess coagulant to produce more solids to be flocculated for sedimentation. In general, coagulant dosing is controlled by levels of NOM and the need to destabilize raw water particles, so coagulant dosing is often the same regardless of the solid separation process. If coagulant doses are lower, then cost savings are realized for both chemicals and sludge treatment and disposal. Overall, the cost savings can be substantial, making direct filtration an attractive alternative.

There are, however, several significant disadvantages to direct filtration. The most significant is the reliance on a single process, media filtration, for all particulate matter removal; thus there is only one physical treatment barrier for pathogens, which is inconsistent with a multiple-barrier approach. Since effective media filter performance requires effective coagulation, and the time between coagulant addition and filter effluent is short, the direct filtration process has more inherent risk of failure than conventional treatment, thus requiring more careful and extensive monitoring and automatic controls. Without a clarification process, the filtration process must respond effectively to all changes in raw water quality; thus there are rational limitations on the types of raw waters amenable to direct filtration (see next section). In order to recycle waste FBW in direct filtration, a high level of removal of solids from the recycle flow must occur because there is no other location for solids removal to occur; recycle stream treatment options are discussed in Chap. 22. Because of less flocculation time and no clarification process, there is less detention time available for controlling

seasonal tastes and odors via intermittent adsorbent or oxidant addition; if this is expected, a pretreatment or contact basin may be used to provide the needed contact time with powdered activated carbon or oxidizing chemicals (Conley and Pitman, 1960b).

Appropriate Source Waters for Direct Filtration. Media filtration performance (i.e., particle removal and head loss) typically is limited and challenged by the amount of solids in the filter influent. Thus there are limits on suitable maximum levels of raw water parameters such as turbidity, algae, and NOM (as measured by color, TOC, and UV_{254} absorbance). Turbidity and algae are direct sources of solids, whereas the level and character of source water NOM usually controls coagulant addition and thus the coagulant-produced solids. Oxidation of high levels of reduced iron and manganese also can lead to significant solids production; this is usually an issue for groundwater treatment. The combination of cost-based advantage and process-based water quality limits has resulted in the development of guidelines for appropriate source waters for direct filtration (e.g., Culp, 1977; Letterman, 1987).

The type and dosage of coagulants needed to achieve desired quality of filtrate, as demonstrated by pilot- or full-scale observations, are probably the most important consideration in assessing the feasibility of direct filtration. If alum is the primary coagulant, Hutchison (1976) suggested that 12 mg/L of alum on a continuous basis would yield 16 to 20 hour filter runs at 12 m/h (5 gpm/ft²). This was considered sufficiently long to limit backwash water volume to 4 percent of the product. Waters with up to 25 color units were considered as suitable candidates for direct filtration with partial substitution of polymer for alum. Hutchison also suggested that diatom levels from 1000 to 2000 areal standard units per milliliter (asu/mL) required use of coarser anthracite and more frequent use of polymer to prevent breakthrough. One areal standard unit (asu) is $20 \times 20 \mu\text{m}$, or $400 (\mu\text{m})^2$. Anthracite with 1.5 mm ES was effective for 2500 asu/mL of diatoms and produce 12 hour filter runs at 12 m/h (5 gpm/ft²).

Wagner and Hudson (1982) suggested the use of jar tests and filtration through standard laboratory filter paper as a screening technique for selecting appropriate waters for direct filtration. Waters requiring more than 15 mg/L of alum (as filter alum) to produce an acceptable quality of filtrate were doubtful candidates for direct filtration. Waters requiring only 6 to 7 mg/L of alum and a small dose of polymer were considered favorable candidates. If the results of this bench-scale screening test are favorable, then pilot-plant tests are needed to determine full-scale design parameters.

An AWWA report on direct filtration (Committee Report, 1980) defined a water meeting the following criteria as a "perfect candidate" for direct filtration: color < 40 color units; turbidity < 5 ntu; algae < 2000 asu/mL; iron < 0.3 mg/L; and manganese < 0.05 mg/L. Cleasby et al. (1984a) considered the AWWA committee guidelines acceptable except for turbidity, which was considered too low. During seasons with low algae, they suggested turbidity limits of 12 ntu when using alum alone or 16 ntu when using cationic polymer alone. During seasons with high algae, they suggested limits of 7 ntu using alum alone and 11 ntu using cationic polymer alone. Best performance was achieved during seasons with low algae with alum dosages between 5 and 10 mg/L. During seasons with high algae, dosages of up to 20 mg/L were attempted with only moderate success and with runs as short as 12 hours at 7.3 m/h (3 gpm/ft²).

The preceding guidelines were developed prior to the increased attention to removal of DBP precursors (e.g., as TOCs) that arose during the late 1980s and 1990s. Maximizing TOC removal often involves addition of higher levels of precipitating coagulants and thus higher solids levels. Based on pilot and laboratory experiments, Edzwald et al. (1987) recommended TOC < 5 mg/L for direct filtration. More recently, based in part on full-scale plant surveys, Valade et al. (2009) recommended that average TOC and turbidity be less than 3 mg/L and 5 ntu, whereas maximum levels should be less than 5 mg/L and 25 ntu, respectively, for direct filtration.

In addition to the quantitative measures of water quality described earlier, consideration may be given to the probability or risk of the presence of pathogens in the source water. Increased concerns over waterborne disease from chlorine-resistant pathogens may contribute to selection of treatment with both clarification and filtration processes in lieu of direct filtration, especially when combined with the impact of potentially increased coagulant dosing for NOM control. The increasing use of low-pressure membrane filters, with or without prior clarification, instead of media filters, may reflect the potential increased reliability of a sieving removal mechanism independent of chemical dosing; the very frequent backflushing of low-pressure membranes also may be better suited for higher solids loading than direct filtration with media filters (see Chap. 11).

Chemical Pretreatment for Direct Filtration

The selection of the coagulant dosage for direct filtration is best determined by full-length filter cycles using pilot- or full-scale filters. Jar tests are often misleading because the goal in direct filtration is to form small pinpoint flocs that are barely visible but will filter effectively. Thus the usual criteria used to judge jar test observations such as formation of a large floc, or a clear supernatant liquor after settling, are not appropriate for direct filtration. The jar test and filter paper filtration technique (Wagner and Hudson, 1982) is somewhat better, but it provides no information on terminal breakthrough behavior or rate of generation of head loss; in addition, particles that are restabilized by charge due to coagulant overdosing can be retained by the filter paper but would not be removed by media filtration. Substitution of a miniature granular bed filter for the filter paper (Bowers et al., 1982) avoids the latter problem but suffers from the first two weaknesses. Kreissl et al. (1968) demonstrated that a clean filter could be operated at very high rates to simulate the hydraulic shear that would exist in the more clogged layers of the filter late in the filter run. This would predict whether the chemical dosage would be successful through the full length of the filter run. Despite these various techniques of using bench or pilot tests to select chemical dosages, the most common approach involves confirmation of the selected dosage with pilot- or full-scale filter runs of full duration at the design filtration rate.

When using alum or iron salts alone, the optimal dosage of coagulant for direct filtration is the lowest dosage that will achieve filtrate quality goals. An optimal dosage is normally not observed based on filtrate quality alone. Rather, as the dosage is increased, the filtrate quality gets marginally better, but the head loss develops at a higher rate, and early breakthrough is encouraged (Cleasby et al., 1984a).

When using cationic polymer alone as a primary coagulant, a distinct optimal dose may be found that produces the best-quality filtrate. In pilot studies, one method of detecting whether a particular dosage is above or below the optimum is to shut off the polymer feed for a few minutes. If the filtrate improves momentarily, the prior dose is excessive. If the filtrate deteriorates immediately, the prior dose was at or below optimum (Cleasby et al., 1984a).

A number of studies have reported successful use of alum and cationic polymers simultaneously. Typical dosages are 2 to 10 mg/L of alum plus about 0.2 to 2 mg/L of cationic polymer (McBride et al., 1977; Tate et al., 1977; Monscivitz et al., 1978; Cleasby et al., 1984a; Tobiason et al., 1992). These dosages are drawn from pilot- and plant-scale experience.

The impact of flocculation on direct filtration has been the subject of several studies that have been summarized by Cleasby et al. (1984a). These studies can assist in deciding whether flocculation should be provided in direct filtration. Comparing operation with and without flocculation, the provision of flocculation generally was found to improve filtrate quality before breakthrough, shorten the initial improvement period of the filter cycle, and reduce the rate of head loss development, but it also resulted in earlier breakthrough.

As noted earlier in this chapter, results of laboratory studies with model particles have shown that for the same suspended particle mass concentration, submicron particles cause much greater head loss than larger particles (Habibian and O'Melia, 1975; Tobiasson et al., 1993) possibly because of greater exposed surface area for smaller particles (O'Melia and Ali, 1978) or greater deposit volume (more pore clogging) because of the fractal nature of the deposit (Veerapaneni and Wiesner, 1997). Implications for treatment application are that optimal pretreatment for filtration, especially direct filtration, may be based on increasing particle size via flocculation to decrease head loss development; a laboratory study (Westerhoff and Tobiasson, 1991) and pilot results for in-line versus direct filtration (Glaser and Edzwald, 1979; Edzwald et al., 1987) support this concept.

The benefits or detriments of providing flocculation are best determined on a case-by-case basis by pilot- or full-scale studies. In some cases, flocculation has been found of no benefit (Al-Ani et al., 1986). Nevertheless, current practice usually includes a short flocculation period in direct filtration plants, typically about 10 minutes of high-energy flocculation at a velocity gradient G of up to 100 s^{-1} , although the range of flocculation detention times in existing plants has been very great, ranging from no flocculation to up to 60 minutes of flocculation (Letterman and Logsdon, 1976).

In-line filtration is appropriate for source waters that are consistently very low in turbidity and color. If flocculation were provided for such waters, long flocculation times would be required because of the poor opportunity for collision of particles. For example, flocculation was added to the in-line filtration plant at Las Vegas, but 30 minutes of detention was needed for this excellent source water (Monscivitz et al., 1978). Therefore, source waters are more economically treated by the addition of coagulant and an extended rapid mix of 3 to 5 minutes to achieve only the initial stages of particle aggregation before filtration. Few in-line plants are being built because flocculation adds flexibility to the plant operation. A bypass around the flocculator can be provided for contingencies.

Filter Details for Direct Filtration

Older summaries of direct filtration (Committee Report, 1980; Letterman and Logsdon, 1976) indicated filtration rates of full-scale operating plants of between 2.4 and 15 m/h (1 and 6 gpm/ft²). Direct filtration pilot studies at three locations showed, however, that effluent turbidity was nearly constant over the range from 5 to 29 m/h (2–12 gpm/ft²) and in one case as high as 44 m/h (18 gpm/ft²) (Trussell et al., 1980). In these studies, both alum and cationic polymer were used for chemical pretreatment. Dual-media and deep beds of coarse sand were compared. Some larger direct filtration plants with deep beds of coarser media operated at high HLR have been put into operation; a few examples follow.

A high-rate direct filtration plant is operated by the Los Angeles Department of Water and Power to treat water from the Los Angeles Aqueduct. The plant design was based on extensive pilot studies that led to the choice of deep beds of anthracite (1.8 m, or 6 ft) with an ES of 1.5 mm and UC < 1.4. The design filtration rate is 33 m/h (13.5 gpm/ft²). Pretreatment includes ozone to assist coagulation with ferric chloride and cationic polymer, and flocculation is provided before filtration. The filters are backwashed by air alone first at 1.2 m/min (4 cfm/ft²), followed by air plus water at 24 m/h (10 gpm/ft²). The air is terminated before overflow occurs to prevent loss of filter media, and the water wash is continued alone at a higher rate during overflow (McBride and Stolarik, 1987). Some of the pilot studies were reported by Trussell et al. (1980).

Pilot studies for the then-proposed plants for Sydney, Australia, included deep-bed single-media and dual-media configurations (Murray and Roddy, 1993). The dual-media configuration studied included anthracite 1.0 to 3.0 m (3.2–9.8 ft) in depth with 1.7 to 2.5 mm ES over 0.15 to 0.30 m (0.5–1.0 ft) of crushed sand with 0.65 to 1.0 mm ES. The

coarser dual media performed best in production per cycle and in filtrate quality. The Sydney Prospect Water Filtration Plant, the largest direct filtration plant in the world at a capacity of 3000 ML/d (780 mgd), was commissioned in 1996 and has 2 m (7 ft) of 1.7 mm ES sand media.

Patania et al. (1995) used deep beds of dual media (2.0 m, or 6.7 ft) of 1.25 mm-ES anthracite over 0.25 m (0.83 ft) of 0.6 mm-ES sand for in-line filtration pilot studies of cyst removal in Seattle. In 2000, the 454 ML/d (120 mgd) capacity Seattle Tolt Plant went into operation, incorporating preozonation, coagulation (ferric chloride and cationic polymer), and hydraulic flocculation prior to single-media filtration with 1.8 m (6.0 ft) of 1.3 mm ES anthracite with a UC < 1.4 (Tarbuck et al., 2002). The filters are approved for an HLR of 29 m/h (12 gpm/ft²) and regularly operate at more than 25 m/h (10 gpm/ft²); the underdrains have nozzles and no gravel.

In late 2009, commissioning was performed for the new 1800 ML/d (475 mgd) Seymour-Capilano Direct Filtration Plant for the metro Vancouver, BC, water supply. The configuration for the 24 dual-media filters is 1.7 m (5.6 ft) of 1.4 mm ES anthracite (UC < 1.5) over 0.3 m (1.0 ft) of 0.7 mm ES sand (UC < 1.5) (Phelan, 2010). The design filter HLR is 15 m/h (6 gpm/ft²) in winter and 20 m/h (8 gpm/ft²) in summer; initial winter operation indicates that filter-aid polymer is needed to have filter runs longer than 20 hours.

PRESSURE GRANULAR BED FILTERS

Pressure filters are sometimes used for rapid granular media filtration. The filter media are contained in a steel pressure vessel. The water to be filtered enters the filter under pressure and leaves at slightly reduced pressure because of the head loss caused by the filter media, underdrain, and piping connections.

Description of Pressure Filters

The pressure vessel may be a cylindrical tank with a vertical axis, such as shown in Fig. 10-27, or a horizontal-axis cylindrical tank. The horizontal cylindrical configuration has the disadvantage that the width of the filter bed is not constant from top to bottom, usually being wider at the top. This leaves dead areas along the walls that do not receive adequate fluidization during backwashing and therefore may not be washed effectively.

FIGURE 10-27 Cross section of a typical pressure filter.

In some horizontal-axis cylindrical tanks, the filter is divided into multiple (four or five) cells by vertical bulkheads. Cost advantages are gained by this configuration because only a single pressure vessel is needed. One filter cell can be backwashed by the production of the other cells that remain in service. This requires a filtration rate sufficiently high that the total production of the operating cells is sufficient to fluidize the media of the single cell being backwashed.

Comparison of Pressure and Gravity Filtration

While the outward appearances of a pressure and a gravity filter are quite different, the filtration process is the same. The same mechanisms for capturing particles are functioning in both. The same filter media, the same filtration rates, and the same terminal head loss should be used if comparable filtrate quality is desired.

The use of higher filtration rates and high terminal head loss in a pressure filter is tempting because the influent is under pressure, and more potential head loss is available. This temptation should be resisted, however, unless no detriment to the quality of the filtrate can be demonstrated on a case-by-case basis.

One advantage gained by pressure filtration is that water leaves the filter under a positive gauge pressure, and therefore, no negative pressure can ever exist in the filter bed. The potential problems associated with negative pressure, as discussed earlier, are therefore avoided.

Operation of Pressure Filters

Because of the similarities between pressure and gravity filters, the operating principles are identical. For example, appropriate pretreatment is equally important to pressure and gravity filters, patterns of filtrate quality will be the same, the impact of sudden rate increases will be just as detrimental, and the importance of proper backwashing is equally important.

The operation of a pressure filter is similar in most respects to the operation of a gravity filter. Proper backwashing of a pressure filter is more difficult, however, because the filter bed is not conveniently visible to the operator during the backwash operation. The visual observations that can be conveniently made for gravity filters are difficult or impossible with pressure filters. These include (1) the presence of filter cracks before the backwash or mudballs after the backwash, (2) the uniformity of backwash water distribution, (3) the uniformity of rate of cleanup of the wash water over the full filter areas, (4) the proper functioning of the auxiliary scour device such as surface wash or air scour, (5) the elevation and appearance of the top surface of the filter media after the backwash, (6) whether the media are fully fluidized during the backwash (if that is the intended washing method) and the extent of expansion of the filter media, and (7) the extent of loss of the filter media.

Because of these difficulties, failures of pressure filters have resulted in waterborne disease outbreaks partially attributed to the poor condition of the media in the filters (Kirner et al., 1978; Lippy, 1978). Prior concerns about the reliability of pressure filters and other concerns have caused some state regulatory agencies to exclude the use of pressure filters in the treatment of surface waters or other polluted source waters and lime-softened waters (e.g., Great Lakes–Upper Mississippi River Board, 2003).

Rate Control for Pressure Filters

Rate control for pressure filters is as important as it is for gravity filters because the same filtration mechanisms are functioning in both cases. Fewer options are available for pressure filters, however, because the pressure filter operates full of water under pressure. As a result, options involving changing water level are not available, and influent gravity flow

splitting is not available. Therefore, the benefits of slow rate changes by allowing water levels to change are not available to pressure filters.

Typically, a bank or set of pressure filters is piped in parallel; thus the total head loss across each filter is identical, and the flow through each filter is inversely proportional to the clogging head loss in the filter. The total filter area of the filter bank is sized appropriately to meet local regulatory requirements based on feed-pump capacity. Individual filter flow controllers and flowmeters are not provided. After the backwash of all the filters in short succession, if one filter is passing more flow than it should, that filter is assumed to clog more quickly than the other filters, and the flow will be reduced because of the clogging resistance. Thus the system is considered self-equalizing during operation. However, if the multiple filters are backwashed at random intervals during a filter cycle, the cleanest filter will have the highest flow and the dirtiest filter the lowest flow. The extent of these differences will not be known if individual flowmeters are not provided.

Despite the common practice described earlier, it is desirable to have a flowmeter on each pressure filter in a bank of several filters. Flowmetering is useful to plant operators for diagnostic purposes to observe if something is wrong with one filter causing the flows not to be equally split. This could happen if one filter is not cleaned properly during backwashing, perhaps because of a clogged underdrain, or one filter flows at an excessive rate due to loss of some or all of the filter media.

Applications of Pressure Filters

Pressure filters tend to be used in small water systems. Many pressure filters are used in industrial water and wastewater filtration applications. They also are used widely in swimming pool filtration.

Advantages of pressure filters over gravity filters include the following: The filtrate, which is under pressure, can be delivered to the point of use without repumping. In some treatment plants, source water (often from a well) can be pumped from the source through the treatment plant and directly to the point of use by the source water pumps. Also, it is somewhat easier to automate the operation of a treatment plant equipped with pressure filters.

Some groundwaters containing iron can be treated by pressure aeration and/or chemical oxidation and then filtered directly by pressure filters. This approach has received considerable application for small communities. Not all iron-bearing waters respond successfully to this method of treatment, however, and prior pilot testing usually is required. Similarly, some groundwaters that require manganese (and possibly iron and organic matter) removal can undergo chemical oxidation and pressure media filtration with direct introduction to the distribution system.

SLOW SAND FILTRATION

Description and History

The slow sand filter is a sand filter operated at low filtration rates (<0.3 m/h, or <0.12 gpm/ft²), traditionally without the use of coagulation in pretreatment. The sand size is somewhat smaller (~ 0.15 – 0.30 mm) than that used in a rapid-rate filter, and this, plus the low filtration rate, results in the solids being removed almost entirely in a thin layer on the top of the sand bed and in the uppermost portion of the sand bed. The layer on top of the sand, composed of dirt and living and dead micro- and macroorganisms from the water (i.e., the *schmutzdecke*, or “dirty skin”), becomes the dominant filter medium as the filter cycle progresses. When

the head loss becomes excessive, the filter typically is cleaned by draining the supernatant water below the sand surface and physically removing (scraping) the dirty layer along with 1 to 3 cm (0.5–1 in) of sand. Typical filter cycle duration between cleaning may vary from 1 to 6 months (or longer) depending on source water quality and the filtration rate. Biological activity is a key aspect of the slow sand filtration process, and this must be considered in the design and operation of slow sand filters.

Slow sand filtration was developed in England by James Simpson in the early nineteenth century and continues to be used successfully in the United Kingdom and Europe. In the United States, this treatment process has been used to treat high-quality upland surface waters in New York and New England since the late 1800s and early 1900s, but because it could not treat turbid waters in the Midwest and elsewhere in the United States, the process was not used widely. As a result, rapid-rate filtration came to be the filtration process of choice for most water utilities.

Renewed interest in slow sand filters occurred because numerous waterborne outbreaks of giardiasis occurred in the latter 1970s and early 1980s in communities using unfiltered or poorly filtered water. Slow sand filtration is a simple technology requiring no knowledge of coagulation chemistry and is quite attractive for small installations treating high-quality surface waters. The possibilities for applying this treatment process for small water systems led to research efforts demonstrating the efficacy of the slow sand filter in removal of *G. lamblia* and to its application in numerous communities in New England, the Rocky Mountain Region, and the Pacific Northwest in the United States, as well as in Canada.

Mechanisms of Filtration and Filter Performance

Biological action is the key to removal of microbes, and it influences turbidity removal in slow sand filters. This is one important difference between how these filters and rapid-rate filters work. Design and operation of slow sand filters need to be consistent with the objective of maintaining an active biological population within the sand bed.

The Organisms in a Slow Sand Filter. Haarhoff and Cleasby (1991) undertook an in-depth review of the ecosystem in a slow sand filter, which typically includes bacteria, protozoa such as rhizopods and ciliates, rotifers, copepods, and aquatic worms. They explained that the kinds of organisms found change as water flows deeper into the sand bed. At the surface of the filter bed, a layer of decaying biological matter and bacteria called the *schmutzdecke* develops. This is a German word for “dirty skin.” Some straining occurs in the *schmutzdecke*. As the water enters the *schmutzdecke*, biological action breaks down some organic matter, and inert suspended particles may be physically strained out of the water. The water then enters the top layer of sand, where more physical straining and biological action occur, and attachment of particles onto surfaces of the sand grains takes place. Algal mats of filter-clogging species may form at the *schmutzdecke*, and some algal cells may penetrate into the top inch (about 30 mm) into the sand in large numbers.

Duncan (1988) studied the ecology of slow sand filters in facilities owned by Thames Water Utilities and reported that bacteria are most numerous within the top 5 cm (2 in), decreasing at lower depths. In a biologically mature filter, protozoa were most numerous from near the surface to depths of 5 to 10 cm (2–4 in). They feed on bacteria and sometimes also on algae cells. Among the largest organisms found in a slow sand filter bed are round worms, flatworms, and segmented worms, which can be as large as a few millimeters in size. Some of the worms feed on detritus, that is, fragments of organic matter, and tend to be deeper in the bed than bacteria and protozoa.

Understanding that the sand bed is inhabited by living organisms is important to the design and operation of slow sand filters. The organisms need both food and oxygen to

metabolize the food they ingest, and having a steady input of food and oxygen to the filter bed helps to stabilize their population. Long-term interruptions of flow can lead to depletion of oxygen in the filter bed and to die-off of organisms that are the key to effective slow sand filtration. Drying a slow sand filter bed has even more serious consequences and could lead to elimination of most or all of the biota in the bed. Therefore, the flow of influent water should be continuous during water production, and filter-bed maintenance activities need to be performed in a prompt manner to minimize downtime and harmful effects to the biota.

The Schmutzdecke. The *schmutzdecke* that develops on the sand bed surface provides significant removal of particulate matter, and an initial improvement period (or ripening period) frequently can be observed at the beginning of each cycle after removal of the *schmutzdecke* along with a thin layer of sand at the end of the previous filter run (Cleasby et al., 1984b; Cullen and Letterman, 1985). The initial improvement period was observed by Cullen and Letterman (1985) to vary from 6 hours to 2 weeks, although most improvement periods have been reported to be less than 2 days (Cleasby et al., 1984b; Cullen and Letterman, 1985). A filter-to-waste period of 2 days was recommended, in which cysts of *G. lamblia* are of concern (Cleasby et al., 1984b), but Bellamy et al. (1985a) found no effect of scraping on *Giardia* cyst removal after 41 weeks of filter operation, when the sand bed of a pilot filter was biologically mature.

In addition to the initial improvement after scraping, a distinct improvement in the performance of a filter with new sand occurs as it matures over several cycles or runs, as indicated by the removal of coliform bacteria, particles, and *Giardia* cysts (Fox et al., 1984; Cleasby et al., 1984b; Bellamy et al., 1985a). In a Midwestern pilot study, after the first four filter cycles, average reduction of turbidity was 97.8 percent or better, removal of cyst-sized particles (7–12 μm) was 96.8 percent or better, removal of total particles (1–60 μm) was 98.1 percent or better, removal of total coliform bacteria was 99.4 percent or better, and removal of chlorophyll *a* was 95 percent or better after the first 2 days (the ripening period) of each run (Cleasby et al., 1984b).

Removal of Microorganisms. Slow sand filtration was effective in removing pathogens and reducing the incidence of waterborne disease in London and other cities in the 1800s even before scientists understood that microbes could cause communicable diseases such as cholera and typhoid fever. Bacteria removal can be as great as 3 log to 4 log (Fox et al., 1984; Cleasby et al., 1984b; Bellamy et al., 1985a; 1985b). Following the identification of viruses as a cause of waterborne illness, researchers at the Metropolitan Water Board in London (now part of Thames Water Utilities) evaluated virus removal and again reported values as high as 3 log to 4 log (Poynter and Slade, 1977). Research sponsored by the USEPA in the 1980s demonstrated that *Giardia* cyst removal also could be in the range of 3 log to 4 log (Bellamy et al., 1985a, 1985b; Pyper, 1985). Similar removals have been attained for *Cryptosporidium* oocysts (Economic and Engineering Services and Thames Water Utilities, 1996). Mature slow sand filters evaluated at the University of Waterloo (Anderson and Huck, 2005) also performed in this range and sometimes better for removal of *Giardia* cysts and *Cryptosporidium* oocysts. These results have been attained with filters having a developed, or mature, biota.

The removal of microorganisms in filtration by predatory action is probably unique to slow sand filtration. The role of ciliate protozoa as bacterial predators was investigated in laboratory studies (Lloyd, 1996) of a pilot filter having a bed of sterilized sand. Removal of bacteria in filtration tests without ciliate protozoa present was about 1 log lower than the 2 log to 3 log removal attained when ciliate protozoa were inoculated into the sand bed. Bichai et al. (2009) presented photomicrographs of *Cryptosporidium* oocysts ingested by rotifers in a review of work on slow sand filters undertaken at the Weesperkarspel plant.

This is further evidence that predation of microbes occurs in slow sand filters and thus is a mechanism by which microbes are removed by slow sand filtration.

Because slow sand filters are biological filters, microorganism removal declines when water is cold and the metabolism rate of the biota facilitating microbial removal slows greatly. *Giardia* cyst removal by a small slow sand filter used for demonstration testing was in the range of 3 log to 4 log when water was 7.5 to 21°C. When water was less than 1°C, cyst removal generally was in the 1 log to 3 log range (Pyper, 1985). The effect of low temperature on filter performance needs to be considered by designers if cold source water will be treated.

Removal of Inorganic Particles. Removal of organic particles in a slow sand filter can be explained in part by predatory action of the larger organisms as they use smaller ones for food, but clay and other mineral particles are not an organic food source, so some other explanation for removal of inorganic turbidity particles is needed.

Experiments in which Horsetooth Reservoir water originating high in the Rocky Mountains was used (Bellamy et al., 1985b) showed that turbidity and total coliform removals were lower in a slow sand filter that had been chlorinated between filter runs to minimize biological activity compared with a control filter operated in the normal manner. On the other hand, a slow sand filter treating water with supplemental sterile nutrients for promotion of biological growth removed both turbidity-causing particles and total coliform bacteria more effectively than the control filter. This work indicated that biological action played an important role in turbidity removal. Huisman and Wood (1974) stated that the action of microbes in a slow sand filter results in the formation of a sticky gelatinous film on surfaces of the *schmutzdecke* and on sand grains that can hold inert matter until it is removed when the filter bed is cleaned.

Additional explanation for removal of inorganic particles by slow sand filtration was found in literature on the activated-sludge wastewater treatment process. Pavoni et al. (1972) reported that some kinds of bacteria release exocellular polymers that can flocculate not only bacteria in the activated-sludge liquor but also clay particles. If higher levels of bacterial growth in a slow sand filter result in release of greater concentrations of exocellular polymers that can make the surfaces of sand grains more "sticky," this could enhance clay particle removal by attachment to the sand. The results of Bellamy et al. (1985b) reinforce the importance of maintaining a healthy and active biological population in the filter bed and strongly suggest a role for exocellular polymers in slow sand filters.

Biological Filtration for Removal of Dissolved Organic Matter. The extent to which dissolved organic matter can be removed in slow sand filters depends on the biodegradability of the dissolved organics. Although readily degradable organic matter can be removed effectively by the biota in a slow sand filter, biota also exist in natural waters, and they use organic matter there. Readily degraded dissolved organic matter may have been used already as a food source before source water is treated by slow sand filtration. Organic matter that is not readily degraded in natural waters and thus is persistent, such as natural color or humic substances, is not likely to be used easily as a food source by the biota in a slow sand filter. Water sources with the potential to have high concentrations of color include marshes, swamps, and lakes having large quantities of vegetation, and removal of color from such waters may be in the range of 25 percent. Rooklidge et al. (2005) studied removal of antimicrobial compounds and reported that only those with high filter media sorption coefficients were removed well by slow sand filtration. Based on these observations, slow sand filters would not be expected to be effective for removal of some of the pharmaceutical compounds and personal-care products that pass through biological wastewater treatment plants and persist in low (e.g., microgram per liter) concentrations in surface waters.

Slow Sand Filter Design

Facility and Filter Bed. Slow sand filters are the least complex type of granular media filter. They consist of a basin with a bed of relatively fine sand placed over support gravel and underdrain piping (Fig. 10-28). The basin can be a concrete filter box or an earthen embankment. In modern designs, the embankment and basin bottom may have an impervious liner to prevent water loss through the bottom of the basin and erosion of the basin slopes. In the usual operating mode, influent water is introduced above the filter bed in a way that does not disturb the sand, but for the initial filling and after the bed has been dewatered, water must be introduced from beneath the filter to drive air out of the bed as it is filled.

Twort et al. (2000) indicated that five valves are needed for a slow sand filter. They are provided for the purposes of filling the filter from the bottom to drive air out of the bed during initial filling and after maintenance procedures, filtering to waste and draining water out of the bed, draining supernatant water down prior to dewatering the bed for maintenance, controlling influent flow, and controlling effluent flow.

At the bottom of the filter box or basin, collector piping is surrounded by support gravel about 0.4 to 0.6 m (1.3–2 ft) deep. Above the gravel layer is filter sand with an initial depth of 0.8 to 1.2 m (2.7–4 ft). Depth of supernatant water over the media is typically about 1 m (3 ft).

The effective size of filter sand usually is in the range of 0.15 to 0.30 mm, with $UC < 5$ and preferably < 3 . Smaller media sizes tend to provide more effective particle removal but cause head loss to be higher than larger media. Bellamy et al. (1985b) studied the effect of sand size and reported that total coliform removal was 96 percent for a filter having an effective size of 0.6 mm and 99.4 percent when the effective size was 0.1 mm. The recommendations for sand size, bed depth, UC, and supernatant water depth just given are similar to criteria suggested by Visscher (1990) for filters in developing countries.

Slow sand filters designed for operation in cold regions generally are covered because scraping sand in an ice-covered slow sand filter cannot be done until the ice layer is removed from the water. Providing structures to cover filter beds requires additional capital investment, so some exceptions have been made to this general concept of covering the filters when extended freezing conditions are expected. A second reason for covering slow sand filters to

FIGURE 10-28 Slow sand filter influent control. (Source: Logsdon, 2008.)

prevent freezing is the possible damage that may be caused if a thick layer of ice forms on the supernatant water and pushes against the filter walls. Note that if filters are covered, it is important that sufficient headroom for maintenance workers be provided between the surface of the sand bed and the bottom of the roof structure covering the filter.

Filtration Rates and Rate Control. The filtration rate may range from 0.1 to 0.3 m/h (0.04–0.12 gpm/ft²), and sometimes even higher rates are provided. Higher filtration rates result in smaller sizes for filter beds, but removal of microbes and turbidity can decrease when the filtration rate is higher. The low filtration rates require filter bed areas 20 to 50 times larger than filter areas for rapid-rate filtration for production of the same quantity of water per day. For many small installations in rural areas, however, the much larger filter area needed for slow sand filter beds does not present a problem because of the availability of land. Good design practice provides multiple filter beds that are sized so that when one filter is removed from service for cleaning by removal of a thin layer of sand or for replacing sand to restore the initial bed depth, the other filter or filters can produce sufficient water to meet the system demand.

Filter efficiency is influenced by water temperature because the metabolic rate of the biota in a slow sand filter and in the *schmutzdecke* is impeded or decreased by cold water. As a result of the temperature effect, removal of microbiological contaminants has been demonstrated to be reduced somewhat in water when the temperature is near freezing. Operating at a slower filtration rate can help to counteract this decrease in filtration efficiency. In many communities, water demand peaks in warm weather when lawns and gardens are watered, so lower filtration rates can be used in winter. An exception to this could be a community that has a heavy influx of tourists and high water demand during the winter season. If cold water will be encountered, this can be a consideration in selection of the filtration rate used for plant design.

As with rapid-rate filtration, rate control is important and can be accomplished by influent or effluent rate control, as shown in Figs. 10-28 and 10-29. The simplest modes of rate control involve manual operation of valves to adjust the rate of flow to the desired value. Influent rate control can be applied simply by use of an influent water channel and a weir at each filter in plants with multiple filters, with each weir having the same design and elevation for equal flow splitting. A gate or other device is needed to block the weir and stop inflow when maintenance is performed. A splash plate is needed to prevent erosion of the sand as it falls from the weir into the sand filter, and a discharge weir higher than the top of the sand bed is provided to prevent dewatering of the bed during operation. An example of influent rate control is provided in Fig. 10-28. Rate changes will occur gradually as the

FIGURE 10-29 Slow sand filter and effluent control. (Source: Logsdon, 2008.)

water level in the filter box raises or lowers depending on the rate of inflow versus outflow and the available head to cause flow through the filter bed.

For filter effluent rate control (shown in Fig. 10-29), rate changes are made by adjusting an effluent valve, and these changes should be made gradually and as seldom as possible. Guidelines for two water utilities in the United Kingdom limit filtration rate increases to about 10 percent per hour (Ratnayaka, 2009). Particles that are not part of the biofilm in a slow sand filter may be weakly bound and can be flushed out by a rapid increase in filtration rate. A practice to avoid in effluent rate control is to maintain the desired supernatant water level in the filter by frequently opening and closing the effluent valve. Frequent on-off operation is not acceptable, and shutdowns of filter flow are to be avoided except for filter maintenance.

When filtered water storage is sufficient to cover variations in system demand over a day's time, adjustment of filtration rate can be made as infrequently as once per day, which is appropriate for small systems that are operated by part-time personnel who have only an hour or two each day to devote to water treatment operations. Sizing finished water storage so that it is sufficient to account for hourly fluctuations in demand throughout the day enables the filter to operate throughout the day at a production rate similar to the total water demand for that day.

Other Information Sources. With the increased interest in slow sand filtration in the 1980s, the AWWA Research Foundation sponsored development of a design manual for slow sand filters (Hendricks et al., 1991). This is no longer available, but a book by Hendricks (2006) contains a chapter, "Slow Sand Filtration," with about 50 pages of text and photos. The author states that the chapter was adapted, to a large extent, from the slow sand filter design manual for which he was the senior author in 1991.

Another important source of information for slow sand filter design is pilot-plant filtration testing data obtained by treating the source water that will be treated by the full-scale plant that is being planned. This is especially important if no pretreatment is planned to prepare the water for slow sand filtration. Pilot-plant studies are not labor-intensive because with the low filtration rate used for slow sand filtration, changes in filter performance do not occur in short periods of time. One daily check on filter operation for sample collection and data recording is often sufficient, and the testing results can provide guidance for design when a source water has not been treated previously by slow sand filtration.

Source Water Quality

Slow sand filters have not been successful in treating clay-bearing river waters because the clay penetrates too deeply into the filter and cannot be removed in the normal surface-scraping operation. In addition, they are not effective for removing color, typically achieving only 25 percent removal.

A 1984 survey of 27 existing full-scale plants in the United States found that the mean turbidity of the source water was about 2 ntu, with the peak about 10 ntu (Slezak and Sims, 1984). Mean lengths of filter runs varied from 42 days in the spring to 60 days in the winter. Wide variations were reported, with two reports of cycles as long as 1 year.

Performance of seven plants in New York was evaluated by Cullen and Letterman (1985), including three of the plants reported on by Slezak and Sims. In New York, the turbidity of the source waters being used generally was less than 3 ntu. One plant with 6 to 11 ntu source water was not meeting the existing (1984) 1 ntu finished water turbidity MCL. Average run lengths varied from 1 to 6 months.

Short filter runs may occur when algal blooms take place in source water. In a pilot-plant study, Cleasby et al. (1984b) observed a 10 day run when the chlorophyll *a* concentrations were 131 and 132 $\mu\text{g/L}$ in two samples of raw water obtained during the run. Algae and diatoms

that have been classified as filter-clogging species are most likely to have an adverse effect on filter run length. Color plates of filter clogging algae can be found in *Standard Methods* (APHA, AWWA, and WEF, 2005).

When slow sand filters are used without pretreatment or posttreatment other than disinfection and corrosion control, source water quality must be good based on how these filters work. Cleasby (1991) has recommended the following guidelines for source water that is ideal for slow sand filters: turbidity < 5 ntu; no heavy seasonal algal blooms occur, and chlorophyll *a* < 5 µg/L; Fe < 0.3 mg/L; and Mn < 0.05 mg/L. His recommendations did not cover synthetic organics or inorganic contaminants such as arsenic. Since the capability of slow sand filtration for removal of microbiological contaminants is excellent, it is most suited for application without supplemental treatment other than disinfection when source waters do not contain contaminants that resist removal by biological filtration.

Modifications to Slow Sand Filtration for Enhanced Performance

When source water quality is beyond the range recommended for slow sand filters used alone, pretreatment can extend the capability of this process so that a wider variety of source waters can be treated. Higher turbidity, color and natural organic matter, and synthetic organic chemicals can be removed when pretreatment or posttreatment processes are added.

For some source waters, roughing filters, infiltration galleries, or infiltration wells in or near streams or rivers can remove sufficient turbidity that the remainder can be dealt with in a slow sand filter. These concepts were reviewed in detail by Cleasby (1991). Although chemical pretreatment is usually not used, an emergency pretreatment practice using chemical coagulation followed by flocculation and sedimentation in channels and basins at Salem's slow sand filter facility on Geren Island was carried out during and following a major flood in Oregon in early 1996. This ad hoc pretreatment attained turbidity reductions ranging from 80 to 90 percent and enabled the filters to continue operating without being plugged over a period of several weeks of abnormally high turbidity (Krueger et al., 1999).

Changing the nature of dissolved organic constituents can increase their biodegradability. This is most readily accomplished by use of ozone for pretreatment ahead of a slow sand filter. Preozonation has been shown to increase the biodegradability of dissolved organics in biologically active rapid-rate filters, and it does the same for slow sand filters (see Chap. 7 for a discussion of ozone). The extra microbiological growth resulting from increased availability of food can result in formation of biofilms on slow sand filter media to the extent that head loss may increase at a faster rate than if ozone were not used. Adapting ozone to an existing slow sand filter might decrease filter run times, whereas for a new filter with preozonation, designers can consider using a slightly larger media size to compensate for the possibility of added head loss caused by more biofilm formation.

Preozonation proved beneficial in a slow sand filtration study performed in the United Kingdom. Reduction of true color by slow sand filtration alone was about 20 percent, whereas reduction by preozonation and slow sand filtration was almost 75 percent (Greaves et al., 1988). In addition, preozonation increased removal of TOC from 8 to 15 percent for slow sand filtration alone to 25 to 35 percent, indicating that ozone was breaking apart organic molecules that were not readily biodegradable and creating substances that were more easily used as food by organisms living in the filter bed.

To enable slow sand filter plants to effectively treat source water containing pesticides and satisfy the European Community limit of 0.1 µg/L for individual pesticides, Thames Water Utilities, Ltd., developed the GAC Sandwich filter (Bauer et al., 1996). A full-scale filter consisting of a layer of 300 mm of filter sand as the bottom layer, 150 mm of Chemviron 400 GAC in the middle, and 450 mm of filter sand on top was operated at filtration rates ranging from 0.1 to 0.3 m/h and demonstrated excellent removal of pesticides.

Treatment with slow sand filtration supplemented by preozonation, a roughing filter for enhanced particle removal, and a GAC filter following the slow sand filter was evaluated at the University of Waterloo in Canada (Anderson and Huck, 2005). Source water was the Grand River, which has a watershed in agricultural and urban areas in Ontario. When the roughing filter and slow sand filter were biologically mature, filtered water turbidity was maintained below 0.3 ntu even when source water turbidity exceeded 25 ntu and the slow sand filter was operated at a rate of 0.4 m/h. TOC removal for the entire process train was 58 to 65 percent compared with about 15 percent for a slow sand filter operated in parallel but with neither pretreatment nor posttreatment. The pretreatment processes combined with slow sand filtration reduced THM formation by 58 to 60 percent. The test results demonstrated that pretreatment compatible with slow sand filtration can extend its capabilities for removal of turbidity and organic contaminants substantially.

Startup and Maintenance Procedures

Placing a New Filter into Service. When a new slow sand filter is placed into service, a period of weeks is needed for the biota to develop within the sand bed and provide effective treatment. With passage of time, the *schmutzdecke* develops, and a variety of organisms grow within the filter bed. Among the approaches taken for evaluation of slow sand filter efficacy are measurement of turbidity, *Escherichia coli*, total coliform bacteria, viruses, and *Giardia* cysts in filter effluent (Haarhoff and Cleasby, 1991). In their review of the slow sand filter literature, Haarhoff and Cleasby reported five studies in which a new filter bed was reported to have matured within a time of 35 to 60 days. In three of the five studies, the monitoring done for filter maturity was for total coliform bacteria or *E. coli*. Colder water would slow the development of biota in the bed and the maturation time, and one study done in Vermont was reported by Haarhoff and Cleasby to have had a 100-day initial operating period before erratic removal results were no longer observed.

Locally obtained sands have been used for the filtering material in some slow sand filters. When this was done without thoroughly washing the local sand, turbidity in filter effluent exceeded that of the filter influent during startup. Tanner and Ongerth (1990) reported that a new slow sand filter with beds of locally obtained sand that initially contained clay fines to the extent of 4 percent by weight produced filtered water turbidity that generally exceeded raw water turbidity from 3 to 15 months of operation after startup. Filtered water turbidity at this plant exceeded the MCL during 6 of the 12 months of Tanner and Ongerth's study. This performance was attributed to incomplete washing of the filter sand before it was placed in the beds. The gradual discharge of fine particles that cause turbidity has the potential to lengthen the time between starting the initial flow of water through the filter and acceptance of the filter as being capable of producing potable water for public consumption.

Cleaning When Terminal Head Loss Is Reached. Slow sand filters are cleaned by removing the *schmutzdecke* along with a small amount of sand, an operation known as *scraping*. The sand that is removed can be cleaned hydraulically and stockpiled for later replacement in the filter. The scraping operation can be repeated until the depth of the filter bed has decreased to about 0.5 to 0.6 m (1.6–2 ft), at which time the design depth should be restored, a procedure referred to as *resanding* the filter. Resanding is described later in this section.

The sand in small plants is usually skimmed by hand using broad shovels. Scraping and resanding are labor-intensive operations, and consideration should be given to reducing the manual labor involved. By the use of efficient motorized buggies or hydraulic transport, and by limiting removal to a 2.5 cm (1-in) depth, 5.4 h/100 m² (5 h/1000 ft²) was considered to be an adequate allowance for labor (Cullen and Letterman, 1985). One small plant reported

use of asphalt rakes to scrape the dirty surface into windrows from which it was then shoveled into buckets for transport. Using this technique, the filter could be cleaned using labor at a rate of 1.3 h/100 m² (1.2 h/1000 ft²) when the depth of sand removed from the filter surface was about 0.5 cm (0.2 in), according to Seelaus et al. (1986).

The longer a filter is drained for the scraping operation, the longer will be the initial improvement period during the subsequent run (Cullen and Letterman, 1985). Therefore, cleaning should be accomplished quickly to minimize the time during which the filter has been drained.

Another approach to cleaning a slow sand filter bed is *wet harrowing*. This method of cleaning has been used with success at a large slow sand filter plant in New England (Collins et al., 1991). To accomplish wet harrowing, the supernatant water is drained from the filter down to a depth of about 30 cm (12 in). Then a rubber-tired tractor equipped with a comb-tooth harrow is used to stir the top 30 cm (12 in) of sand while the remaining supernatant water is allowed to drain off to the side of the filter bed. The horizontal flow of water carries away the dirt and *schmutzdecke* stirred up by the harrowing. If the harrowing is not completed by the time the water level drops to 8 cm (3 in) over the bed, harrowing is stopped, and the bed is refilled to about 30 cm (12 in) so that the harrowing can resume. This cleaning method has been reported to extend the time for removing sand from the beds for a thorough cleaning to intervals of 8 to 10 years.

After filter cleaning or scraping, operating the filter and wasting filtered water for a day, or perhaps longer, may be appropriate. A conservative approach would be to test for coliform bacteria in filter effluent and filter to waste until coliform data are acceptable. The time needed to verify that filtered water quality is satisfactory after scraping is a reason for having multiple filter beds.

Replacing Sand When Bed Level Reaches Minimum Depth. Adding sand to the filter bed (resanding) is done when a minimum acceptable bed depth, about 0.5 to 0.6 m (1.6–2 ft), is reached after repeated filter scrapings. To do this, the bed must be dewatered first and then scraped to remove the *schmutzdecke* and accumulated dirt at the top of the sand layer. Next, starting at one wall of a rectangular or square filter bed, a trench parallel to the wall is excavated about 1 m (3 ft) wide, equal to the depth of the layer of sand that needs to be added to restore the filter to its original surface elevation. The excavated sand can be set aside for use at completion of the resanding task. New sand or cleaned, recycled sand that had been scraped off the filter previously is placed in the trench formed by removing the old sand, and then a trench of old sand is excavated adjacent to the previous trench that was filled. The old sand removed from the second trench is placed on top of the new sand that was placed in the first trench. This procedure results in placing sand from the lower part of the filter onto the top portion of the bed in the resanded filter. The pattern is repeated across the entire filter. When the last trench is excavated adjacent to the far wall (the one opposite the wall where excavation was first performed), the sand that was excavated first then is placed in over the new or reused sand that was placed into the last trench.

Use of the trenching procedure is more laborious than merely putting sand on the top of a filter that needs a deeper bed, but a couple of advantages can result from doing the trenching. If the resanding is done in a prompt manner, especially in smaller installations, some of the biota in the sand bed may survive the resanding procedure and be able to serve as a source for organisms in the resanded bed. A second reason for using the trenching procedure instead of just adding more sand to the shallower filter is to prevent development of a less pervious layer of sand in the upper zone of the undisturbed sand. For example, if a filter is repeatedly resanded when the depth decreases to 60 percent of the original depth, the sand just below the 60 percent level may become clogged, resulting in increased clean-bed head loss.

Letterman (1991) has indicated that resanding can require as much as 50 hours of labor per 100 m² (53 h per 1000 ft²). This is a procedure that calls for advanced planning, and for a small system with limited staff, finding extra workers on a temporary basis to help with

this task is a way to accomplish it in a timelier manner. Washing used sand again just before resanding would be helpful for keeping dirt and contamination out of the filter bed.

Following resanding, the renovated filter may need to be run to waste for a few days. Letterman (1991) reported that earlier literature had suggested a period of 1 to 2 days for filter-bed ripening. Monitoring filtered water turbidity and coliform bacteria will provide information on the quality of water produced after resanding and will indicate when filter effluent again can be sent to the distribution system.

Recommended Standards for Water Works (Great Lakes–Upper Mississippi River Board, 2003) specifies that slow sand filters should be operated to waste after scraping or resanding until the filter effluent turbidity is consistently less than the standard required for the system. For slow sand filters, the SWTR requires that representative samples of filter effluent should be equal to or less than 1 ntu in 95 percent of the measurements taken each month (USEPA, 1989). Therefore, an appropriate turbidity goal is less than 1 ntu.

When coliform bacteria monitoring is done to assess the condition of a filter bed with regard to ripening, coliform bacteria density in undisinfected filtered water samples during the ripening period can be compared with data for similar samples prior to termination of the filter run for scraping or resanding. Comparable numbers of bacteria in the effluent after filter maintenance or comparable removal percentages would indicate that the filter had returned to its earlier capability for removal of microbiological contaminants.

Performance Monitoring

As a result of the low filtration rate, monitoring of slow sand filter performance can be done on a daily basis, in contrast to the regulatory requirement in the United States that filtered water turbidity must be monitored at 15-minute intervals for rapid-rate granular media filtration. Furthermore, whereas a filter run at a rapid-rate filtration plant sometimes can last less than 24 hours, slow sand filter runs can last for days, weeks, or even months, except for unusual events such as an algae bloom that results in formation of a mat of filter-clogging algae on the slow sand filter surface. Because head loss increases slowly, monitoring head loss once per day is adequate, and this can be done by use of water piezometers rather than by sophisticated instrumentation and electronics. The filtration rate also must be monitored, but if the filter effluent passes through a totalizing water meter that also has a rotating dial that can be used to calculate a rate, this may be sufficient for obtaining needed operating data. Total volume filtered per day for each filter also would be included in daily operating data. In the United States, other regulatory requirements related to disinfectant residual and coliform sampling need to be met.

Application to Small Systems

Slow sand filters are especially well adapted for use by small systems because of their simplicity of operation. These filters are quite suitable for the part-time mode of operation affordable at small systems because coagulation chemistry usually is not involved. Duties for an operator would include checking head loss, checking and adjusting filter production to provide for system demand, and measuring and recording filtered water turbidity and disinfectant residual.

Tanner and Ongerth (1990) reviewed the performance of slow sand filters operated by small water systems in northern Idaho. During their 1-year study, the plants were sampled weekly for measurement of turbidity, total coliforms, fecal coliforms, and heterotrophic plate count bacteria. The authors concluded that if a slow sand filter is designed and operated according to accepted standards, it should provide effective water treatment on a consistent

basis. Of special relevance to small systems, they noted that plant operators should be educated about proper operating techniques for slow sand filters. They indicated that drinking water regulatory personnel should provide training to operators and perform sanitary surveys to help ensure that slow sand filters are operated and maintained acceptably.

Green and Benjamin (2000) reported that 23 slow sand filtration plants had been constructed in First Nation communities in British Columbia. Of these, 11 used only slow sand filtration, and 12 included pretreatment consisting of alum coagulation and settling. In some instances, a limestone contactor was used in pretreatment to aid alum coagulation.

Pre-engineered slow sand filtration plants similar in design to the process train studied by Anderson and Huck (2005) at the University of Waterloo, but with the GAC filter placed between the roughing filter and the slow sand filter, have been fabricated and are in use in several Canadian provinces and in some states in the United States. As of 2007, more than two dozen of these full-scale pre-engineered (package) slow sand filtration plants had been installed or were under construction in the United States and Canada (Jobb et al., 2007).

An interesting development for small systems is the use of precast concrete filter boxes (Riesenberg et al., 1995) rather than constructed-in-place concrete filter boxes. The precast boxes were reported to provide better quality control during fabrication at a reduced cost compared with filters constructed in place. This type of construction would lend itself well to a concept of modular slow sand filter units and might decrease the time needed for constructing the plant, as well as overall construction costs.

Summary

Slow sand filtration is a biological process as well as a physical process. Without the biological effects, slow sand filters are not very effective. Therefore, these filters must be managed and operated with the goal of maintaining an active biological system within the bed so that all the benefits of this process can be realized. Because of their simplicity of operation, slow sand filters are well suited for application in small water systems that may rely on part-time operators.

PRECOAT FILTRATION

Precoat filtration is a USEPA-accepted filtration technique for potable water treatment. When the SWTR went into effect in 1989, it provoked a renewed interest in this filtration process. Precoat filters use a thin layer of very fine material such as DE as a filter media. In precoat filtration, the water to be filtered is passed through a uniform layer of the filter media that has been deposited (precoated) on a septum, a permeable material that supports the filter media. The septum is supported by a rigid structure termed a *filter element*. As the water passes through the filter media and septum, suspended particles about 2 μm and larger are captured and removed (AWWA, 1995). The majority of particles removed by the filter are strained (i.e., trapped) at the surface of the layer of filter media, with some being trapped within the layer. As the filter cycle proceeds, additional filter media, called *body feed*, are regularly metered into the influent water flow in proportion to the solids being removed. Without the regular addition of body feed, the head loss across the precoat layer would increase rapidly. Instead, the removed particles intermingle with the body-feed particles so that permeability of the cake is maintained as the thickness of the cake increases gradually. By maintaining permeability of the cake in this way, the length of the filter cycle is extended.

Ultimately, a gradually increasing pressure drop through the filter system reaches a point where continued filtration is impractical. The forward filtration process is stopped,

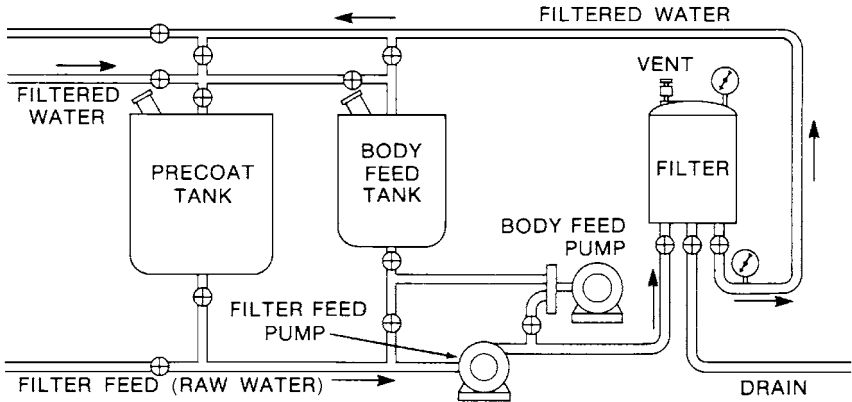

FIGURE 10-30 Typical precoat filtration system. (Courtesy of Manville Filtration and Minerals Division.)

the filter media and collected particles are washed off the septum, a new precoat of filter media is applied, and filtration continues. A typical flow schematic diagram is shown in Fig. 10-30.

Precoat filters accomplish particle removal by physical straining. The thickness of the initial layer of precoat filter media is normally about 3 mm (1/8 in), and the water passageways through this layer are so small and numerous that even very fine particles are retained.

Five or six grades of filter media (sometimes called *filter aid*) are used commonly in potable water treatment. They offer a range of performance with respect to clarity and flow characteristics. With an appropriate selection from among these grades, particles as small as 1 μm can be removed by the precoat filter cake. Where colloidal matter or other finely dispersed particles are present, however, filtration alone may not be adequate to produce 1 ntu water, as required by the SWTR based on earlier results obtained by Logsdon et al. (1981b).

Applications and Performance

Precoat filters are used widely in industrial filtration applications and in swimming pool filtration. They also have been used in municipal potable water treatment, primarily in the direct, in-line filtration of high-quality surface waters (turbidity 10 ntu or less and acceptable color) and in the filtration of iron and manganese from groundwaters after appropriate pretreatment to precipitate these contaminants.

Since 1949, more than 170 potable water treatment plants using precoat filtration with DE or other filter media have been designed, constructed, and operated (AWWA, 1995). About 90 percent are surface water supplies, and 10 percent are groundwater supplies. The largest existing plant is the 76 ML/d (20 mgd) San Gabriel, CA, plant.

Where the source water and other conditions are suitable, precoat filtration can offer a number of benefits to the user, including the following: (1) Capital cost savings may be possible because of smaller land and plant building requirements; (2) treatment costs may be slightly less than conventional coagulation/sedimentation/granular media filtration when filterable solids are low (AWWA, 1995; Bryant and Yapijakis, 1977), although sedimentation usually would not be needed for such high-quality source waters; (3) the process is entirely a physical/mechanical operation and can attain high log removals of *Giardia* cysts and *Cryptosporidium*

ocysts (as described in the introduction of this chapter) without operator expertise in water chemistry relating to coagulation; (4) the waste residuals are easily dewatered, and in some cases, they may be reclaimed for other uses, including soil conditioning and land reclamation; (5) acceptable finished water clarity is achieved as soon as precoating is complete and filtration starts—a filter-to-waste period is generally not necessary to bring turbidity of the finished water within acceptable limits; and (6) terminal turbidity breakthrough generally is not observed because it is predominantly a surface filtration process.

The disadvantages of precoat filtration are (1) the continued cost of the filter media (body feed) that are usually discarded at the end of each filter cycle and the problems and costs associated with that disposal; (2) less cost-effective for waters that require pretreatment for algae, color, taste and odor problems, or DBP precursor removal, although waters containing only larger plankton such as diatoms sometimes can be treated economically by microstraining prior to the precoat filtration; and (3) proper design, construction, and operation are absolutely essential to prevent dropping the filter cake off the septum or cracking of the filter cake during operation that might result in failure to remove the target particulates.

Precoat filtration has been shown to be very effective in the removal of *Giardia* cysts over a broad range of operating conditions typical of potable water filtration (Logsdon et al., 1981b; Lange et al., 1986). The need for proper operation and maintenance is emphasized, however, and a precoat rate of 1 kg/m^2 (0.2 lb/ft^2) is recommended.

The ability to remove protozoan cysts without chemical coagulation makes precoat filtration attractive to very small communities that may need filtration because of concern about cysts in source waters. Operators skilled in coagulation are less likely to be available in small installations, but operators with mechanical skills are required.

The removal of small ($<1\text{--}2 \text{ }\mu\text{m}$) particles such as bacteria and viruses depends on the grade of filter aid used and other operating conditions (Lange et al., 1986). Capture of smaller particles can be enhanced by using aluminum or iron coagulants or cationic polymers to coat the filter media (Burns et al., 1970; Brown et al., 1974; Baumann 1975; Lange et al., 1986).

The Filter Element and Septum

The filter element is a vital component of a precoat filter because it supports the septum and the filter cake. The attributes of good filter elements and septa are detailed in the *AWWA Precoat Filtration Manual* (AWWA, 1995). Filter elements may be either flat or tubular (Figs. 10-31 and 10-32). Flat elements, often referred to as *leaves*, may be rectangular or round. Tubular elements are available in several different cross-sectional shapes but generally are round.

Overlaying the filter element is the septum material, consisting of either tightly woven stainless steel wire mesh or a tightly fitted synthetic cloth bag, usually made from monofilament polypropylene weave. The precoat layer forms on and is supported by the septum. For this to occur, the size of the clear openings in the septum must be small enough for the filter media particles to form and maintain stable bridges across the openings. Generally, a clear opening of about $125 \text{ }\mu\text{m}$ (0.005 in) or less in one direction is desirable.

The septum must be firmly supported so that it does not yield, flex, or become distorted as the differential pressure drop increases during the filter cycle resulting in temporary cracks in the filter cake.

The Filter Vessel

Two basic types of precoat filter vessels that contain multiple filter elements and septa are available. They are the vacuum filter and the pressure filter.

Rectangular Leaf

Circular Leaf

Tubular Filter Element

Flat Filter Elements

FIGURE 10-31 Types of filter elements for precoat filters and construction details of a flat-leaf element.

Vacuum Filters. The vessel containing vacuum filter elements and their septa is an open tank at atmospheric pressure. A filter discharge pump or a vacuum discharge leg downstream of the filter creates suction, enabling the available atmospheric pressure to move water through the precoat and filter cake as it develops. The open filter tanks permit easy observation of the condition of the septa and elements and general condition of the filter during filtration and cleaning.

FIGURE 10-32 Typical pressure tubular filter and leaf filter for precoat filtration.

The maximum available differential pressure across the vacuum filter is limited to the net positive suction head of the filter pump or the vacuum leg. This limitation influences the length of filter cycles.

The effect of any entrained air or dissolved gases coming out of solution because of the decrease in pressure also must be considered with vacuum filters. Gas bubbles will have an adverse effect on the filter cake, tending to disrupt the integrity of the filter cake on the septum. One advantage of the vacuum filter is that the condition of the cake can be observed easily at the open water surface; this is not possible in a pressure filter.

Pressure Filters. A filter feed pump or influent gravity flow produces higher than atmospheric pressure on the inlet (upstream) side of a pressure filter, forcing liquid through the filter cake (Fig. 10-32). Large pressure drops across the filter are theoretically possible (limited only by the strength of the filter shell and the filter elements and septa), but the maximum economic differential pressure drop generally is limited to 205 to 275 kPa (30–40 psi). Typically, a higher pressure drop across a pressure filter will yield longer cycles than with vacuum filters, which, in turn, will yield greater removal of suspended solids per pound of filter media. Increased pumping costs for differential pressures much over 205 to 275 kPa (30–40 psi), however, usually offset savings in costs of filter media.

Filter Media

Precoat filters use DE or perlite as a filter media. Both materials are available in various grades to allow creation of a filter cake with the desired pore size. AWWA B101, Standard for Precoat Filter Media, covers quality control, density, permeability, and particle size distribution of precoat filter media (AWWA, 2002). DE (or diatomite) is composed of the fossilized skeletons of microscopic diatoms that grow in fresh or marine waters. Deposits of this material from ancient lakes or oceans are mined and then processed by flux calcining, milling, and air classification into various size grades for various filtration applications. The grades used in potable water filtration have a mean pore size of the cake of from about 5 to 17 μm . A less common material for precoat filtration is perlite, which comes from

glassy volcanic rock. It is a siliceous rock containing 2 to 3 percent water. When heated, the rock expands to form a mass of glass bubbles. It is crushed and classified into several size grades. Pilot testing can determine two or three grades of filter media that will produce a desired clarity, simplifying the task of optimizing a final selection when working with a full-scale plant.

Filter Operation

Precoating. Successful precoating requires the uniform application of precoat filter aid to the entire surface of the clean septum. This is accomplished by recirculating a concentrated slurry of clean water and filter media (generally 12 percent or greater) through the filter at 2.4 to 3.7 m/h (1.0–1.5 gpm/ft²) until most of the media have been deposited on the septum and the recirculating water turbidity is lowered to the desired treated water quality.

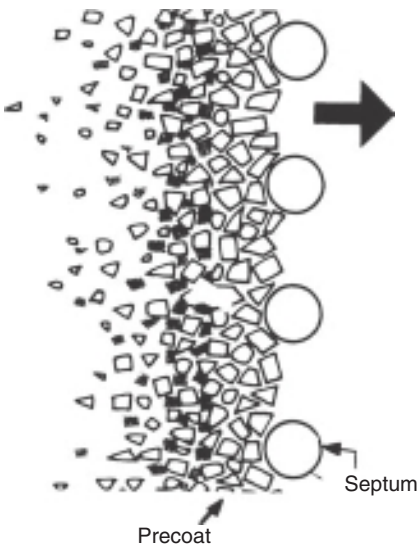

FIGURE 10-33 Illustration of precoat formation, with bridges of precoat between the elements of the septum material. (Courtesy of Manville Filtration & Minerals Division.)

Because particles of the media are much smaller than the clear openings in the septum, their retention and the formation of a stable precoat take place as a result of bridging. As the particles crowd together when passing through the openings, they jam and interlock, forming a bridge over the openings (Fig. 10-33). As bridges form, additional particles are caught, and the filter septum is coated. A typical precoating system is shown in Fig. 10-30. The thickness of the precoat layer is typically 1.5 to 3 mm (1/16–1/8 in) or 1 kg/m² (0.2 lb/ft²) of precoat media.

Body-Feeding. The amount of body feed to be added to the source water is determined by the nature and amount of solids to be removed. Pilot testing during representative source water quality periods generally will indicate the type and range of solids that will be encountered and the amount and type of body feed needed to provide an incompressible and permeable cake.

Typical body-feed ratios of 1 to 10 mg/L of diatomite for each 1 mg/L of suspended

solids are required depending on the type of solids being filtered. Details of selecting the appropriate ratio are presented later. Compressible solids such as alum or iron coagulation solids require the highest ratios. Proper control of the body-feed dosage is the most important factor contributing to economic operation of a precoat filtration plant.

Body-feed equipment can be classified as dry or wet systems. Wet, or slurry, feeders are the most common. The attributes of good precoat and body-feed equipment have been presented in the AWWA Manual M30, *Precoat Filtration* (AWWA, 1995).

Spent Cake Removal. At the end of each filter cycle, the spent filter cake is removed from the filter in preparation for the precoat that will begin the next cycle. If spent solids are not fully removed from the filter vessel, the material could be resuspended and deposited on the filter septa. The resuspended dirty material could foul the septa, although the effect

usually would develop gradually so that the operator would become aware of it only after a number of cycles.

The most reliable determination of cleanliness of the septa requires visual observation of the bare septa, followed by observation of the uniformity and completeness of the precoat. When the septa cannot be fully inspected, a higher than normal differential pressure immediately after precoating (at the start of the filtration cycle) would suggest that the septa are becoming fouled.

Techniques for removing the spent cake vary with the different kinds of filter vessels and filter elements. Spent cake removed from a precoat filter is a mixture of filter media and the materials removed from the source water. This waste matter is usually removed from the filter in slurry form. Although some systems may be able to dispose of the slurry into a sanitary sewer system, most plants must dewater the waste material and make separate provisions for the solid and liquid wastes. Methods of handling wastes are covered further in Chap. 22 on water treatment residuals management.

Theoretical Aspects of Precoat Filtration

Understanding the probable effect of flow rate, terminal head loss, and body-feed rate on the operation of the filter is necessary to obtain maximum economy in the design and operation of a precoat filter. The most important of these items affecting filter operation is the prudent use of body feed during a filter run.

Effect of Concentration of Body Feed. The results of a typical series of filter runs conducted at a constant rate of filtration and to a constant terminal pressure drop, but with varying amounts of body feed, are shown in Fig. 10-34. The total volume of filtrate is plotted against the total head loss in feet of water. The initial head loss is caused by the clean precoat layer, septum, and filter element. With no body feed or insufficient amounts of body feed, the head loss will increase more rapidly as the run continues. This is so because suspended solids that are removed on the surface of the precoat layer soon form a compressible, impermeable layer of solids that will not readily permit the passage of water.

FIGURE 10-34 Effect of varying the concentration of body feed C_D on the relationship of head loss to volume of filtrate for flat septa.

With increased amounts of body feed, the mixture of body feed and solids removed from the water will be less compressible and of higher porosity and permeability. As a result, the head loss will develop more slowly (e.g., $C_D = 5$ units in Fig. 10-34). With sufficient body feed, the cake will be incompressible, and head loss will develop in a linear manner when using flat

septa (e.g., $C_D = 10$ units in Fig. 10-34). With still higher rates of body feed, the slope of the straight-line plot will get flatter. The most economical use of body feed generally occurs at the lowest concentration that generates a linear head loss curve when using flat septa.

The linear head loss curves shown in Fig. 10-34 for higher body-feed concentrations only occur with flat septa at constant total flow rate. With tubular septa, as the body-feed layer gets thicker, the area of filtration increases, and the effective filtration rate decreases for the outer layers of the cake. This causes head loss to increase more slowly as the cycle progresses (Dillingham et al., 1967a).

Effect of Filtration Rate. Consider the linear head loss curve for a flat septum at constant flow rate and adequate body feed, as shown in Fig. 10-34. The total head loss at any time is the sum of the initial head loss (caused by precoat layer, filter element, and septum) plus the head loss of the body-feed layer. The flow through the entire filter cake at the usual filtration velocities is laminar. Therefore, the following can be stated with regard to head loss development:

1. Head loss for a particular instant (i.e., cake thickness) is proportional to the filtration rate Q because of laminar flow conditions.
2. Head loss across the body-feed layer is proportional to the thickness of the layer. This, in turn, is proportional to the volume of filtrate \dot{V} = filtration rate Q times running time t at constant-body-feed concentration.
3. Thus, combining 1 and 2 above, the head loss in the body-feed layer at any instant is proportional to Q^2t .

Using these concepts, the rate of head loss development at two different filtration rates Q_1 and Q_2 can be compared:

$$h_1 \propto Q_1^2 t_1 \quad \text{and} \quad h_2 \propto Q_2^2 t_2 \quad (10-27)$$

Dividing these two expressions for the case of the same terminal head loss, $h_1 = h_2$, we get

$$\frac{t_1}{t_2} = \frac{Q_2^2}{Q_1^2} \quad (10-28)$$

Similarly,

$$V'_1 = Q_1 t_1 \quad \text{and} \quad V'_2 = Q_2 t_2 \quad (10-29)$$

Dividing these two equations and inserting the previous relation for t_1/t_2 , we get

$$\frac{V'_1}{V'_2} = \frac{Q_2}{Q_1} \quad (10-30)$$

According to these expressions, for a given terminal head loss, the length of the filter run is inversely proportional to the square of the filtration rate, and the filtrate volume is inversely proportional to the filtration rate. These relationships are approximate because the impact of the precoat head loss has been ignored as it is usually trivial compared with the body-feed head loss. Equations 10-28 and 10-30 help to explain why the most economical operation of precoat filters usually occurs at fairly low filtration rates, 2.4 m/h (1 gpm/ft²) being most common, but with 1.2 to 7.3 m/h (0.5–3 gpm/ft²) used in some plants.

Mathematical Model for Precoat Filtration. A rigorous mathematical model has been presented for head loss development for a precoat filter operating at constant total flow rate. The model describes the head loss for either flat or tubular septa operating with adequate

body feed to achieve an incompressible cake (Dillingham et al., 1967a; Weber, 1972). To use the model, empirical filter cake resistance indices must be determined for the precoat and body-feed layers by pilot filter operation. The body-feed resistance index can be correlated empirically with the ratio of source water suspended solids concentration to the body feed concentration (Dillingham et al., 1967b). The model can be used in an optimization program to select the best combination of filtration rate, terminal head loss, and body-feed concentration for best overall economy (Dillingham et al., 1966).

DEDICATION

We dedicate this chapter to the memory of two people whose work as researchers, advisors, mentors, and teachers has greatly affected the understanding and practice of filtration using granular media: Kenneth (Ken) Ives and Appiah (Amit) Amirtharajah. Professor Ives led many fundamental and significant studies of filtration in his nearly 40 years of work at University College London. Professor Amirtharajah, beginning with his M.S. and Ph.D. studies with Professor John Cleasby at Iowa State University and latter in his academic career at Montana State University and Georgia Tech, conducted extensive studies of filter backwashing, initial filter effluent quality, and many other fundamental and applied aspects of media filtration and coagulation.

ABBREVIATIONS

A	cross-sectional area
ASTM	American Society for Testing and Materials
AWWA	American Water Works Association
BOM	biodegradable organic matter
DAF	dissolved air flotation
DBPs	disinfection by-products
DE	diatomaceous earth
ES	effective size
FBRR	Filter Backwash Recycling Rule
GAC	granular activated carbon
gfd	gallons per square foot per day
gpm	gallons per minute
GWR	Ground Water Rule
GWUI	groundwater under the influence
HGL	hydraulic grade line
HLR	hydraulic loading rate
IESWTR	Interim Enhanced Surface Water Treatment Rule
lmh	liters per square meter per hour
<i>L/d</i>	ratio of media depth to media size
LT1ESWTR	Long Term 1 Enhanced Surface Water Treatment Rule

LT2ESWTR	Long Term 2 Enhanced Surface Water Treatment Rule
MCL	maximum contaminant level
MF	microfiltration
ML/d	mega liters per day
NOM	natural organic matter
ntu	nephelometric turbidity units
PAC	powdered activated carbon
PACl	polyaluminum chloride
PIC	polyiron chloride
Q	flow rate

SDWA	Safe Drinking Water Act
SWTR	Surface Water Treatment Rule
TT	treatment technique

EQUATION NOTATION

av	grain surface area per unit grain volume
A_1	dimensionless porosity function
C	mass or volume concentration of particles
d	filter media grain size (diameter)
d_e	effective size of media = d_{10}
d_{eq}	grain diameter of sphere of equal volume
d_p	particle diameter
d_{10}	media size for which 10% (by weight) of the media grains are smaller
d_{60}	media size for which 60% (by weight) of the media grains are smaller
d_{90}	media size for which 90% (by weight) of the media grains are smaller
D	pipe diameter
D_{bm}	Brownian diffusivity
f	friction factor
F	theoretical filter capacity
g	acceleration due to gravity
Ga	Galileo number
h	head loss
J	hydraulic head loss gradient

k	dimensionless Kozeny constant
k_1, k_2, k_3	empirical constants
L	depth of filter media
L_0	depth of fixed (unexpanded) bed of filter media
Q	filtration flow rate
Q_a	airflow rate
Re	Reynolds number
Re ₁	modified Reynolds number
t	time
U	mean flow velocity in pipe
UC	uniformity coefficient
V	approach or superficial velocity
V_{mf}	minimum fluidization velocity
V'	filtration volume
z	bed-depth variable
α	attachment efficiency factor
ε	porosity
ε_0	clean-bed porosity
ε_σ	porosity of the deposited material
η_T	total single-collector efficiency
λ	filter coefficient
μ	absolute viscosity of fluid
ρ	density of fluid
ρ_b	bulk density of media (grains and water-filled pores)
ρ_p	density of particle
ρ_s	density of media grains
σ	specific deposit, volume of deposit per volume of bed
ϕ	empirical coefficient
ψ	grain sphericity

Membranes represent an important set of processes for potable water treatment. Benefits of their use include demonstrated universal treatment capabilities and competitive costs. Membrane systems have experienced significant growth in water quality applications in the last three decades, and are now available in a variety of forms that can differ in size, shape, and operation, and yet each is uniquely able to resolve a particular need or purpose. There are very few drinking water contaminants that cannot be removed economically by synthetic membrane processes. Several applications have been described in books on water treatment (Nalco, 1988; Mallevalle, Odendall, and Wiesner 1996; MWH, 2005). Membrane processes with the greatest immediate application to drinking water treatment are microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO), and electrodialysis/electrodialysis reversal (ED/EDR). Common terminology for membrane processes appears in Table 11-1. A list of abbreviations and equation symbols along

TABLE 11-1 Membrane Terminology

Term	Definition
Array, train, or pass	Multiple interconnected stages in series by concentrate staging or permeate staging
Asymmetric	A membrane that varies in density or porosity across its structure, and having a varying consistency throughout
Backwash	The intermittent residual stream from a MF or UF membrane system
Brine	Concentrate stream containing a TDS concentration greater than seawater (approximately 35,000 mg/L total dissolved solids)
Brackish water	Water having a TDS concentration ranging from approximately 1000 to 15,000 mg/L
Chemical cleaning or clean in place	The periodic application of a chemical solution to a membrane system to remove accumulated foulants in order to maintain productivity and return the membrane to baseline operation levels
Concentrate, reject, retentate, residual, or blow-down stream	The membrane output stream that contains higher TDS (NF, RO) or higher TSS (MF, UF) than the feed stream
Concentration-polarization	A phenomenon that occurs when dissolved and/or colloidal materials concentrate on or near the membrane surface in the boundary layer
Conventional MF or UF process	A treatment system consisting of a configured group of pressure- or vacuum-driven membranes contained in modules or basins consisting of a pretreatment strainer, air and reverse filtration discharges, filtrate tankage and associated appurtenances, including chemical feed for posttreatment
Conventional RO or NF process	A treatment system consisting of acid and/or scale inhibitor addition for scaling control, cartridge filtration for pretreatment, the RO or NF membrane treatment process, including the processes of aeration, corrosion control stabilization and pH adjustment, and disinfection for posttreatment

(Continued)

TABLE 11-1 Membrane Terminology (*Continued*)

Term	Definition
Differential pressure	A pressure drop across a membrane element or module from the feed inlet to concentrate outlet
Feed	Input stream to the membrane array
Flux	The throughput of a membrane process expressed as a mass ($\text{mL}^{-2}\text{t}^{-1}$) or volume (Lt^{-1}) rate of transfer through a membrane surface
Fouling	Deposition of solid material from the feed stream onto the membrane surface or within a porous membrane structure that restricts the passage of water decreasing productivity
High-recovery array	Array where the concentrate stream from one array becomes feed to a succeeding array to increase recovery
Hollow fiber membrane	A geometry in which the membrane material is configured into a very small diameter and mounted in a housing or pressure vessel, or submerged in a basin
Instantaneous flux	The flux that occurs in a MF or UF membrane when the unit is operating between backwash operations and is generally the highest flux reported for a system, as it does not account for system downtime or filtrate losses during treatment
Lumen	The center or bore of a hollow fiber membrane
Mass transfer coefficient (RO, NF), or specific flux (MF, UF)	Mass or volume unit transfer through a membrane based on driving force expressed in volume per unit area per unit time
Membrane element	A single membrane unit containing a bound group of SW or HFF membranes to provide a nominal surface area
Module or cartridge	The smallest component of a MF or UF membrane unit where the membranes are placed in a housing device with a filtrate outlet structure
Membrane softening	The use of membranes for removing hardness from water most often accomplished using NF membranes
Net driving pressure	The hydraulic pressure differential across the membrane minus the osmotic pressure differential across the membrane that is available to force water through the membrane
Permeate, product (filtrate)	The membrane output stream that contains lower TDS (lower TSS) than the feed stream
Pressure vessel	A single tube with several membrane elements in series
Raw	Input stream to the membrane process
Recovery	The ratio of the permeate flow to the feed flow expressed as a percentage
Rejection	Percentage solute concentration reduction of the permeate stream relative to the feed stream
Scaling	Precipitation of solids in an element due to solute concentration in the feed stream
Solute	Dissolved solids in raw, feed, permeate, and concentrate streams
Solvent	Liquid, usually water, containing dissolved solids
Stage or bank	Parallel pressure vessels
System arrays	Several arrays that produce the required plant flow
Transmembrane pressure	Pressure drop across the membrane barrier

Abbreviation key: TDS, total dissolved solids; TSS, total suspended solids; MF, microfiltration; UF, ultrafiltration; NF, nanofiltration; RO, reverse osmosis.

with their meanings that are used throughout the chapter can be found at the end of this chapter.

The use of synthetic membrane processes for desalination has increased over the past five decades primarily in coastal areas with limited fresh water sources. Between 1970 and 1990 the membrane market was dominated by desalting applications; however, since 1990 the use of MF and UF has increased exponentially, with over 200 operating installations ranging up to 380,000 m³/d (100 mgd) in size at the turn of the century, primarily a result of increase regulatory focus on *Cryptosporidium* and lower capital and operating costs. Initially, municipal membrane applications were limited to desalting with the first municipal brackish water RO plant commencing operation in October 1971 serving the Key Largo Ocean Reef Club in the Florida Keys. The plant operated at 4200 kPa (600 psi) and produced 225 m³/d (0.06 mgd) of permeate, unlike today, when RO plants are large as 190,000 m³/d (50 mgd) can be constructed to operate at half the operating pressure than at the time the Key Largo plant was placed online. The concept of membrane softening was first practiced at Pelican Bay, Florida, in 1977, yet was limited in use until the mid-1980s when spiral-wound polyamide nanofiltration elements became available. Since that time there has been steady growth in the development of NF plants for softening and disinfection by-product precursor removal and continued use of RO and ED/EDR for brackish water desalting. Florida also was host to the introduction of the largest seawater RO plant in the Western Hemisphere at Tampa Bay Water's Big Bend site, when the facility became operational in 2004. The use of ED/EDR also has continued to expand in niche markets, one plant as large as 265,000 m³/d (70 mgd) placed online in Barcelona Spain in 2009 for bromide removal and disinfection by-product (DBP) control.

SIZE RANGES FOR MEMBRANE PROCESSES

The applicable size ranges for membrane processes are shown in Fig. 11-1. In the broadest sense, a membrane—the common element of all these processes—could be defined as any barrier to the flow of suspended, colloidal, or dissolved species in any solvent. MF and UF membrane technologies are increasingly popular alternatives to conventional treatment for potable water production, and are typically employed to remove particles from water. MF and UF are used to remove turbidity, pathogens, and particles from freshwaters. Both UF and MF processes and coagulation/filtration processes remove particulates from drinking water. However, UF and MF have a significant advantage over conventional processes in that a membrane forms a static pathogen barrier. The pathogens are simply too big to pass through the membrane, so 6-log pathogen removal is not unexpected and small chance remains that pathogen removal will fail.

NF is used to soften freshwaters and remove *disinfection by-product (DBP)* precursors. RO and ED are typically employed to remove dissolved substances from water. Electrodialysis is used to demineralize brackish water and to soften freshwater. RO is primarily used to remove salt from brackish water or seawater, although RO is also capable of very high rejection of *synthetic organic compounds (SOCs)*. Desalting techniques are primarily intended for the removal of *total dissolved salts (TDS)* that generally cannot be removed by conventional treatment processes.

Drinking water contaminants are presented as biological, inorganic, and organic contaminants, as well as radionuclides, particulates, and other groupings. The ability of membranes to remove these contaminants can be inferred from Table 11-2 and Fig. 11-1, both of which show effective size ranges of contaminants that can be partially or completely removed by each membrane process. If sieving or size exclusion is the mechanism of solute rejection, complete removal can be achieved by a membrane free of defects. All membrane processes can reject contaminants such as turbidity or pathogens, but UF and MF are the most cost-effective processes for control of large particles. Smaller contaminants are removed via

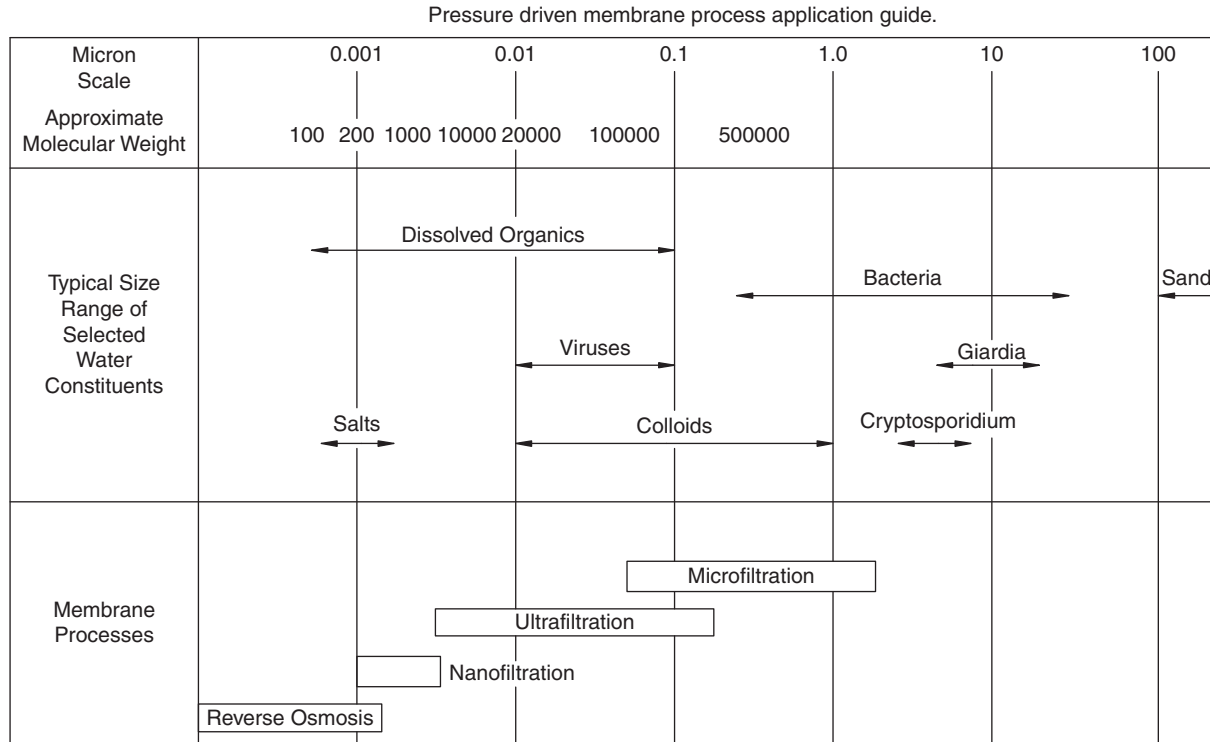

FIGURE 11-1 Size ranges of membrane processes and contaminants.

TABLE 11-2 Potable Water Contaminants Classified by Effective Membrane Size Range and Removal by Application

Particle category	Classification	Regulatory rule	Ionic	Size range		Membrane process application by name with contaminant size removed				
				Macromolecular and colloidal	Fine	MF 0.10 µm	UF 0.01 µm	NF 0.001 µm	RO 0.0001 µm	EDR 0.0001 µm (charged)

¹SWTR: Includes initial SWTR regulations implemented in 1989 and any revisions to the SWTR including Interim Enhanced Surface Water Treatment Rule (IESWTR), Long Term ¹Enhanced Surface Water Treatment Rule (LT1ESWTR) and Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR)

²DBPR: Includes Phase I and Phase II of the DBPR

size exclusion, charge repulsion, or diffusion mechanisms in membrane processes, leaving some residual. Although such a residual may be below the detection level, it is present.

Typically, the cost of membrane treatment increases as the size of the solute removed decreases. The ionic range in Fig. 11-1 encompasses potable water solutes such as sodium, chloride, total hardness, most total dissolved solids, and disinfection by-product precursor matter. The macromolecular range includes large and small colloids, bacteria, viruses, and color. The fine particle range includes larger turbidity producing particles, most total suspended solids, cysts, and larger bacteria. The membrane processes normally used in the ionic range remove macromolecules and fine particles, but because of operational problems, they are not as cost effective as membranes with larger pores.

Contaminants larger than the maximum pore size of the membrane are completely removed by sieving in a diffusion-controlled process. Contaminant rejection by diffusion-controlled membrane processes increases as species charge and size increases. Consequently, satisfactory removal of metals, TDS, biota, radionuclides, and disinfection by-product precursors can be attained. No commercially available membrane effectively removes uncharged species such as hydrogen sulfide (H_2S) and small, uncharged organic contaminants. Other aqueous contaminants should be treatable by membrane processes, although, once again, the cost of this treatment generally increases as the size of the removed contaminant decreases. Many membrane manufacturers specify the molecular weight cutoff (MWC) values for membranes. The MWC represents a nominal molecular weight of a known species that would always be rejected in a fixed percentage, using a specific membrane under specific test conditions.

Although many factors affect solute separation by these processes, a general understanding of drinking water applications can be achieved by associating minimum size of solute rejection with membrane process and regulated contaminants (Taylor et al., 1989). One correct interpretation of Fig. 11-1 is to assume that each membrane process has the capability of rejecting solutes larger than the size shown in the exclusion column. As shown in Table 11-2, regulated drinking water solutes can be simplified to the categories of pathogens, organic solutes, and inorganic solutes. Pathogens can be subdivided into cysts, bacteria, and viruses. Organics can be subdivided into DBPs and SOCs. Inorganic parameters are total dissolved solids, total hardness, and heavy metals, among others.

Electrodialysis (ED) and *electrodialysis reversal (EDR)* processes are capable of removing the smallest contaminant ions to $0.0001 \mu m$, but a charge is required. Consequently ED and EDR are limited to treatment of ionic contaminants and are ineffective for pathogen removal and most organic applications. RO and NF perform both diffusion and sieving. They can remove all pathogens and many organic contaminants by sieving; by diffusion, they can achieve almost total removal of ionic contaminants. RO and NF processes have the broadest span of treatment capabilities. UF can achieve greater than 6-log removal of all pathogens from drinking water. MF can achieve greater than 6-log removal of cysts. Consequently, these processes effectively remove turbidity and microbiological contaminants, making them ideal for treating the majority of drinking water sources in the United States.

Existing regulations have been and will be modified to include more stringent control of chemical and biological toxins. Table 11-2 correlates various drinking water regulations to specific contaminants and the appropriate membrane process application that can satisfy regulation requirements. The SDWA amendments that were modified in 1996 still require the USEPA to create new drinking water regulations. The regulatory changes will continue to create a need for new drinking water technology to meet these challenges. The growth of drinking water regulations for both chemical and biological species has created treatment applications that can be met by membrane processes. Membranes, along with post-disinfection, can be effectively used for total removal of pathogens, high removals of inorganic and organic contaminants, and maintaining the highest possible distribution system integrity. There are very few instances where membranes cannot be utilized to meet or exceed all drinking water regulations.

CLASSIFICATIONS AND CONFIGURATIONS OF MEMBRANE PROCESSES

Some membrane processes rely on pressure as the driving force to transport fluid across the membranes. They can be classified by the types of materials they reject and the mechanisms by which rejection occurs. The progression of microfiltration (MF) to ultrafiltration (UF) to nanofiltration (NF) to reverse osmosis (RO) corresponds to a decreasing minimum size of components rejected by membranes as well as increasing transmembrane pressures required to transport fluid across the membranes and decreasing recoveries. Although a continuum of mechanisms likely contribute to separation in these pressure driven processes, very clear differences in separation methods distinguish reverse osmosis from microfiltration. These mechanisms are discussed later in the text.

While pressure driven processes like RO pass water through the membranes, electrodialysis involves the passage of the solute rather than the solvent through the membrane. As a consequence, both the mechanism of separation and the physical characteristics of membranes in electrodialysis differ substantially from those in pressure driven processes. ED membranes are fundamentally porous sheets of ion exchange resin with a relatively low permeability for water.

Membranes are classified by solute exclusion size, which is sometimes referred to as *pore size*. A reverse osmosis or hyperfiltration membrane rejects solutes as small as 0.0001 μm , which is in the ionic or molecular size range. A nanofiltration membrane rejects solutes as small as 0.001 μm , which is also in the ionic and molecular size range. Solute mass transport in these processes is diffusion controlled. Ultrafiltration and microfiltration membranes have a minimum solute rejection size of 0.01 and 0.10 μm , respectively. These membranes reject colloidal particles, bacteria, and suspended solids by size exclusion and are not diffusion controlled. Pressure drives the transport of water (the solvent) through these membranes. MF and UF require the use of pretreatment processes such as coagulation and/or oxidation or powdered activated carbon (PAC) to remove dissolved organic and inorganic constituents. ED relies on charge for solute separation and pulls ions through ED membranes, so it is unaffected by pore size.

Membranes can be classified by molecular weight cutoffs, solute and solvent permeability, solute and solvent solubility in the membrane film, active film material, active film thickness, surface charge, and active film surface. The molecular weight cutoff is the degree of exclusion of a known solute, as determined for a given set of test conditions in the laboratory. Typical known solutes used for determination of molecular weight cutoff are sodium chloride, magnesium sulfate, dextrose, and some dyes. Solute mass transport through a diffusion-controlled membrane is influenced by solute type and aqueous environment, so attempts to characterize them benefit from the use of additional organic solutes such as aromatic and aliphatic compounds of known molecular weight and structure.

Classification by Material

The development of a variety of membrane materials, both synthetic and modified natural polymers coupled with various manufactured forms, has played an integral part in the development of industrial-scale membrane separation applications. In any such process, several important membrane characteristics must be considered. Membrane selectivity, permeability, mechanical stability, chemical resistance, and thermal stability are among these critical factors, which are highly dependent on the type of material and the process control variables applied during manufacturing (Rautenbach and Albrecht, 1989).

Among the many raw materials used for membrane manufacturing, most basic types involve various forms of modified natural cellulose acetate materials and a variety of

synthetic materials. To name a few, these synthetic materials are primarily composed of polyamides, polysulfone, vinyl polymers, polyfuran, polybenzimidazole, polycarbonate, polyolefins, and polyhydantoin. The diverse chemistries of the specific polymers and the associated production kinetics yield the individual attributes that provide for the myriad of membrane selectivity and productivity combinations (Rautenbach and Albrecht, 1989). Common MF and UF membrane materials used today include polyvinylidene fluoride (PVDF), polyethersulfone (PES), polysulfone, and cellulose triacetate. Recently, the use of ceramic materials made by sintering inorganic materials such as aluminum oxide, titanium oxide, or a carbon nanocomposite formulation have been considered for MF applications. Common NF and RO materials include polyamide and polyamide for spiral-wound configurations, and cellulose triacetate for RO hollow fine fiber membranes.

Porous materials produced by precipitation from a homogeneous polymer solution are termed *phase inversion membranes*. They incorporate both symmetrical (homogeneous) and asymmetrical structures. The basic production process consists of five fundamental steps. A homogeneous polymer solution must first be produced. The polymer film is then cast followed by partial evaporation of the solvent from the polymer film. Immersion of the polymer film in a precipitation solution then allows the solvent to be exchanged for the precipitation agent. Imperfections in the precipitated membrane film are restructured by treatment in a heated bath solution (Bungay et al., 1986). Variations in environmental conditions for each of these steps can generate an assorted range of membrane structures that affect system performance. Typical membrane structural profiles can range from well-defined cavities in the shape of fingers to pores arranged in a dense sponge structure. These configurations result from the membrane structure both at the membrane surface and within the support structure itself (Rautenbach and Albrecht, 1989).

Both symmetric and asymmetric membranes can be produced by the phase inversion process. The difference between these two membrane classifications is the environmental conditions in which the membranes are produced and their resulting structural profiles. In the production of symmetrical membranes, homogeneous conditions for material formation throughout the membrane matrix lead to a uniform polymer structure. Conversely, structural properties vary throughout asymmetric membranes. Production of an asymmetric membrane forms a dense surface layer of submicron thickness that gives the membrane its selectivity properties. This active layer is in turn supported by a porous support structure. The combination yields membrane materials that are both selective and mechanically stable with enhanced productivity. Given the reduced thin active layer, hydraulic losses in head across the membrane are significantly less than those associated with comparable symmetric membranes. Consequently, development of the asymmetric membrane structure is an additional component integral to the commercial success of both RO and UF.

Another classification of phase inversion membranes is the composite membrane. In such a membrane, the materials comprising the active surface are different from those of the support material. These membranes are produced by lamination of the active surface layer onto the support layer, for example, polysulfone. This class of membranes is generally regarded as an improvement in membrane material design in that a specific active surface layer can be matched with a support layer of optimum porosity. This combination enhances membrane productivity while retaining the desired rejection properties offered by the dense active surface layer. Figure 11-2 shows the characteristic layers in a composite membrane, showing three distinct components, the polyamide membrane film (active layer), a polymeric supporting layer, and a fabric-backing material.

The active layer or membrane film is a polymer or combination of polymers forming a composite layer of varying thin films or a single thin-film layer. These polymers are generally in the form of straight chain compounds such as cellulose acetate or aromatic compounds such as a polyamide. Several different interactions occur between

FIGURE 11-2 Composite membrane structure. (Courtesy of Toray Membrane America, Inc.)

the polymers that form the active layer of the membrane, and consequently between the membrane and solutes that pass through it. The three types of secondary forces are dipole forces, dispersion forces, and hydrogen bonding forces. Covalent and ionic forces are primary forces, with stronger effects than those of the secondary forces in the active membrane film. Average values of primary and secondary forces in membrane polymers are 400 kJ/mole for covalent and ionic forces, 40 kJ/mole for hydrogen bonding forces, 20 kJ/mole for dipole forces, and 2 kJ/mole for dispersion forces. These membrane forces can interact with corresponding forces associated with solutes, possibly promoted by functional groups on pesticides, for example.

Hyperfiltration (reverse osmosis at 5516 to 8274 kPa [800 to 1,200 psi]) and nanofiltration membrane films have active layers of cellulose compounds, aliphatic or aromatic polyamides, and thin-film composites. Cellulose triacetate is used as the active film for many desalination applications. Cellulose derivatives have good properties for membranes, since their crystalline and hydrophilic properties enhance durability and their capacity to transport water. Cellulose membranes are subject to chemical degradation by hydrolysis and biological degradation by oxidation. They must be operated at ambient temperatures from pH 4.0 to 6.5 with a biocide to avoid degradation.

Polyamide membranes are also effective films. Aromatic polyamides are generally preferred over aliphatic polyamides because of their mechanical, thermal, chemical, and hydrolytic stability and their permaselective properties. The aliphatic polyamides are porous and therefore not permaselective.

The development of the cross-linked fully aromatic polyamide thin-film composite membrane in the late 1970s represented a major advance in membrane technology. Thin-film composites provided thin active films that required much less energy to induce fluid passage than previous materials, making them more economical to use on a large scale. As mentioned previously, thin-film composites layer asymmetric films to form membranes

with several different characteristics. Both hydrophilic and hydrophobic films are laid in a composite film by cross-linking different polymers. The thickness of the nonporous layer is typically less than 1 μm . Cross-linking to the porous film provides needed support for the nonporous film. Removal of macromolecules and ionic species is achieved by a nonporous film in a pressure driven membrane process.

Classification by Geometry

MF, UF, NF, and RO membranes are made from different materials and in different configurations. Both the material and configuration of such a membrane affect its mass transport or performance. As the effects of materials and configurations on solute rejection by membranes are largely unknown, the following paragraphs briefly discuss pressure-driven membrane materials and configurations.

MF/UF Configuration. The flow in microfiltration or ultrafiltration processes can run from inside out or outside in through hollow fibers. MF and UF inner and outer diameters vary between manufacturers; however, a typical membrane fiber's inner and outer diameter approximates 90 and 1900 μm , respectively. Figure 11-3a shows a single MF PVDF fiber under magnification, and Fig. 11-3b presents the structure and dimensions for a MF PVDF fiber having an inner and outer diameter of 0.7×10^{-4} m (2.5×10^{-3} ft) and 1.3×10^{-3} m (4.2×10^{-3} ft), respectively. Typical MF poresize ratings range from 0.1 to 0.5 μm , whereas commonly used UF membranes range from 150,000 dalton to 2000 dalton molecular-weight cutoff. Although some UF membranes have been produced in spiral-wound (SW) configurations for industrial applications, SW UF configurations have not been applied to any significant degree for drinking water production in the United States.

(a)

FIGURE 11-3 (a) Microscopic image of an asymmetric MF membrane.

FIGURE 11-3 (b) Lumen dimensions of an outside-in asymmetric MF membrane. (Continued)

In a conventional UF or MF process, the driving force to produce filtrate can work in two ways; positive pressure moves fluid through the fibers, usually at a rating lower than 241 kPa (35 psi), and negative pressure moves fluid through fibers under vacuum pressure. Combining the two different flow regimes and the two driving forces allows three different processes.

1. Inside-out flow with positive pressure
2. Outside-in flow with positive pressure
3. Outside-in flow with negative pressure

Both inside-out and outside-in flow patterns can be further characterized as either dead end or crossflow operations, as shown in Fig. 11-4. In a dead end operation, the entire feed flow passes through the membrane. The dead end mode of operation is analogous to conventional media filtration in that the retained particles accumulate and form a type of cake layer at the membrane surface. In a crossflow operation, only a portion of the flow passes through the membranes, and only a portion of the retained solutes accumulate at the membrane surface. The remaining flow (retentate) is recycled on the feed side. The crossflow regime also incorporates a tangential flow that shears the cake and minimizes the accumulation of solids on the membrane surface, which can lead to fouling of the material and reduce performance.

FIGURE 11-4 Individual fiber flow pattern. (a) Outside-in dead end filtration, (b) Inside-out dead end filtration, and (c) Inside-out cross flow filtration.

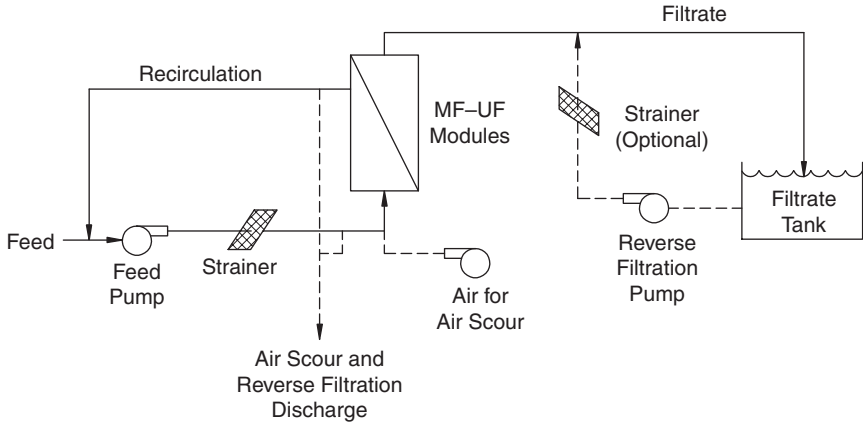

FIGURE 11-5 Typical MF and UF system process flow schematic. (Courtesy of the American Water Works Association *Manual of Water Supply Practices M53 Microfiltration and Ultrafiltration Membranes for Drinking Water*.)

Because the permeate flow produced through a membrane filter is roughly two orders of magnitude lower than loading rates through conventional media filters, MF and UF plants require on the order of 100 times the filter area to produce an equivalent amount of water. However, because of the packing densities achieved through the incorporation of hollow fibers into modules, MF and UF processes require less floor space than typical conventional media filtration processes. Figure 11-5 depicts a typical MF and UF process flow schematic. In Fig. 11-5 the feedwater is pumped to the membrane. In a crossflow mode, the water that does not permeate the membrane is recirculated as concentrate just ahead of the prefilter and blended with additional feedwater. A bleed stream may be employed to control the concentration of the solids in the recirculation loop. In direct filtration during which no crossflow is applied, or dead end filtration, prestrained water is applied directly onto the membrane, and there is 100 percent recovery of this water, except for those times a backwash or system flush is required.

MF processes are typically available in pressure-vessel configurations, with each pressure vessel housing thousands of fibers. UF membrane processes are available in two basic configurations, where the membranes are housed in pressure vessels and vacuum-type systems where the membranes are submerged or immersed in nonpressurized tanks. There are significant differences with regard to the design and layout of these two types of configurations, requiring that the configuration type be determined prior to commencement of facility design. .

Figure 11-6 shows one pressure-vessel module that is generally 10.2 to 45.7 cm (4 to 18 in.) in diameter and from 1.8 to 5.5 m (6 to 18 feet) long, and contain packing densities that provide between 9.3 and 93 m² (100 and 1000 ft²) of filter area. Figure 11-7 illustrates a submerged, or immersed, membrane process where membranes suspended in modules are suspended inside basins containing pretreated feedwater. Transmembrane pressure is developed by using suction on the permeate side of the membranes which limits immersed membrane transmembrane operating pressures to between 41.4 and 48.3 kPa (6 and 7 psi), and pressure on the influent side is limited to the static pressure provided by the water column. Table 11-3 provides the typical operating characteristics of MF and UF facilities.

TABLE 11-3 Typical Operating Characteristics of Membrane Filtration Facilities

Parameter	Units	Range of typical values
Permeate flux		
Pressurized systems	L/m ² ·h	30–170
	Gal/ft ² ·d	18–100
Submerged systems	L/m ² ·h	25–75
	Gal/ft ² ·d	15–45
Typical transmembrane pressure		
Pressurized systems	Bar	0.4–1
	Psi	6–15
Submerged systems	Bar	0.2–0.4
	Psi	3–6
Maximum transmembrane pressure		
Pressurized systems	Bar	2
	Psi	30
Submerged systems	Bar	0.5
	Psi	7.4
Recovery	%	>95
Filter run duration	Min	30–90
Backwash duration	Min	1–5
Time between chemical cleaning	Day	5–180
Duration of chemical cleaning	Hour	1–6
Membrane life	Yr	5–10

RO-NF CONFIGURATION

RO and NF membranes for drinking water treatment have either spiral-wound (SW) or hollow fine-fiber (HFF) configurations. The SW configuration is the most common for production of drinking water. The HFF configuration was used extensively for desalination of seawater in the Middle and Far East; however, the use of spiral-wound configurations has increased over time. The geometry of a SW membrane is subject to fewer “dead areas” than that of a HFF membrane, it can be cleaned more thoroughly, and it is less subject to fouling. The ratio of surface area to volume is higher for a HFF element than a SW element. The recovery from a hollow fine-fiber element ranges from 10 to 50 percent and is typically higher than that from a SW element. The radial feed-stream velocity along the outside surface of the HFF varies from approximately 0.003 to 0.0003 m/s (0.01 to 0.001 ft/s) which give Reynolds numbers ranging from 100 to 500 for transport through the membrane.

From 1969 until about 2000, E. I. DuPont de Nemours, Inc. (DuPont) produced a polyamide hollow fine-fiber (HFF) membrane that was designated as B-9 and was used for brackish water desalting. DuPont produced a significant number of HFF membrane elements using this type of fiber material. In 1974, DuPont introduced its seawater membrane referred to as B-10, which was used predominantly overseas. In 2000 DuPont ceased the manufacture of B-9 and B-10 HFF membranes. Between 1982 and 2002, the city of Sarasota, Florida, operated a 17,000 m³/day (4.5 mgd) DuPont HFF B-9 membrane process, which was the largest operating brackish HFF drinking water facility in North America. However, the city converted the HFF process trains to SW thin-film composite membranes after DuPont withdrew from the membrane market. Shortly thereafter, the Key West Aquaduct Authority replaced its DuPont B-10 seawater HFF membranes with Toyobo HFF modules.

Today HFF membranes can be acquired through Toyobo Company Limited, which produces Hollosep[®] HFF membranes. In the hollow fine-fiber (HFF) RO configuration, feed-water flows radially from the center pipe, passes across the hollow fibers in the bundle, and flows away from the element as concentrated brine flow. A depiction of a double cartridge HFF RO membrane configuration housed in a pressure vessel is in Fig. 11-8. In this configuration, permeate water is recovered from both ends of the RO HFF module. Permeate water is collected with each supporting end that is held in position using compression snaps and an O-ring seal on the face of the open end, so that concentrate water cannot penetrate into the permeate. The compression snap has another function; it is placed in the center of the pressure vessel and forms a narrow space between the pressure vessel and the RO element for the concentrated brine water flow. Brine water flows on the periphery of the RO element, passes through the narrow space between pressure vessel and supporting plate and flows to the brine port of the pressure vessel. The Toyobo HFF RO membranes are made of cellulose triacetate (CTA), that unlike polyamide RO membranes, are chlorine tolerant. This unique chlorine tolerance has demonstrated stable production and easy maintenance by eliminating biofouling in many seawater desalting applications (Burashid, 1994). The Toyobo HFF RO membranes are manufactured using a winding technology in a cross and overlapped arrangement that yields a self-supporting HFF bundle. The winding technology provides uniform flow throughout the entire volume of the bundle, resulting in a lower pressure drop across the bundle that provides additional resistance to accumulation of any fouling matter.

SW thin-film composite RO membranes were introduced in the mid to late 1970s and were designed for brackish- and seawater application. Low-pressure thin-film composite, spiral-wound membranes were first introduced in the early 1980s by Fluid Systems (now Koch Membrane Systems) and by FilmTec Corporation (now a division of Dow Chemical Company). These composite membranes are in common use, and many manufacturers offer similar products.

SW elements are manufactured using flat-sheet membranes, as opposed to bundles of fibers, as shown in Fig. 11-9. A typical SW element consists of envelopes attached to a

FIGURE 11-8 Depiction of hollow fine-fiber RO bundles housed in a pressure vessel. (Courtesy of Toyobo Co., Ltd.)

FIGURE 11-9 Diagram of a spiral wound reverse osmosis membrane. (a) Open construction, (b) Wound construction, (c) End construction, and (d) Cut-away element view. (Courtesy of the American Membrane Technology Association, Stuart, FL.)

center tube that collects the permeate stream. Designs of SW elements differ among manufacturers; however, the following description is applicable to Filmtec, Toray, Hydranautics, and Koch SW membranes. Typically, in a SW element an envelope is formed by folding one flat sheet over a permeate stream spacer. The sheet itself consists of two layers, a nonporous active membrane film and a porous membrane support. The active layer is on the outside of the fold. The envelope is glued along three open sides and near the fold, completely enclosing the permeate spacer. The glue line on the fold end is a short distance away from the fold, because the fold end is attached to the center collection tube. The glue line at the fold end stops the flow of the feed stream and allows the remaining pressure in the permeate stream to drive it through the membrane into the center collection tube. A feedstream spacer is attached to each envelope prior to establishing the fold end glue line. Several envelopes and feedstream spacers are attached to the center collection tube and wrapped in a spiral

around it. An epoxy shell or tape wraps are applied around the envelopes, completing the SW element. An anti-telescoping device is attached both ends of the element to maintain a fixed space between elements and facilitate flow from one element to the next. Multiple elements are housed in a series of cylindrical pressure vessels.

The feed stream enters the end of the SW element in the channel created by the feed stream spacer. The feed stream can flow either in a path parallel to the center collection tube or through the active membrane film and membrane supports into a channel created by the permeate-stream spacers. The permeate stream follows a spiral path into the center collection tube and is taken away as product water in a drinking water application. As with hollow fine-fiber membranes, the feed stream becomes progressively more concentrated as it passes to a succeeding element. As an example, a 100 mm (4 in.) Dow Filmtec NF70 membrane contains four envelopes with approximately 8.3 m^2 (90 ft^2) of surface area in a sheet that measures 0.91 m (3 ft) by 1.14 m (3.75 ft). The total element is 1.01 m (3.33 ft) long, but the feed stream path along the active membrane film is approximately 0.91 m (3 ft).

The amount of membrane surface area offered by SW elements varies between manufacturers, depending on application, element diameter, and spacer thickness. In recent times, both brackish- and seawater elements have been made with increased area. Brackish elements have increased from 34 to 37 m^2 (365 to 400 ft^2) and most recently to 40 or 41 m^2 (430 or 440 ft^2). These changes have mostly been done by changing element construction, not by changing the membrane. A combination of thinner permeate spacers, optimized glue line placement, and material thickness control has led to the improvements. These same improvements are now being applied to seawater membranes as well. Seawater elements in the 1990s were typically around 29 to 30 m^2 (310 to 325 ft^2) and then increased to 34.4 to 35.3 m^2 (370 to 380 ft^2) in the mid- to late 1990s. By the early 2000s, most seawater elements contained 37 m^2 (400 ft^2). Recently, 41 m^2 (440 ft^2) seawater elements have been produced. A 102 mm (4 in.) diameter SW membrane will provide approximately 6.5 m^2 (70 ft^2) of membrane surface area per membrane. In comparison, a 203 mm (8 in.) diameter SW membrane could provide upward of 37.2 m^2 (400 ft^2) of surface area per membrane element. Newer 406 mm (16 in.) diameter RO membrane elements that recently entered the market place possess an active surface area on the order of 160 m^2 (1725 ft^2), more than 4 times that of the standard 203 mm diameter element. The increase in active surface area greatly decreases the number of membrane elements needed for the same quantity of feedwater, reducing the system's footprint and equipment needs and providing capital cost savings for plant operators.

The recovery in a SW element varies from approximately 5 to 15 percent. The maximum feed and concentrate stream flows in a 10.2 cm (4 in.) element are approximately $4.2 \times 10^{-3} \text{ m}^3/\text{min}$ (16 gpm) and $7.9 \times 10^{-4} \text{ m}^3/\text{min}$ (3 gpm). Neglecting the effect of the feedstream spacer, the Reynolds number typically ranges from 100 to 1000. The feedstream spacer creates additional turbulence and increases the Reynolds number. The physical configuration of the SW element produces a more turbulent feed stream than that in a HFF element and leaves the membrane more easily accessible to cleaning agents. The highest and lowest feedstream velocities occur at the entrance and exits of the element, respectively. The feed flow is in the laminar region and is most likely to produce chemical or colloidal fouling in the last elements in series. Fouling from particle deposition occurs mainly in the first elements in series.

Classification by Driving Force

Membrane processes can be classified based on the driving force that induces transport of materials across the membranes. Examples of driving forces and corresponding membrane processes are listed in Table 11-4. Although interest in industrial applications for pervaporation is growing, industrial-scale applications of membrane processes for environmental quality control have so far been dominated by the pressure driven processes such as RO and

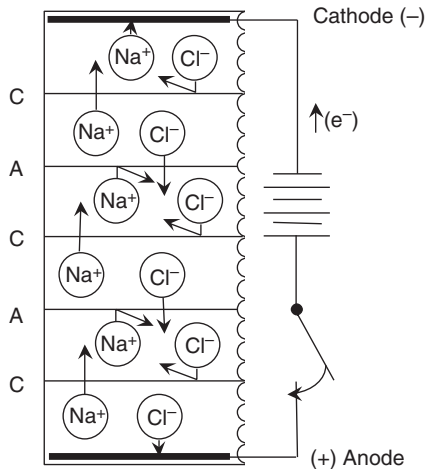

TABLE 11-4 Categorization of Membrane Processes by Driving Force

Driving force	Examples of membrane processes
Temperature gradient	Thermo-osmosis, distillation (thermal)
Concentration gradient	Dialysis, pervaporation, direct (forward) osmosis
Pressure gradient	RO, NF, UF, MF, piezodialysis
Electrical potential	ED, EDR, electroosmosis

by electro dialysis and electro dialysis reversal (EDR), which employ electrical potential as the driving force.

Electrodialysis. Electrodialysis is a membrane process driven by electric potential and is used for removing charged species (ions) from an aqueous stream using cation- and anion-selective membranes. In this electrochemical separation process ions are transferred through ion exchange membranes by means of a direct current (DC) voltage. In a simple electrolytic cell, negatively charged ions (anions) are drawn toward the positively charged electrode, or anode, and positively charged ions (cations) are drawn toward the negatively charged electrode, or cathode.

The ED/EDR process differs fundamentally from the pressure-driven membrane processes by mechanism and effect. An electrochemical separation process removes ions from a process stream, whereas a pressure-driven separation process removes water from the process stream. Both membrane processes can remove ions, but electrochemical separation processes cannot remove pathogens, as pressure-driven processes can, so they have no role in disinfection. Electrochemical separation processes are often less costly than NF/RO, however, because they achieve higher recoveries through lower salt rejection and mass transport advantages. A basic diagram of a batch electro dialysis process is shown in Fig. 11-10.

A = Anion membrane
 C = Cation membrane

FIGURE 11-10 Diagram of an electro dialysis batch process under applied DC voltage. (Courtesy of GE Water & Process Technologies Ionics, Inc.)

ED Cell

The basic ED cell consists of alternating anion-permeable and cation-permeable membranes, which provide a basis for separation of ions under DC voltage. Redox reactions occur during ED. Water and chlorine are oxidized at the cathode, and water is reduced at the anode. These by-products of the ED cell are removed as electrode waste products and treated by aeration and neutralization (reduction), if necessary.

A simplified diagram of a complete cell for NaCl removal is shown in Fig. 11-11. Sodium ions pass through the cation-transfer membrane, and chloride ions pass through the anion-transfer membrane. The sodium and chloride ions are trapped in the brine channel by the alternating ion-exchange membranes, as only cations can pass the cation-permeable membranes and only anions can pass the anion-permeable membranes. The alternating ion-exchange membranes produce a demineralized stream and a concentrate stream, as shown in Fig. 11-11. Water flows across these membranes, not through them, as it does in pressure-driven processes.

As shown in Fig. 11-12 an ion-exchange membrane has a polymeric support structure with fixed sites and representative water-filled passages that reject common ions and pass counter ions through the membrane. In Fig. 11-12 a fixed, negatively charged, sulfonated functional group and a fixed, positively charged, tertiary amine are shown in the anionic and cationic membranes, respectively. These membranes are (1) impermeable to water, although water does participate in the transport process, (2) electrically conductive, and (3) ion selective. The anion membrane is composed of a cast anion exchange resin with a fixed negative charge in sheet form. The fixed negative charge assists cations in passing and

keeps anions from passing through the anion membrane. The cation membrane has a fixed positive charge and utilizes the same mechanism to repel cations and pass anions.

A spacer is placed between the anion-exchange and cation-exchange membranes to form a basic cell pair, as shown in Fig. 11-13. The cell pair consists of an anion-exchange membrane, a concentrating spacer, a cation-exchange membrane, and a demineralizing spacer as shown in Fig. 11-14. The spacers are assembled with cross straps to promote turbulence and reduce polarization at the membrane surfaces. Several hundred cell pairs are grouped into a common arrangement known as a *membrane stack* or *module*, as shown in Fig. 11-15a and are protected by removable stack siding enclosures that must be heat resistant. These streams either pass to succeeding cells for additional treatment or are discharged from the ED cell as concentrate waste and demineralized water (also termed *product*) as shown in

FIGURE 11-13 Basic electrodiolysis cell pair. (Courtesy of GE Water & Process Technologies Ionic, Inc.)

MEMBRANE PROPERTIES AND REJECTION CHARACTERISTICS

Characterization of membrane properties is desirable because of the potential of relating these characteristics to solute rejection and membrane-fouling studies. This information could be used to modify existing membranes or develop new membranes that would effectively reject inorganic and organic solutes from drinking water sources without fouling the membranes.

Fundamental research for mass transfer, membrane fouling and solute-solvent interactions has been conducted or is in progress using several different techniques. Currently, feasible techniques are capable of measuring membrane surface charge, pore size, thickness, roughness, surface energy, and surface atomic composition. These techniques are presented in Table 11-5.

TABLE 11-5 Techniques to Characterize Membrane Surfaces

Techniques	Application on membrane research	References
Streaming potential	Charge on membrane surface to determine electrostatic interactions.	Elimelech, Chen, and Waypa (1994)

Scanning electron microscopy (SEM)	High resolution image to characterize roughness and pore size for clean and fouled membrane	Fritsche, et al. (1992)

Diffusion-controlled solute and solvent permeability are best described by mass transfer coefficients, although percent rejection is sometimes used to describe solute mass transfer for a given environment. The solvent and solute mass transfer coefficients, like molecular weight cutoffs, are measured in the laboratory with standardized test conditions and a test cell. Continuous-flow test cells that operate at less than 1 percent recovery can be used to minimize concentration polarization so that linearly determined mass transfer coefficients can be used to characterize membranes. Such test cells can also be used to determine the changes in solvent mass transfer coefficients over time for different films (membranes) to determine a possible correlation between films and fouling.

Solute and solvent solubility in the membrane film are important characteristics of diffusion-controlled membrane processes. Ideally the active film would have no solubility for the contaminants or foulants and complete solubility for water. The solute mass transfer coefficient increases as the solubility of the contaminant in the film increases. Hence the lower the contaminant solubility in the film, the lower the contaminant concentration in the permeate. If needed, the film material can be modified to effect solubility by the inclusion of functional groups, or a different film material can be substituted.

The thickness and chemical structure of the film are important membrane characteristics and are difficult to measure, although techniques do exist. Plasma etching has been used to measure film thickness. A plasma is introduced to initiate a chemical reaction with the top layer of the film, producing gases. The rate of gas production during etching indicates surface morphology and thickness of a nonporous film. Electron spectroscopy and X-ray photoelectron spectrometry can be used to determine the thickness of the top layer.

Dissolved Solute–Membrane Interactions

Dissolved inorganic and organic solutes markedly influence electrokinetic properties of RO and NF membranes through various solute-membrane interactions. Among such interactions

are, adsorption of inorganic and organic solutes on the membrane surface and/or within the membrane pores. These solute-membrane interactions have a significant impact on membrane rejection and fouling behavior. In the following text, the effect of solution composition (i.e., dissolved solutes) on membrane rejection and fouling is documented from recent publications.

Influence of Dissolved Solutes on Electrokinetic Properties of Membranes

The effect of dissolved solutes on electrokinetic properties of RO and NF membranes has been investigated by the streaming potential technique, which estimates charge on membrane surface and in membrane pores (AWWA committee report, 1998). Streaming potential measurements by Childress and Elimelech (1996) demonstrated that typical commercial RO and NF membranes are amphoteric, and the isoelectric point ranges from pH 3 to 5. This pH dependence is attributed to deprotonation of membrane surface functional groups originated from manufacturing processes.

Membrane charge is also greatly influenced by divalent cations. Hong and Elimelech (1997) showed that membrane surface charge becomes less negative with increasing divalent cation concentration. The decrease in the negative charge of the membrane was attributed to charge neutralization and effective screening of the membrane surface charge by divalent cations. Specific adsorption of divalent cations to membrane surface functional groups may also, in part, have been responsible for the decrease in the negative charge of the membrane.

Dissolved organic solutes such as natural organic matter (NOM) readily adsorb to the membrane surface and/or pores, affecting the membrane charge. It has been observed that membrane surface becomes more negatively charged in the presence of humic acids (Childress and Elimelech, 1996; Hong and Elimelech, 1997). The increase in the negative charge is ascribed to adsorption of the humic acids to the membrane surface. The adsorbed humic substances mask inherent membrane charge and dominate the surface charge of the membrane.

Impacts on Membrane Rejection

Charge repulsion is an important rejection mechanism of RO and NF membranes. Thus, changes in electrokinetic properties of the membrane due to solute-membrane interactions have a significant influence on membrane rejection characteristics (Braghetta, 1995). Hong and Elimelech (1997) observed a decline in NOM removal by NF membranes with decreasing pH. This observation can be explained by the reduced electrostatic repulsion between organic matter and membrane surfaces due to the lower membrane surface charge at low pH.

Impacts on Membrane Fouling. The degree of membrane fouling is determined by interplay between several chemical and physical interactions. Electrostatic repulsion, one of the critical interactions, is affected by solution composition (Song and Elimelech, 1995; Zhu and Elimelech, 1997). A recent NF study by Hong and Elimelech (1997) reported that NOM fouling increases with increasing electrolyte concentration and decreasing solution pH. In particular, at fixed solution ionic strength and pH, the presence of divalent cations markedly increases NOM fouling. Divalent cations substantially reduce the electrostatic repulsion between NOM and the membrane surface, resulting in a substantial increase in NOM deposition on the membrane. Jucker and Clark (1994) also recognized the effect of divalent cations on NOM adsorption to membrane surfaces.

Organic Solute Removal

The removal of disinfection by-product (DBP) precursors or *dissolved organic carbon (DOC)* by RO or NF has been studied extensively (Taylor et al., 1986, 1987, 1989a, 1989b; Jones and Taylor, 1992). Nanofiltration membranes have been shown to control trihalomethane formation potential (THMFP) in highly organic (>10 mg/L DOC) potable water sources (Taylor et al., 1986). These efforts have often been necessitated by inadequate efficiency of DBP removal using conventional coagulation and softening treatment processes.

An early investigation using diffusion controlled membrane processes had shown that membrane material would achieve the same solute rejection (Reinhard, 1986). In addition to membrane chemistry, characterization of raw-water organic fractions was found to be an important consideration for appropriate membrane selection (Fourrozi, 1980; Conlon, 1989; Taylor, 1989a, 1989b; Tan and Amy, 1991). In research conducted by Jones and Taylor (1992), over 90 percent of the DOC was removed for both surface water and ground-water supplies by membranes for which a manufacturer reported a molecular weight cutoff (MWC) of 300 to 500 daltons. The THMs and haloacetic acids (HAAs) in the permeate averaged 15 and 4 ug/L, respectively, and represented more than a 90 percent disinfection by-product formation precursors (DBPFP) reduction. However, lower MWC membranes removed little additional DBPFP.

Effective DBPFP removal has also been demonstrated for highly organic potable water sources where limited removal of inorganic contaminants was desired. Research published by Taylor (1989a, 1989b) and Spangenburg et al., (1997) have shown high DBP removal capability while simultaneously meeting treatment objectives for hardness or alkalinity concentrations in the treated permeate. It should also be noted that energy requirements for membranes offering comparable DBPFP removal efficiency have been shown to vary as much as 50 percent. This has been demonstrated in single-stage membrane pilot systems operated in parallel using different film chemistries and membrane manufacturers (Tan and Amy, 1991). Research has also focused on the rejection of specific THM species using membranes. The relative percentage of brominated THMFPs increased in permeates from membrane processes with increasing MWC (Laine et al., 1993). While NF was found to control brominated DBPs, advanced pretreatment was necessary to sustain production when using the bromide-spiked surface water source. Many NF membranes do not remove bromides effectively; hence, higher ratios of brominated DBPs are formed as the Br:NOM ratio increases in the permeate.

High DBPFP reduction has been demonstrated for groundwaters and surface waters alike. However, due to increased fouling potential, surface water is generally more difficult to treat by membrane processes than groundwaters with high organic matter concentrations. Consequently, advanced pretreatment is frequently required to counter significant membrane production losses in these applications. Long-term investigation of THMFP control at the Flagler Beach, Florida, water treatment plant (a groundwater site) and at the Punta Gorda, Florida, water treatment plant (a surface water site) provided for comparison of groundwater and surface water membrane treatment. Although consistent control of permeate THMFP was achieved, severe water flux loss was experienced in the system treating surface water. Membrane cleanings were conducted on 20 occasions in an attempt to sustain a water flux of 0.407 m³/m²-day (10 gsf). The operating system at the groundwater site required prefiltration and acidification in order to sustain a flux of over 0.611 m³/m²-day (15 gsf) with only a semiannual cleaning frequency (Taylor, 1989a). Similar experience was reported for a surface water of high natural color (Kouadio and Madeleine, 2002). In research reported by European investigators, NOM adsorption onto a membrane surface has been verified by XPS analysis (Heimstra and Nederlof, 1997). As a result, an alternative membrane was studied which offered similar organic removal and sustained operation capability (three-month cleaning frequency).

TABLE 11-6 Summary of DBP Precursor Studies with Membrane Processes

Citation	Water source	Pretreatment	Membrane technology	Feed water THMFP ($\mu\text{g/L}$)	Treated THMFP ($\mu\text{g/L}$)	Percent THMFP removal (%)

NR = not reported.

The referenced DBP investigations are summarized in Table 11-6. In all of these investigations, the removal of naturally occurring DOC or DBPFP by membranes was found to be virtually independent of operating conditions (i.e., flux or recovery); this suggests that natural organics removal is generally sieve controlled. Similar findings using nanofiltration and reverse osmosis to remove trace-level pesticides are reported by Duranceau and Taylor (1990). If the DBPFP are assumed to be uncharged DOC, which is likely, then the removal of uncharged organics such as pesticides and naturally occurring dissolved organic compounds may be controlled by sieving. Removal of sieving controlled organic compounds may be increased if they can be placed in a state of increased size or steric hindrance. Some NOM compounds are diffusion controlled and affected by variations in flux and recovery. However, differences in permeate NOM concentrations due to diffusion-controlled variables (flux and recovery) are in the tenths of mg/L and unlikely to have any effect on DBP MCL compliance.

Suppliers of drinking water are subject to stringent government regulations for potable water quality regarding allowable *synthetic organic compounds (SOCs)* pesticide and herbicide concentrations. In particular, European standards require less than 0.1 $\mu\text{g/L}$ for any one particular pesticide or herbicide and no greater than 0.5 $\mu\text{g/L}$ for total pesticides and herbicides in drinking water. Many investigators have shown that RO and NF are effective techniques for pesticide and herbicide removal. However, specific mechanisms underlying SOC rejection is largely unknown. Some general statements can be made about SOC rejection in membranes. Rejection has been observed to increase as SOC molecular weight and charge increased and membrane polarity increased. In Table 11-7, results and significant findings from published accounts of pesticide and SOC removal are summarized.

TABLE 11-7 Literature Summary for SOC and Pesticide Removal

Membrane	SOC and pesticides	Rejection %	Significant findings	Researchers
CA	Sodium alkyl benzene Sulphonate	99.9	Flat sheet application	Ironside and Sourirajan (1967)

More recently, there is concern over the presence of pharmaceuticals, personal care products and endocrine disruptors in water supplies. UF and MF were shown to be ineffective in removing pharmaceuticals, personal care products, and endocrine disruptors from water supplies (Snyder et al., 2008). NF and RO were shown to remove a wide variety of these emerging contaminants, but were not effective on low-molecular-weight organics such as N-nitrosamines, acetaminophen, and phenacetine. Additional studies are ongoing that further evaluate membrane processes for the removal of these organic contaminants.

Pathogen Removal

The removal of *Giardia* cysts by microfiltration and ultrafiltration has been well documented in the literature (Jacangelo et al., 1991; and Coffey, 1993). In these studies, a removal higher than 4 log was reported with ultrafiltration (Fig. 11-16) and microfiltration membranes having provided absolute removal of this protozoan cyst. In these cases, the removals were limited only by the concentration of the cysts in the feedwaters. One study reported that at bench scale, all the tested membranes (three MF and three UF) except one MF membrane (for which the membrane seal ring was found to be defective) removed *Cryptosporidium* and *Giardia* below the detection limit (1 cyst/L) (Jacangelo, Adham, and Laine, 1995). These results were confirmed at pilot scale. Removal effectiveness ranging from 6 to 7 logs was limited only by the influent concentration of the *Cryptosporidium* and *Giardia*. Polymeric MF and UF membranes behave as significant barriers to protozoan cysts as long as they remain intact. However, no process should be regarded as an absolute barrier to pathogens.

Coffey observed a 0.32 mean log removal for heterotrophic plate count (HPC) in a MF process. Permeate contained an average of 182 CFU/mL for a mean of 1480 CFU/mL in the feedwaters. In the same study, no *E. Coli* or *Giardia muris* were found in the filtrate for a feed concentration of 9.8×10^5 to 2.67×10^6 and 2.75×10^4 , respectively. The low HPC removal was due to regrowth on the permeate channel and the low HPC in the feed stream. These results are consistent with the results published by Yoo et al., (1995). An intact 0.2 μm MF filtration process appears to provide a significant barrier to *Cryptosporidium* and *Giardia*. A microfiltration pilot plant has been used at the Fishing Creek water supply for Frederick,

FIGURE 11-16 Removal of seeded microorganisms by UF of Mokolumme and Delta Waters.

Maryland, removing all the total coliforms in the feedwaters, which ranged from 10 to 1000 per mL (Olivieri, 1991). At Manitowoc, Wisconsin, no total coliforms, fecal coliforms, or *E. Coli* were detected in the MF filtrate. The feed contained 0 to 140 total coliform, 0 to 10 fecal coliform per mL, and 0 to 6 *E. Coli* per mL (Kothari, 1997). For the Saratago Water Treatment Plant, a microfiltration process achieved more than 6-log removal of *Giardia* and *Cryptosporidium* (Yoo et al., 1995). Between 1.7 and 2.9 log removal of MS2 virus in a California surface water with a 0.2 μm pore size hollow fiber microfiltration membrane was observed. The range of MS2 virus number in the feedwaters was from 1.3×10^6 to 3×10^7 , and in the filtrate was found at 2.2×10^4 to 3.4×10^5 MS2 viruses (Coffey, 1993). Total removal of the MS2 virus was found for these feed concentrations using a hollow fiber UF membrane with a 0.01 μm nominal pore size (Jacangelo et al., 1991). Membrane processes, like any process, will eventually fail, and pathogen passage is more likely to be detected as feed concentration increases. However, membrane processes offer greater pathogen removal than other water treatment processes intended for the removal of suspended or dissolved matter. Typically, UF membranes remove a greater percentage of viruses than MF, greater than 3 logs of viruses, where MF remove less than 2 logs viruses.

Membrane Integrity

Membrane integrity is an essential issue in membrane processes. The high efficacy of MF and UF processes for removal of turbidity and pathogens can be compromised if the membranes are damaged. Membrane integrity can be extended to NF and RO membranes as dissolved contaminants can pass if membrane integrity is compromised. MF and UF integrity breaches can include a severed fiber, a pinhole puncture, or a weakened area due to abrasion. As an example, testing of an intact UF membrane achieved 7.0 log removal of *Bacillus subtilis*, but with a pinhole puncture the log removal was reduced to 5.2, and with two fibers cut, the log removal decreased to less than 4.0 (Côté et al., 2003). NF and RO integrity breaches can include a tear or weakened area of the membrane film, however, like MF and UF, can be compromised by a failed seal or O-ring. Hence, monitoring membrane integrity is important to avoid any water quality degradation.

As shown in Table 11-8, different membrane integrity tests are divided into direct and indirect monitoring methods. Currently available direct integrity test methods represent the

TABLE 11-8 Different Membrane Integrity Tests

Indirect monitoring	Direct monitoring
Particle counting	Air-pressure testing: <ol style="list-style-type: none"> i. Pressure decay test ii. Diffusive air flow test or water displacement test
Particle monitoring	Bubble-point testing
Turbidity monitoring	Sonic sensors
Conductivity monitoring	Marker or dye-based tests

most sensitive means of detecting integrity breaches, but these tests cannot be conducted on a continuous basis while the membrane filtration system is in operation. Thus, direct integrity testing is implemented at regular intervals and complemented by indirect integrity monitoring, which is generally less sensitive but can be conducted continuously during filtration. Indirect methods do not assess the integrity of the membrane barrier directly. Instead, water quality parameters are used as a surrogate to infer information about membrane integrity based on a comparison of the levels of monitored parameters relative to known baseline conditions of an integral system.

Integrity testing is required for regulatory requirements when MF or UF membranes are used for drinking water production. NF and RO processes are not at this time required to perform direct integrity tests primarily because no established methods are available. For MF and UF indirect integrity monitoring, the *Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR)* requires continuous indirect monitoring; this means measurements are collected at least every 15 minutes on the filtrate of each membrane module (Duranceau, 2004). A direct integrity test is initiated once a problem has been identified. The LT2ESWTR does not specify the use of a particular type of direct integrity test, but rather allows for the utilization of any type of test meeting the requirements for test resolution, sensitivity, and frequency. Specifically, the direct integrity test must be conducted once every 24 hours, detect a breach of size 3 μm or less, and verify the *log reduction value (LRV)* equal to or greater than the credit that had been given to the membrane system initially. The sensitivity of a direct integrity test is expressed in terms of a LRV, which must be equal to or greater than the *Cryptosporidium* removal credit awarded to the system in order to achieve compliance with the LT2ESWTR. However, state or local county regulatory agencies are allowed to make their requirements more stringent than federal regulations, so each membrane facility may have its own specific permit requirements with respect to integrity monitoring.

Air-Pressure Direct Testing Processes. Air-pressure tests are more sensitive than water-quality monitoring and have been reported to be capable of detecting one broken fiber in a membrane module containing 20,000 fibers (MWH, 2005). Air-pressure testing can be subdivided into two general tests, the pressure decay test (PDT) and the diffusive airflow test. The PDT is an online method that determines the membrane's ability to maintain a hold on a specific pressure that is generated by applying air to the membrane module. The rate of pressure decay is measured over time, and if the rate exceeds a specific test value, dependent on manufacturer, the membrane integrity has been breached. Air-pressure testing is accomplished in a series of actions or steps. For a pressurized system, the test requirements are:

1. Isolate each module by closing all their inlets and outlets
2. Drain membrane lumens via the filtrate exhaust line
3. Pressurize the filtrate side to 103 kPa (15 psi) with the feed side open to ambient pressure
4. Turn off the membrane test pressure to the filtrate side and watch for any decay in filtrate pressure
5. Exhaust the pressure to the filtrate exhaust line.

Usually the pressure is monitored after 2 and 4 min. A pressure drop between the readings at 2 and 4 min exceeding 2.8 kPa (0.4 psi) may indicate breaks in one or more fibers. The air-pressure test method cannot be used for air-permeable membranes. For immersed UF processes testing is analogous, except that a vacuum-pressure hold test is performed. The diffusive airflow, or water displacement, test is similar to a PDT, except that the rate of flow of either air or water is measured in lieu of pressure. If the flow of air or water exceeds specific criteria, a breach has occurred.

BUBBLE-POINT DIRECT TESTING

The bubble-point test is used to detect a compromised fiber. The pressure at which the membrane structure is sufficiently deformed to allow air bubbles to pass through the fiber is called the bubble-point pressure. The pressure is measured by applying increasing air

pressure to the hollow fiber until bursting occurs. For example, to conduct a bubble-point test, the module is first taken off-line, and then the water outside the fiber is drained. Air pressure of 200 kPa (29.4 psi) is applied on the external side of the fibers. A low-concentration surfactant solution is applied at the surface of the module end to assist in identifying any air bubbles coming through damaged fibers (Adham, 1995). Pressure decays higher than 5 kPa (0.7 psi) in 5 min indicate damage to one or more fibers.

RO and NF Sonic Sensor Direct Testing. Sonic testing is a direct measure of the air-induced vibration within a membrane module during a PDT, as air bubbling through a damaged fiber will make enough noise to be detected by an inline sonic sensor. The sensor located on the module is monitored for hydraulic noise in a certain frequency range, which indicates membrane integrity loss. When membrane integrity is compromised, hydraulic noise increases due to a rise in turbulence in the module. A single broken fiber in a module containing 20,000 fibers can be detected by sonic monitoring (Landsness, 2001).

RO and NF Process Integrity Monitoring. For NF and RO systems there are currently no guidelines or established direct methods for element integrity testing. Typically NF and RO process skids are fitted with sample panels where aqueous samples can be analyzed for conductivity, dissolved solids, color, or hardness and process performance is monitored by profiling each pressure vessel of that process train once or twice daily. If contaminant or salt passage has been detected within a single pressure vessel (PV), then while in operation, the permeate end of the suspect pressure vessel is then probed by inserting a conductivity probe into the permeate collection tube. As the probe moves between elements, conductivity is measured at discrete distances. If an O-ring or membrane has failed, the probe will identify the location or element within the individual PV. The process train is then taken off-line, and the PV is emptied of the elements and either the breached membrane is replaced, an O-ring or stub-tube adapter is replaced, the PV is reloaded with the elements, and the process train is placed back into operation. Desalting plants are monitored online with conductivity instrumentation; however, monitoring of NF plants with conductivity does not offer the sensitivity as perhaps a specific contaminant such as calcium, sulfate, color, or total dissolved solid water-quality parameter monitoring may offer.

Fiber Breakage and Module Repair Considerations. The versatility of membrane filtration with regard to fiber integrity has been documented and shows that in general membrane fibers do not typically break (Coffey, 1993). However, when fibers are found to have been breached, they are typically removed from use by an action referred to as *pinning* where a pin is inserted and glued into the end of a compromised fiber. Removals of fibers from service over time affect the instantaneous flux of the module, effectively increasing the velocity of filtrate through the module in which the fiber or fibers have been pinned. The permeate water quality is thus influenced by compromised fibers. Several different commercially available membrane fibers were recently evaluated for membrane integrity, with an annual fiber failure rate of 1 to 10 per million fibers, with an average annual fiber failure rate of one per 100,000 fibers to be considered representative for state-of-the-art membrane facilities (Gijsbertsen-Abrahamse, 2006). It was also found that broken fibers were not randomly distributed through the fiber bundle, rather in proximity of the potting material located in the top and bottom of the fiber bundle or pressure vessel. This finding had previously been documented by mechanical analysis of fiber integrity (Childress, 2005). When a fiber breakage is detected, the module can be repaired by isolating each individually broken fiber and making the necessary repair or replacing the broken fiber.

MASS TRANSPORT AND SEPARATION

For an isothermal process, the total driving force $F_{\text{total},i}$ for the transport of component i across the membrane can be expressed as the sum of contributions from an electrical potential, a concentration gradient (assuming activity coefficients equal to one), and a pressure gradient.

$$F_{\text{total},i} = \frac{R_g T}{\delta_m} \frac{\Delta c_i}{c_i} + \frac{z_i F}{\delta_m} \Delta \phi + \frac{v_i}{\delta_m} \Delta p \quad (11-4)$$

Different driving forces typically come into play in transporting solutes, colloids, larger particles, and water across the membrane. Summing flux values for individual components of a raw water (e.g., Na^+ , Cl^- , and H_2O) gives J_p , a weighted sum of a minimum number of driving forces F_k affecting all of the components. This sum is mathematically described by the Onsager relationship (Onsager, 1931) as

$$J_i = \sum_{k=1}^n L_{ik} F_k \quad (11-5)$$

Each phenomenological coefficient L_{ik} relates the flux of component i to force F . When one driving force dominates mass transport across the membrane, Eq. 11-4 can be simplified in conjunction with the Onsager relationship to obtain expressions for the transport of water or solutes in a pressure-driven or electrically driven membrane process. Thus, these two expressions are the basis for describing a variety of membrane processes. For example, in electrodialysis, the last term in Eq. 11-4 is negligible and expressions can be derived for the transport of solute across the electrodialysis membrane. This issue will be taken up in a later consideration of principles of separation in electrodialysis. First, however, some simplifications allow descriptions of performance for pressure-driven membrane processes such as microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO).

Mass Transport Considerations in Pressure-Driven Membrane Processes

Mathematical Models. If pressure is the only driving force, as in UF and MF, Eqs. 11-4 and 11-5 reduce to a Darcy-type expression for the flux of water across the membrane.

$$J = \frac{\Delta p}{\mu R_m} \quad (11-6)$$

where Δp is the pressure drop across the membrane (the transmembrane pressure drop or TMP), μ is the absolute viscosity (of the water), and R_m is the hydraulic resistance of the clean membrane with dimensions of reciprocal length. In this case, there is a single phenomenological coefficient L_{11} , which by comparison of Eqs. 11-5 and 11-6, is seen to be equal to $(\mu R_m)^{-1}$. This expression is similar in form to the Kedem-Katchalsky equation commonly derived from irreversible thermodynamics to describe solute transport across reverse osmosis membranes. However, in this case, the flux of solute and the buildup of an osmotic pressure across the membrane must be accounted for. If the flux J of permeate is much greater than the flux J_s of solute, then such a derivation leads to the following result:

$$J \approx \left(\frac{L_p}{V_w} \right) (\Delta p - \sigma \Delta \Pi) \quad (11-7)$$

where L_v is a phenomenological coefficient, V_w is the molar volume of water, σ is the reflection coefficient (derived as the ratio of two phenomenological coefficients), and $\Delta\Pi$ is the difference in osmotic pressure across the membrane. Empirically, permeate flux is calculated from Eq. 11-7 as a function of the transmembrane pressure, the osmotic pressure, and two empirical constants corresponding to L_v/V_w and σ . By analogy, Eq. 11-6 may be modified directly to account for the reduction in the net transmembrane pressure due to the effects of osmotic pressure.

$$J = \frac{(\Delta p - \sigma_k \Delta \Pi)}{\mu R_m} \quad (11-8)$$

Thus, permeate flux across a clean membrane is not predicted to occur until the transmembrane pressure Δp exceeds the difference in osmotic pressure across the membrane. The osmotic pressure of a solute is inversely proportional to its molecular weight. Larger macromolecules, colloids, and particles produce little osmotic pressure. As a result, the correction for osmotic pressure is negligible for pressure-driven processes such as MF or UF that reject only these larger species.

Example 11-1 Determination of Hydraulic Resistance Coefficient

The membrane hydraulic resistance coefficient can be calculated from laboratory experiments. The flux of a new membrane can be determined by filtering clean, deionized distilled water for a given water temperature and pressure. One UF membrane's flux was determined by laboratory procedure to be 1700 L/m²-hour (1000 gal/ft²-day) at 20°C and 70 kPa (10 psi or 70,000 N/m²). The viscosity of water at 25°C is about 0.89×10^{-3} kg/m-s (51.7 lb/ft-day) (see Appendix D).

Solution Rearrangement of Eq. 11-6 provides

$$R_m = \frac{\Delta p}{\mu J}$$

$$R_m = \frac{(70 \text{ kPa}) \left[\frac{10^5 (\text{kg}/\text{sec}^2 - \text{m})}{100 \text{ kPa}} \right] \left[\frac{3600 \text{ sec}}{\text{hour}} \right] \left[\frac{1000 \text{ L}}{\text{m}^3} \right]}{(0.89 \times 10^{-3} \text{ kg}/\text{m} - \text{s}) \left[\frac{1170 \text{ gal}}{\text{m}^2 - \text{hr}} \right]}$$

$$R_m = 1.7 \times 10^{11} \text{ m}^{-1} (5.1 \times 10^{10} \text{ ft}^{-1}) \blacktriangle$$

Concentration Polarization. Osmotic pressure is one of many phenomena that may reduce permeate flux as the result of the rejection of materials by the membrane. Reductions in permeate flux due to the accumulation of materials on, in, or near the membrane are referred to as *membrane fouling*. As water moves across the membrane, it draws solutes and particles toward the membrane. If these materials do not pass through the membrane, they may begin to accumulate on or near its surface, leading to the formation of additional layers of material through which water must pass. Particles may form cakes on the membrane surface, and macromolecules may form gel layers. Virtually all species achieve higher concentrations near the membrane surface in a flowing concentration boundary layer referred to as the concentration-polarization layer. Concentration-polarization is often a precursor to cake or gel formation. In addition, materials may precipitate or adsorb on or in the membrane leading to reductions in permeate flux that may be difficult to reverse. Elevated concentrations near the membrane resulting from the

rejection of and subsequent concentration-polarization of these materials tend to exacerbate precipitative or adsorptive membrane fouling.

Permeate flux decline can be described mathematically by generalizing Eq. 11-8 to the case where resistance to permeate flux is produced by both the membrane and by materials accumulated near, on, and in the membrane. These layers are assumed to act in series to present additional resistance to permeation, designated as R_c and R_{cp} , respectively. These components of resistance vary as a function of the composition of materials rejected and thickness of each layer. The resulting expression for permeate flux is

$$J = \frac{(\Delta p - \sigma_k \Delta \Pi)}{\mu [R_m(t) + R_c(\delta_c(t), \dots) + R_{cp}(k, J)]} \quad (11-9)$$

where δ_c is the thickness of the cake (or gel) layer and k is the mass transport coefficient (MTC) of the material in the concentration-polarization layer. The resistance terms are all functions of time and are related to the hydrodynamics of the membrane system and the raw-water quality. Adsorption or precipitation of materials within the membrane matrix as well as compaction of the membrane may lead to an increase in the membrane resistance $R_{m(t)}$ over time. The resistance of the cake R_c can be expressed as the product of the specific resistance of the material that forms the cake \hat{R}_c and the cake thickness δ_c . From the Kozeny equation, the specific resistance of an incompressible cake composed of uniform particles can be calculated as

$$\hat{R}_c = \frac{180(1 - \epsilon_c)^2}{d_p^2 \epsilon_c^3} \quad (11-10)$$

where ϵ_c is the porosity of the cake, and d_p is the diameter of particles deposited. This expression predicts that resistance to permeation by a deposited cake should increase as the particles comprising the cake decrease in size. The resistance produced by RO and NF membranes is likely to be large in comparison with the resistance of deposited colloidal materials or cakes. However, gel layers of macromolecular materials may produce significant resistance. Cake resistance may also be small in comparison with the resistance of a UF or MF membrane if the particles deposited in the cake are large compared with the effective pore size of the membrane. For feed streams containing large particles, permeate flux may be relatively independent of the concentration of particles. The morphology of the cake appears to be an important variable in particle filtration, and cake porosity appears to vary as a function of the hydrodynamics of the membrane module as well as the size distribution of the particles. By comparison with the resistance produced by cake or gel layers, resistance from the concentration-polarization layer is typically small.

Equations 11-6 through 11-9 at first appear to predict that permeate flux increases indefinitely with increasing transmembrane pressure (TMP). However, it is frequently observed that as pressure increases, a maximum permeate flux is eventually attained and permeate flux becomes pressure-independent. This maximum is usually interpreted as a mass transport-limited flux. Under conditions of mass transport-limited flux, an increase in pressure that would otherwise increase the flow of permeate across the membrane is instantaneously balanced by an increased accumulation of permeate-limiting materials near the membrane. In other words, increases in the resistance terms in the denominator of Eqs. 11-7 through 11-9 offset the increase in Δp in the numerator.

For a given TMP or under conditions of mass transfer-limited permeate flux, the accumulation of materials near the membrane can be envisioned as a balance between advection of materials toward the membrane due to permeation and back-diffusion that occurs as a concentration gradient builds up near the membrane. Assuming, therefore, a constant

permeation rate and concentration-polarization layer with axial distance, mass balance on the concentration-polarization layer yields

$$-D \frac{\partial c}{\partial y} = Jc \quad (11-11)$$

where c is the concentration of the species subject to concentration-polarization, D is the diffusivity of this species, and y is the distance with the boundary layer such that $c = c_{\text{mem}}$ at $y = 0$ and $c = c_{\text{bulk}}$ at $y = \delta_{cp}$. Integrating this expression over the thickness δ_{cp} of the concentration-polarization layer results in the following expression for the concentration of solute at the membrane surface c_{mem} :

$$c_{\text{mem}} = c_{\text{bulk}} \exp\left(\frac{\delta_{cp}}{D} J\right) \quad (11-12)$$

For constant operating conditions, the exponential term in Eq. 11-12 can be taken as a constant, referred to as the *polarization factor* (PF). Thus, concentrations of rejected materials at the membrane surface exceed the local bulk concentration by a factor of PF ; sometimes estimated as an exponential function of the recovery r , such that $PF = \exp(kr)$. The semiempirical constant k typically takes on values of 0.6 to 0.9 for commercially available RO modules.

When permeate flux is mass transfer limited, Eq. 11-12 can be rearranged to describe the limiting permeate flux J as a function of the bulk concentration c_{bulk} , the limiting concentration at the membrane c_{mem} , the diffusion coefficient for the solute, and the concentration-polarization layer thickness.

$$J = \frac{D}{\delta_{cp}} \ln\left(\frac{c_{\text{mem}}}{c_{\text{bulk}}}\right) \quad (11-13)$$

The ratio of diffusivity to concentration-polarization layer thickness in this “film theory” model defines a mass-transfer coefficient k .

$$k = \frac{D}{\delta_{cp}} \quad (11-14)$$

The thickness of the concentration-polarization layer is a function of the hydrodynamics of the membrane module. For example, for a module with tangential flow across the membrane surface, a higher crossflow velocity tends to decrease the thickness of the concentration-polarization layer if Brownian diffusion is the only mechanism of back transport ($D = D_B$). In this case, the mass transfer coefficient can be calculated directly using correlations for the Sherwood number Sh of the form

$$Sh = \frac{kd_h}{D_B} = A(Re)^\alpha (Sc)^\beta \left(\frac{d_h}{L}\right)^\omega \quad (11-15)$$

where

$$Re = \frac{u_{\text{ave}} d_h}{\nu}$$

$$Sc = \frac{\nu}{D_B}$$

ν = kinematic viscosity

u_{ave} = average crossflow velocity

d_h = hydraulic diameter of the membrane element (e.g., diameter of the hollow fiber)

A , α , β , and ω = adjustable parameters

The Graetz-Leveque correlation, which is valid for laminar flow when the velocity field is fully developed and the concentration boundary layer is not fully developed, is often used to estimate the mass transfer coefficient.

$$Sh = 1.86(Re)^{0.33}(Sc)^{0.33}\left(\frac{d_h}{L}\right)^{0.33} \quad (11-16)$$

The Linton and Sherwood correlation can be used to calculate the mass transfer coefficient in turbulent flow, which may occur in tubular membranes.

$$Sh = 0.023(Re)^{0.83}(Sc)^{0.33} \quad (11-17)$$

Concentration-Polarization and Precipitative Fouling. As one consequence of concentration-polarization in RO and NF membranes, salts may more readily precipitate as a scale on membranes. The average concentrations of scale-forming species rejected by NF or RO membranes in the bulk flow inevitably increase as water permeating through the membrane is removed from the salt-bearing solution. Concentration-polarization further elevates rejected salt concentrations near the membrane and exacerbates the tendency to form a scale.

Principles of solubility and precipitation are covered in Chap. 3. When the reaction quotient (Q) exceeds the solubility constant (K_{s0}), the metal will precipitate and scale membranes. For example, metals such as calcium, magnesium, and iron most commonly precipitate as hydroxide, carbonate, or sulfate scales. In evaluation of whether a metal will precipitate, one must account for the salt concentration (ionic strength) and its effect on activity coefficients. For example, scaling from the precipitation of $\text{CaSO}_{4(s)}$ (gypsum) can be a problem. This occurs for any molar concentration combination of calcium and sulfate such that Q exceeds K_{s0} divided by the product of the two activity coefficients as shown in the following equation:

$$Q = [\text{Ca}^{2+}][\text{SO}_4^{2-}]$$

$$\text{Precipitation Occurs if } Q > \frac{K_{s0}}{\gamma_{\text{Ca}}\gamma_{\text{SO}_4}} \quad (11-18)$$

As water flows across the feed side of the membrane, the dissolved solids are rejected by the membrane and concentrate within the channel. The average (bulk) concentration of the rejected salts (for example, the cation) in the concentrate stream c_r exiting a membrane module increases over the feed concentration c_f as the recovery r and global rejection R increase. This is expressed in equation 11-19.

$$c_r = c_f \frac{1-r(1-R)}{(1-r)} \quad (11-19)$$

The salt may precipitate when the ratio of the product of ion concentrations in the concentrate (the right-hand side of Eq. 11-19 after substituting $[A]_r$ and $[B]_r$ calculated from the feed concentration) to the solubility product K_{s0} is greater than 1. However, concentration-polarization further increases the ion product at the membrane surface since $c_{\text{mem}} = c_{\text{bulk}} * \text{PF} = c_r * \text{PF}$. Thus, taking the case of $x = y = 1$ (calcium sulfate, for example), the theoretical conditions to avoid scale formation are given by

$$(\text{PF})^2 \left\{ \frac{(1-r)(1-R)}{(1-r)} \right\}^2 (B)_f (A)_f < K_{s0} \quad (11-20)$$

Transport of Colloids and Particles

The preceding discussion clearly suggests that the diffusivity of contaminants in water plays an important role in determining the permeate flux. However, Brownian diffusion alone does not adequately describe the transport of particulate and colloidal species near the membrane. The transport of colloidal and particulate species is of greatest significance in MF and UF systems, which are designed to remove these species. In a flowing suspension, particles may collide with one another and produce random rotary and translational motions that, on the average, result in a net particle migration from regions of high concentration and shear (near the membrane) to regions of lower concentration and shear (Davis, 1993). Building on the work of Eckstein and coworkers (Eckstein et al., 1977), Leighton and Acrivos (1987) proposed the following expression for the shear-induced diffusion coefficient. The equation was reported as valid up to particle volume fractions (the concentration of particle volume per volume of water) of $\Phi = 0.5$.

$$D_{SH} = a_p^2 \omega \hat{D}_{sh}(\Phi) \quad (11-21)$$

where a_p is the particle radius, ω is the shear rate, and D_{sh} is a dimensionless function of Φ estimated for suspensions of rigid spheres as

$$\hat{D}_{sh} = 0.33\Phi^2(1+0.5e^{8.8\Phi}) \quad (11-22)$$

Brownian diffusion is more important for smaller species such as solutes and small macromolecules, while shear-induced diffusion is increasingly important for larger particles. Contaminants encountered in water treatment typically span several orders of magnitude in hydrodynamic size, and so require consideration of both Brownian and shear-induced diffusion in estimating concentration-polarization and permeate flux. The sum of Brownian and shear-induced diffusivity D can be rewritten (Sethi and Wiesner, 1997) as

$$D = \frac{kT}{6\pi\mu_o r_p} + \frac{\tau_{wall}}{\mu_o \eta(\Phi)} r_p^2 \hat{D}_{sh}(\Phi) \quad 11-23$$

where τ_{wall} is the shear stress at the membrane wall, μ_o is the absolute viscosity of the water at low particle volume fractions, and $\eta(\Phi)$ is the relative viscosity, which varies with volume fraction. Simultaneous consideration of Brownian and shear-induced diffusivity yields a minimum in particle back-transport for particles in the size range of several tenths of a micron and a corresponding minimum in permeate flux. The sum of the Brownian and shear-induced diffusion coefficients exhibits a minimum for particles approximately 0.1 μm in size for flow conditions typical of hollow fiber or SW modules, as shown in Fig. 11-17. Consequently, the relatively low mass transfer coefficients of species in this unfavorable size range are predicted to produce minimum permeate flux, while species either smaller or larger than this intermediate size are predicted to produce higher permeate fluxes. Until recently, only indirect experimental evidence supported this hypothesized minimum in back-transport as interpreted from permeate flux data (Fane, 1984; Wiesner, Clark, and Mallevialle, 1989; Lahoussine-Turcaud et al., 1990). However, one report gave the first direct experimental confirmation of a minimum back-transport based on measurements of particle residence time distributions (Chellam and Wiesner, 1997).

Diffusive transport is significant near the membrane where boundary layers may develop. Differential transport of smaller species in the bulk flow (outside the boundary layers) is generally negligible. However, in laminar crossflow filtration, the transport of larger particles from the bulk into the boundary layer may be affected by interactions between particles and the fluid flow relatively far from the membrane surface. In particular, inertial lift arising from nonlinear interactions of particles with the surrounding flow field may offset the drag force on particles associated with the flow of permeate across the membrane. This effect

FIGURE 11-17 Brownian and shear-induced diffusivity as a function of particle size for conditions typical of hollow fiber UF membranes.

may occur where the particle Reynolds number becomes important (as it does with large particle sizes or fast crossflow velocities). For fast laminar flows ($Re \gg 1$), as is typical in membrane filtration, the maximum value of the lift velocity in a clean channel is given by

$$u_{lo} = \frac{0.036\rho a_p^3 \gamma_o^2}{\mu_o} \quad (11-24)$$

where ω_o is the shear rate at the membrane (in the absence of a cake layer) and ρ is the fluid density. Particle transport into the boundary layer is favored when the magnitude of the permeation velocity exceeds that of the inertial lift velocity (Belfort, Davis, and Zydney, 1994).

In addition to these processes governing the transport of particulate species to and from boundary layers, rolling or sliding of particles along the membrane surface due to convection must also be considered. In one approach (e.g., Leonard and Vassilieff, 1984; Davis and Birdsell, 1987) particles deposited as a cake and considered as a continuum may, under sufficient shear, begin to flow tangentially along the membrane surface toward the filter exit. An alternative approach (e.g., O'Neill, 1968; Blake et al., 1992; Stamatakis and Tien, 1993) considers the force and torque balances on a single particle on the membrane or cake surface. These balances are used to develop criteria for an estimate of whether the particle will adhere to the surface.

Mechanisms of Separation. Pressure-driven membrane processes may differ from one another substantially in the mechanisms by which they achieve separation, also referred to as rejection. In MF and UF, size exclusion is the primary mechanism of separation.

Rejection of contaminants by RO membranes is largely a function of the relative chemical affinity of the contaminant for the membrane vis-à-vis water. NF and UF membranes often represent intermediate cases that achieve rejection by combinations of mechanisms.

Rejection is usually defined as minus the ratio of the permeate- and feed stream concentration. This *global* rejection R is calculated as

$$R = 1 - \left(\frac{c_p}{c_f} \right) \quad (11-25)$$

where c_p and c_f are the permeate and feed concentrations. Occasionally, as in bench-scale test modules and associated scale-up, analysis focuses on the inherent *local* rejection R_{local} of a given membrane for a specific contaminant. The evaluation must account for local changes in rejection that occur with increases in the bulk concentration of a material as flow proceeds along the membrane (x -coordinate) due to the permeation of water through the membrane. In addition, rejected materials tend to accumulate near the membrane compared with the bulk flow due to concentration-polarization. Thus, the effective rejection of materials by a membrane may be very different from that calculated on the basis of the average feed and permeate concentrations. Local rejection is a function of the concentrations directly on either side of the membrane at a specific location and is defined as

$$R_{\text{local}}(x) = 1 - \left(\frac{c_p(x)}{c_{\text{mem}}(x)} \right) \quad (11-26)$$

where c_{mem} is the concentration at the membrane surface calculated from the bulk concentration at a given location within the module such that $c_{\text{mem}}(x) = (PF)c_{\text{bulk}}(x)$. If a mass balance is performed over a membrane module operating in tangential flow, the following equation is derived relating the global rejection to the apparent rejection:

$$R = 1 - \left(\frac{c_p}{c_f} \right) = 1 - \frac{1 - (1-r)^{(1-R_{\text{local}})PF}}{r} \quad (11-27)$$

where r is the single-pass recovery of the module and the local rejection is assumed constant along the membrane. This latter assumption is intimately related to the mechanism of rejection.

Mechanical Sieving at the Membrane Surface. Membranes intended specifically to remove or separate particles and colloidal materials, such as microfiltration and ultrafiltration membranes, reject materials largely by mechanical sieving. However, electrostatic interactions, dispersion forces, and hydrophobic bonding may significantly affect the rejection of materials with dimensions similar to the pore sizes in UF or MF membranes. These considerations tend to be more important for separations involving larger macromolecules such as humic and fulvic acids, where charge, adsorptive affinity to the membrane, and hydrodynamic size are interrelated.

A quantitative analysis of mechanical sieving (or steric rejection) was first presented by Ferry (1936). Assuming pores of cylindrical geometry and spherical particles, he derived an expression for the fraction x of particles passing through a pore of radius a . For particles with radii equal to or greater than the pore radius, perfect rejection is predicted. For particles much smaller than the pore, no significant rejection occurs. Only particles with radii slightly smaller than pore radius show nontrivial rejection behavior. This expression was subsequently modified (Zeman, 1981) to account for the lag velocity of particles with respect to the fluid permeating through the membrane pore. The rejection of particles by a

membrane $(1 - p)$ can be estimated using this expression, as a function of the nondimensionalized particle radius $\lambda = a_p/a_{\text{pore}}$ as

$$x = \begin{cases} (1 - \lambda^2)[2 - (1 - \lambda)^2] \Gamma & \lambda \leq 1 \\ 1 & \lambda > 1 \end{cases} \quad (11-28)$$

where Γ is the lag coefficient, empirically estimated by Zeman and Wales (Zeman, 1981) as

$$\Gamma = e^{-0.7146\lambda^2} \quad (11-29)$$

Rigorously derived, $(1 - p)$ corresponds to the local rejection R_{local} of the membrane. Measurements of apparent rejection can be used to calculate a value p^* that theoretically corresponds to the product of the polarization factor PF and the particle passage ψ . Removal of materials in deposited cake or gel layers may further alter the apparent rejection of the membrane. Further modifications can account for electrostatic repulsion and dispersion forces near the pore wall (Matsuura and Sourirajan, 1983). A more rigorous treatment would incorporate drag on particles transported through membrane pores by advection and diffusion (Deen, 1987) and the diffusion and convection of flexible macromolecules through cylindrical pores of molecular dimensions (Davison and Deen, 198). One approach extends the physical sieving model for particle removal to describe the rejection of macromolecular compounds such as humic materials by substituting each molecule's hydrodynamic radius for the particle radius. Empirical constants in an expression for the molecule's hydrodynamic radius are then manipulated to fit a given data set. For larger molecular weight materials, the hydrodynamic radius can often be correlated with the compound's molecular weight \bar{M} . These correlations are typically of the form

$$a_p = Z_1(\bar{M})^{Z_2} \quad (11-30)$$

where Z_1 and Z_2 are empirical constants. The constant Z_2 contains information on molecule geometry. For a perfectly spherical molecule, Z_2 takes on its theoretical minimum value of $1/3$. The theoretical maximum value of 1 for Z_2 corresponds to a linear molecule. Z_2 may take on values outside its theoretical range when Z_1 and Z_2 are treated as fitting constants within the context of the sieving model.

Thus, rejection of organic compounds is predicted to increase with molecular weight. Such behavior has been observed in processes removing larger molecular weight fractions of natural organic matter (NOM) by ultrafiltration and nanofiltration membranes (e.g., Taylor et al., 1987, 1988).

While the membrane itself determines the initial removal of materials and serves as an absolute barrier, the rejection characteristics of the membrane system may change over time as materials are deposited on the membrane surface. This concept is exploited in the application of "dynamic" membranes, which formed effective barriers from materials deposited on a porous support that are periodically removed and replenished. Mathematical treatment of this process has borrowed concepts from packed-bed filtration. Suspended colloidal materials transported toward the cake with the permeating water may be removed at the cake surface by simple sieving. Particles entering the cake may be removed by previously deposited particles that form a type of micropacked bed. Removal within the cake may be due to simple interception of mobile colloids, if the streamline they follow brings them in contact with a previously deposited (immobile) colloid. Gravity and Brownian motion may cause particles to deviate from their streamlines, helping to bring particles in contact with the immobile particles composing the cake. The previously deposited particles are termed *collectors* in the packed-bed filtration literature.

Solute Transport and Rejection. The solution diffusion model proposed by Lonsdale, Merten, and Riley (1965) and Merten (1966) describes solute and solvent transport across membranes in terms of the relative affinities of these components for the membrane and their diffusive transport within the membrane "phase." Rejection of a given solute is therefore a function of the degree to which it partitions into the membrane and its diffusivity within the membrane. The driving forces for transport are the differences in chemical potential across the membrane due to differences in concentration and pressure.

A basic diagram representing osmosis and reverse osmosis cells is shown in Fig. 11-18. Osmosis is a special case of diffusion in which the molecules are water and the concentration gradient occurs across a semipermeable membrane. The semipermeable membrane allows the passage of water, but not ions (e.g., Na^+ , Ca^{2+} , Cl^-) or larger molecules (e.g., NOM). Diffusion and osmosis are thermodynamically favorable and will continue until equilibrium is reached. Osmosis can be slowed, stopped, or even reversed if sufficient pressure is applied to the membrane from the concentrated side of the membrane. Reverse osmosis occurs when the water is moved across the membrane against the concentration gradient, from lower concentration to higher concentration.

To illustrate, imagine a semipermeable membrane with freshwater on one side and a concentrated aqueous solution on the other side. If normal osmosis takes place, the freshwater

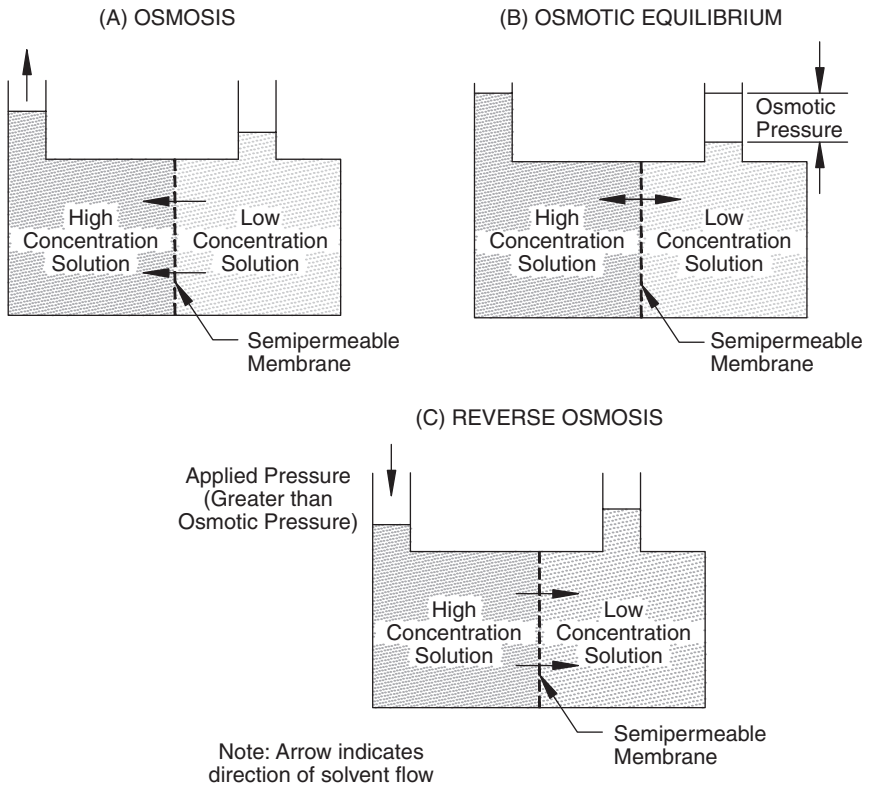

FIGURE 11-18 The principles of osmotic flow.

will cross the membrane to dilute the concentrated solution. In reverse osmosis, pressure is exerted on the side with the concentrated solution to force the water molecules across the membrane to the freshwater side. The transport of water occurs by convection and is dependent on pressure, while the transport of solutes is independent of pressure. Thermodynamically, the osmotic pressure is defined as

$$\Pi = -\frac{R_g T}{V_w} \ln(x_w) \quad (11-31)$$

with the osmotic pressure Π , the molar volume of water V_w , the mole fraction of water x_w , and the ideal gas constant R_g . In dilute solutions, the osmotic pressure can be estimated using van't Hoff's law, which was developed using the ideal gas law.

$$\Pi = -\frac{n_s}{V} R_g T \quad \text{or} \quad \Pi = C R_g T \quad (11-32)$$

with the total amount of solutes in solution n_s [moles], total concentration of solutes C (moles/L), and the volume of solvent V . Considering the dissociation of ions in solution, van't Hoff's equation is typically shown as

$$\Pi = i \Phi C R_g T \quad (11-33)$$

with i representing the dissociation constant, which is equal to the number of ions and molecules per mole of solute produced by the dissolution of the solute, and with ϕ representing a correction factor for non-ideal behavior. As a general rule of thumb the osmotic pressure of brackish water can be estimated by estimating that for every 100 mg/L of total dissolved solids that is present in the feedwaters, 7 kPa (1 psi) of osmotic pressure will be present within the membrane feed channel.

$$\Pi = (\text{TDS, mg/L}) \frac{1 \text{ psi}}{100 \text{ mg/L} - \text{TDS}} \quad (11-34)$$

For a general estimate of the osmotic pressure of seawater, it can be assumed that an NaCl solution of equal total dissolved solids concentration is approximated as (Fritzmman et al., 2007)

$$\Pi = \frac{8 \text{ bar}}{\text{wt}\%_{\text{NaCl}}} \quad (11-35)$$

It should be noted that the actual osmotic pressure of seawater has been shown to be approximately 10 percent less than a solution of sodium chloride that is equal to the total dissolved solids concentration due to the presence of higher molar mass species present in seawater (AWWA, 1999). This phenomenon is not as apparent in brackish waters as in seawater due to differences in composition. Regardless, the permeate water quality is thus a function of the diffusion of salt across the membrane and its associated osmotic pressure gradient, the transmembrane pressure, water recovery, and mass transfer of solute and water with respect to membrane material.

Example 11-2 Determination of Osmotic Pressure by Calculation

The osmotic pressure of a solution can be determined by calculation. Calculate the osmotic pressure of a 7500 mg/L solution of sodium chloride at a temperature of 19°C assuming an osmotic coefficient of 0.95.

Solution Determine the osmotic pressure using van't Hoff's equation Eq. (11-33).

$$\Pi = i\Phi CR_g T$$

$$\Pi = \left(\frac{2 \text{ mols ion}}{\text{mols}} \right) (0.95) \left(\frac{7500 \text{ mg}}{\text{L}} \right) \left(\frac{0.08314 \text{ LL} \cdot \text{bar}}{\text{K} \cdot \text{mols}} \right) (292\text{K}) \left(\frac{1000 \text{ mg}}{\text{g}} \right) \left(\frac{58.4 \text{ g}}{\text{mols}} \right)$$

$$\Pi = 5.92 \text{ bar (85.9 psi)}$$

Discussion Osmotic coefficients for sodium chloride range from approximately 0.94 to 1.04 for the differing ranges of seawater globally. Since the osmotic pressure is a function of the mole fraction of water in the system, and solutes reduce the concentration of water, the effect of multiple solutes cumulatively reduces the mole fraction of water. Solutes that dissociate will have an additional stoichiometric effect on the mole fraction of water. Reported values for the osmotic pressure of seawater tend to be lower than calculated values because seawater is composed of components having a higher molecular weight than that of sodium chloride.

The concentration of the water passing through the RO membrane decreases as pressure increases. In the case of brackish water systems, a general rule of thumb is that for every 100 mg/L of total dissolved solids that is present in the feedwaters, 7 kPa (1 psi) of osmotic pressure will be present within the membrane feed channel. The permeate water quality is thus a function of diffusion of salt across the membrane and its associated osmotic pressure gradient, the transmembrane pressure, water recovery, and mass transfer of solute and water with respect to membrane material. ▲

Thus far, the focus has been on the transport of water across membranes and the role of materials in water in potentially reducing the permeate flux. However, expressions for the flux of solutes across membranes can also be derived from very general principles beginning with Eqs. 11-4 and 11-5. The ratio of solute to water flux J_s/J_w yields the permeate concentration c_p , and therefore, the rejection as calculated by Eq. 11-25. Models for solute rejection tend to differ in the degree of mechanistic detail they offer or the specific mechanisms they invoke. However, where solutes can enter the membrane matrix, the underlying assumption is usually that separation of solutes occurs due to the relative rates of transport across the membrane rather than by size exclusion, as is typically assumed in the rejection of macromolecules, colloids, and particles. An important implication of this distinction is that rejection of solutes depends on the feed (or reject) concentration while rejection due to size exclusion is independent of feed concentration. The flux of water is given as

$$J_w = -\frac{D_w c_{w,\text{mem}}}{R_g T} \frac{d\mu_w}{dz} \approx -\frac{D_w c_{w,\text{mem}}}{R_g T} \frac{d\mu_w}{\delta_m} \quad (11-36)$$

Note that the form of Eq. 11-36 gives the permeate flux in proportion to a driving force (chemical potential), concentration, and mobility (as expressed by diffusivity). Substituting the Lewis equation for osmotic pressure, the following equation is derived for water flux:

$$J_w = -K_w \frac{(\Delta p - \Delta \Pi_w)}{\delta_m} \quad (11-37)$$

where the specific hydraulic permeability K_w is a function of the diffusivity D_w , the concentration $C_{w,\text{mem}}$ of the water in the membrane, and the molar volume of water V_w such that $K_w = \frac{D_w c_{w,\text{mem}} V_w}{RT}$. Comparison of this result with Eq. 11-7 shows a similar result to that obtained

from irreversible thermodynamics. Indeed, the models are identical, given the underlying interpretations of the phenomenological coefficients.

If water and solute transport are not coupled ($\sigma = 1$), the flux of solute J_s is given as

$$J_s = -D_s k_s \frac{(c_{\text{mem}} - c_p)}{l} \quad (11-38)$$

where k_s is the distribution coefficient that describes the relative affinity of the solvent for the membrane. Similar to the result for permeate flux, this equation expresses the solute flux as a function of a driving force (concentration difference across the membrane), mobility (diffusivity), and concentration. Solute flux is predicted to be independent of the transmembrane pressure drop Δp . Therefore, increases in Δp result in an increase in J_w and in local rejection, since

$$R_{\text{local}}(x) = 1 - \left[\frac{\left(\frac{J_s(x)}{J_w(x)} \right)}{c_{\text{mem}}(x)} \right] \quad (11-39)$$

This model has been generalized (Sherwood, 1967) to include advective transport through membrane pores as well as diffusion. This modification leads to the following expression for local rejection by a membrane:

$$R_{\text{local}} = \left[1 + \left(\frac{D_s K_d}{K_w} \right) \left(\frac{1}{\Delta p - \Delta \Pi} \right) + \left(\frac{K_{pf}}{K_w} \right) \left(\frac{\Delta p}{\Delta p - \Delta \Pi} \right) \right]^{-1} \quad (11-40)$$

where K_{pf} is an additional fitting constant describing pore flow through the membrane. Equation 11-40 predicts increasing local (and therefore global) rejection with increasing pressure, but only to an asymptotically limiting value. In practice, higher operating pressures have been observed to increase global rejection as described by the following empirical equation (Sourirajan, 1970):

$$R = \frac{z_1 \Delta p}{(z_2 \Delta p + 1)} \quad (11-41)$$

where z_1 and z_2 are empirically determined constants.

One variation on such a generalized solution-diffusion model, the preferential sorption-capillary flow model, involves a mechanistic interpretation of transport within the membrane matrix based on differential influence on a layer of water by interfacial processes near polymer surfaces. This layer may exist due to (1) repulsion of ions by membrane materials of low dielectric constant, (2) the excessive energy required to strip ions of their hydration spheres as they move from the bulk water to the water-membrane interface, or (3) the hydrophilic nature of the membrane surface, which actively coordinates and orders water near the membrane surface. Transport of the solute across the membrane within this layer is impeded due to the rise in free energies required to move the solute through a progressively more ordered fluid. The solute is assumed to move through the membrane by diffusion, advection, or both (Sourirajan, 1970). Ions with smaller hydrated radii may be able to diffuse through the adsorbed water film or may be convected through pores.

Charges on membrane surfaces can play a significant role in the rejection of ionic solutes. Although these effects are most important in electrically driven membrane separations, they may also play a role in pressure-driven processes. Charged functional groups on membranes attract ions of opposite charge (counterions). This effect in combination with a deficit of like-charged ions (co-ions) in the membrane results in a so-called Donnan potential. Although

co-ions are largely unable to enter the membrane, water can pass through under pressure. The accumulation of co-ions in the membrane concentrate is accompanied by an accumulation of counterions as well, due to the need to preserve electroneutrality in the solution. By this mechanism, membrane rejection is predicted to increase with increasing membrane charge and with co-ion valence (Dresner, 1972). Similarly, for membranes that are semi-permeable to some ionic species, the requirement for electroneutrality in the concentrates and permeates may lead to significant modification of rejection characteristics in the presence of mixed solutes. For example, as a NF membrane rejects calcium, higher rejections of monovalent anions such as nitrate or chloride may also occur. Varying the concentration of competing anions in the concentrate can affect anion rejection by NF membranes. For example, increasing sulfate concentration increases sulfate rejection and decreases nitrate and chloride relative to levels in single-solute solutions (Rautenbach, 1990).

Mass Transport and Process Considerations in ED and EDR

Principles of Mass Transport. In electrodialysis, the driving force for separation is a gradient in electrical potential. An ED system applies an electrical potential across charged ion-exchange membranes, and cations or anions are differentially transported across the membrane and removed from the feed flow. A stack of cation- and anion-selective membranes can remove ionic species in applications such as desalination of brackish water.

In the absence of a pressure drop across the membrane, the driving force for transport of ions across an ion selective membrane becomes

$$F_{tot,i} = \frac{R_g T}{\delta_m} \frac{\Delta c_i}{c_i} + \frac{z_i F}{\delta_m} \Delta \phi \quad (11-42)$$

Assuming ion flux proportional to this driving force and to ion concentration and mobility, the following equation is derived for cation transport across a cation-exchange membrane:

$$J_+ = -U_+ c_+ \left(\frac{R_g T}{\delta_m} \frac{\Delta c_+}{c_+} + \frac{z_+ F}{\delta_m} \Delta \phi \right) \quad (11-43)$$

The fraction of current I carried by the flux of cations FJ_+ is defined as the cation transport number t_+ .

$$t_+ = \frac{FJ_+}{I} \quad (11-44)$$

The flux of cations through a cation exchange membrane under the driving force of an electric potential can then be rewritten as

$$J_+ = \frac{t_+ I}{zF} \quad (11-45)$$

Increases in current are therefore predicted to induce increases in cation transport (or similarly anion transport). The electrical potential E required to produce a given current is calculated from Ohm's law.

$$E = IR_E \quad (11-46)$$

where R_E is the resistance of the total membrane stack. The resistance of the membrane stack can be considered as the sum of n cell pairs, each with a resistance R_{cell} such that

$$R_E = R_{cell} n \quad (11-47)$$

Resistance within each cell pair can be expressed in turn as the sum of resistances due to the anion exchange membrane R_{an} , the cation exchange membrane R_{cat} , the concentrate stream R_{con} , and the dialysate stream R_{dia} .

$$R_{cell} = R_{an} + R_{cat} + R_{con} + R_{dial} \quad (11-48)$$

Unfortunately, the increase in ion flux with current is limited by a theoretical maximum current required to transport all available ions. This maximum is a function of the ion concentration at the membrane surface and the concentration in bulk flows of concentrate and dialysate. Differential transport of cations across the membrane leads to the formation of boundary or concentration-polarization layers near either side of the membrane. On the side of the membrane where cations are depleted (the dialysate), concentrations are lower than the bulk concentration. On the concentrate side of the membrane, cation concentration is greater in the boundary layer than in the bulk flow. The flux of cations through the boundary layers can be calculated as a function of a transport number $t_{+,bl}$ for flux due to the applied potential and the concentration gradient. At equilibrium, cation flux through the membrane must equal the flux of cations through the boundary layer.

$$J_+ = \frac{t_+ I}{zF} = \frac{t_{+,bl} I}{zF} - D \frac{dc_+}{dy} \quad (11-49)$$

Integration of Eq. 11-49 with the boundary conditions $c_+ = c_{bulk}$ at $y = \delta_{cp}$ and $c_+ = c_{+,mem}$ at $y = 0$ yields the following equation:

$$c_{+,mem} = c_{+,bulk} \pm \frac{(t_+ - t_{+,bl})\delta_{cp}}{DzF} \quad (11-50)$$

The plus sign applies to calculations of concentrations on the concentrate side of the membrane, and the minus sign applies to calculations of the depletion of cations in the boundary layer near the membrane on the dialysate side. Analogous results are obtained for transport across anion-exchange membranes. The depletion of ions near the membrane leads to an increase in electrical resistance across the dialysate compartment R_{dial} , which increases power consumption and reduces efficiency. Rearranging Eq. 11-50 yields the following expression for the current density in the concentration-polarization layer on the dialysate side of the membrane:

$$I_{density} = \frac{DzF(c_{+,bulk} - c_{+,mem})}{(t_+ - t_{+,bl})\delta_{cp}} \quad (11-51)$$

The limiting case (maximum current) occurs when the current density is high enough to drive the cation concentration (or similarly the anion concentration) to zero on the dialysate side of the membrane. This limiting current density is then given as

$$I_{density,lim} = \frac{DzFc_{+,bulk}}{(t_+ - t_{+,bl})\delta_{cp}} \quad (11-52)$$

In a situation analogous to concentration-polarization in pressure-driven processes, the thickness of the polarization layer is function of the flow across the membrane. The cross flow can therefore be manipulated to a limited extent to optimize performance.

ED and EDR Processes. ED processes must work within polarization and scaling limitations like those in pressure-driven, diffusion-controlled membrane processes, because of ion concentrations at the membrane surfaces. However, polarization problems arise in ED processes due to the lack of ions at the surface. Ions arrive at a membrane surface

by electrical transport, diffusion, and convection, and they are transported through the membrane electrically. As ions are transported through the membrane, the demineralized stream-membrane interface becomes depleted of ions, causing an exponential increase in electrical resistance and current density. This process continues until polarization occurs, disassociating water into protons and hydroxide ions. This point is identified as the limiting current density. These problems have been reduced in ED applications by reversing module polarity every 15 to 20 min during plant applications. This process, known as electrodialysis reversal (EDR), has advantages of (1) reducing scaling potential, (2) breaking up fresh scale, (3) reducing microbiological growth on membrane surfaces, (4) reducing membrane cleaning frequency, and (5) cleaning electrodes with acid formed during anodic operation. EDR processes reportedly achieve slightly higher recoveries than NF or RO processes; this can become an economic advantage when removal of unionized solutes such as disinfection by-product formation potential or pathogens is not an issue.

The rate of ion removal in an electrochemical separation process is controlled by the feed-water characteristics, design parameters, and equipment selection. The water quality and temperature of the feed waters determine the system recovery and rate of mass transfer. Ion removal increases as temperature increases and as charge increases. System recovery is typically limited by precipitation of the least soluble salt, as in RO or NF systems. Design parameters include current, voltage, current efficiency, polarization, and finished water quality. As current or current density increases, the removal of ions also increases. Voltage is a function of the current, temperature, and ionic water quality. Current efficiency is determined by the efficiency of salt transfer. A 100 percent efficient process would transfer 1 g equivalent of salt for every 26.8 A hours. Polarization is controlled by limiting the allowable current density to 70 percent of the limiting current density. Finished water quality standards are set by design, within limits of back-diffusion. A high concentration gradient between the demineralized and concentrate streams leads to diffusion of ions from the concentrate to the demineralized stream. This effect, termed *leakage*, is controlled by limiting the concentration ratio of the concentrate stream to the demineralized stream to less than 150.

An example of a three-stage EDR process is shown in Fig. 11-19. The system recovery from this process is 90 percent, and the overall TDS rejection from the feed stream is 75 percent. Contrary to a RO or NF process, the product water is taken only from the final stage, as ions are continually removed from the product stream until the desired TDS concentration is obtained. The feed stream to the EDR process is pretreated with acid and/or an inhibitor, as is a RO or NF feed stream, to prevent scaling at the desired recovery. Recycling of the concentrate stream to the feed stream is not shown in Fig. 11-19, but is often used in an EDR process to (1) reduce equipment requirements for a given recovery, (2) reduce concentrate stream discharge, (3) reduce pretreatment, and (4) increase the transfer of ions to the concentrate stream.

Figure 11-20 presents a process flow diagram for an ED/EDR process. In plants working with maximum recommended polarization levels, the tendency to precipitation of calcium carbonate becomes possible when a bicarbonate ion is greater than 67 percent of anions and calcium accounts for more than 50 percent of cations. The larger relative size of the bicarbonate ion makes it more resistant to movement. This fact implies that, when it is a larger percentage of anions, the high resistance generates polarization of the anionic membrane surface. Hydroxide ions produced as consequence of polarization react with the bicarbonate ion to form carbonate ions, which will precipitate with the existing calcium.

In general EDR can operate at higher water recoveries because the periodic reversal of the DC electrical field removes deposited solids and colloids; the self-cleaning reversal technique breaks up polarization films in the system 3 to 4 times per hour, preventing scale. Moreover, where EDR can operate in the presence of higher levels of dissolved silica as silica is not charged and hence not removed in EDR; RO is limited in water productivity when silica is present due to its concentration on the surface (silica is not ionized under pH 9.5).

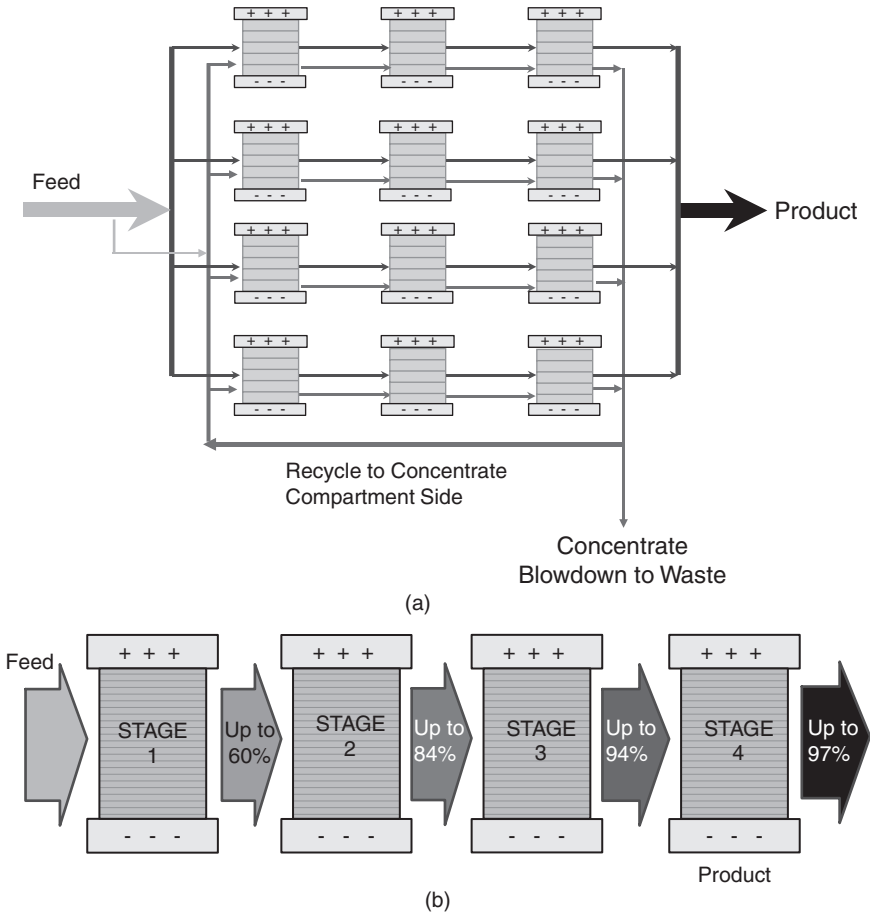

FIGURE 11-19 (a) Four line, three-stage EDR process, (b) Single line, four-stage EDR train. (Courtesy of GE Water & Process Technologies Ionic, Inc.)

One factor of importance that impacts membrane life is cleaning and cleaning intervals. Clean-in-place (CIP) intervals are dependent on site-specific water quality and pretreatment conditions. RO membranes require regular cleaning when employed for surface water applications; monthly cleanings are not uncommon. However, in general EDR CIPs are performed between 800 and 1000 hours of operating time and may take from 30 min to 1 hour (for forward flushing). If EDR stack disassembly is required, then this may take 5 to 6 hours in addition to the cleaning (if CIP unsuccessful in removing a hot spot for example). Caustic cleaning or brine CIPs occur every 3 to 4 months if bacteria are present. Electrode tape is the tape on the electrode that provides protection for the stack to minimize the amount of shorting that takes place. The tape should be confirmed to be greatly heat resistance and caustic resistant. Electrode connecting bars must be monitored, inspected, and maintained, in addition to the confirmation of the presence of electrode gaskets and torque on the stacks must be maintained else the membranes can slip, leading to hotspot formation which can damage the membranes.

Example 11-3 Electrodialysis Power Requirements

An electrodialysis stack consists of 350 cells to be used to demineralize 378.5 m³/day (0.1 mgd) of conventionally pretreated brackish surface water for drinking water production. The salt content of the water is 1000 mg/L and the cation or anion content is 0.09 g equivalent weights per liter. Pilot scale studies determined that the current efficiency E_c and efficiency of salt removed E_r was 90 and 50 percent, respectively. The resistance was measured as 5.0 ohms, and the current density/normality ratio was 450. Determine the current required, the area of the membranes, and the power required.

Solution The current I is given by

$$I = \left[\frac{96,500 \text{ amp} \cdot \text{sec}}{\text{gm} \cdot \text{eq} \cdot \text{wt}} \right] \left[\frac{378.5 \text{ m}^3}{\text{day}} \right] \left[\frac{1000 \text{ L}}{\text{m}^3} \right] \left[\frac{0.09 \text{ gm} \cdot \text{eq} \cdot \text{wt}}{\text{L}} \right] \\ \times \left[\frac{\text{day}}{86400 \text{ sec}} \right] \left[\frac{0.50}{350(0.90)} \right] \\ I = 60.4 \text{ amps}$$

Current density/normality ratio is 450, and since normality equals the number of gram-equivalent weight per liter, normality is 0.09.

The current density I_{density} is then equal to

$$I_{\text{density}} = (450)(\text{normality}) = (450)(0.09) = 40.5 \text{ mA/cm}^2$$

The membrane area A is

$$A = [60.4 \text{ amps}] \left(\frac{\text{cm}^2}{40.5 \text{ mA}} \right) \left(\frac{1000 \text{ Amps}}{\text{mA}} \right) = 14990 \text{ cm}^2$$

If the membranes are square in shape, the size is 38.6 cm by 38.6 cm and the power required is

$$P = RI^2 = (5.0 \Omega)(60.4 \text{ A})^2 = 18,240 \text{ W} \quad \blacktriangle$$

Temperature Effects on Flux

The flux of water through a pressure-driven membrane is affected by temperature. The following section presents three techniques to compensate for the effect of temperature on flux.

Theoretical Normalized Flux Equation. The Hagen-Poiseuille equation, Eq. 11-53, measures flow through pores of a membrane as a function of viscosity, pore diameter, porosity, applied pressure, and membrane thickness (Cheryan, 1986). This equation indicates that water flux is inversely proportional to solvent viscosity. The viscosity of water decreases as temperature increases, which increases flux.

$$F_w = \frac{\Delta P}{R_w} = \frac{\varepsilon r^2 \Delta P}{8 \delta \mu} = \frac{1}{\mu} \frac{\varepsilon r^2 \Delta P}{8 \delta} \quad (11-53)$$

where ε is the porosity, r the pore radius, μ the solvent viscosity, and δ the membrane thickness.

If the porosity, pore radius, viscosity, and thickness are assumed to be constant, Eq. 11-53 can be used to develop a temperature correction factor. The normalized temperature of 25°C is a worldwide reporting standard (PEM, 1982). To derive the normalized flux equation, θ in Eq. 11-54 is determined graphically or by linear regression.

$$\text{TCF} = \frac{F_{T^\circ\text{C}}}{F_{25^\circ\text{C}}} = \theta^{(T-25)} \quad (11-54)$$

where TCF is the temperature correction factor and T the temperature (°C).

Applying the Hagen-Poiseuille equation, Eq. 11-54 can be written as

$$\log \frac{F_{T^\circ\text{C}}}{F_{25^\circ\text{C}}} = \log \frac{\mu_{25^\circ\text{C}}}{\mu_{T^\circ\text{C}}} = (T-25) \log \theta \quad (11-55)$$

Log θ then can be solved by regressing or plotting $\log \frac{\mu_{25^\circ\text{C}}}{\mu_{T^\circ\text{C}}}$ versus $T - 25$. The result for this theoretical derivation is shown in Eq. 11-56. Membrane suppliers have developed temperature correction equations for their products that account for temperature changes of water and membrane. Equation 11-56 accounts only for the viscosity change with temperature.

$$\text{TCF} = \frac{F_{T^\circ\text{C}}}{F_{25^\circ\text{C}}} = 1.026^{(T-25)} \quad (11-56)$$

Temperature Correction Factor Based on Operational Data. The theory developed so far assumes no effect of temperature on the membrane. Another method derives a TCF by developing a statistical relationship of the mass transfer coefficient and temperature using operational data. This technique accounts for temperature effects on both water and the membrane; however, it does assume the membrane is effectively cleaned.

The same equation form as shown in Eq. 11-54 is used.

$$\text{TCF} = \frac{F_{T^{\circ}\text{C}}}{F_{25^{\circ}\text{C}}} = \theta^{(T-25)} \quad (11-54)$$

Flux is proportional to the mass transfer coefficient. Taking the logarithm of both sides gives

$$\log \frac{F_{T^{\circ}\text{C}}}{F_{25^{\circ}\text{C}}} = \log \frac{\text{MTC}_{T^{\circ}\text{C}}}{\text{MTC}_{25^{\circ}\text{C}}} = (T-25) \log \theta \quad (11-57)$$

Again, plotting $\log \frac{\text{MTC}_{T^{\circ}\text{C}}}{\text{MTC}_{25^{\circ}\text{C}}}$ of operational data versus $T - 25$ gives $\log \theta$ as the slope, which is determined by linear regression. Manufacturers commonly develop TCFs for their membranes. For example, a TCF of 1.04 was developed for a Memtec MF product using operational data from Manitowoc, Wisconsin (Kothari, 1997).

DuPont Equation. The TCF for DuPont B-10 membrane is commonly used for normalized flux and is presented in Eq. 11-58 (PEM, 1982). This figure of 1.03 is essentially equal to the theoretical θ of 1.026.

$$\text{TCF} = \frac{F_{T^{\circ}\text{C}}}{F_{25^{\circ}\text{C}}} = 1.03^{(T-25)} \quad (11-58)$$

Example 11-4 Temperature Normalization and Specific Flux

A UF operator determines that the average instantaneous flux was $1.63 \text{ m}^3/\text{m}^2\text{-day}$ (40 gal/sfd) at 89 kPa (13 psi) and 9°C in early spring. One month later the operator finds the flux changed to $1.34 \text{ m}^3/\text{m}^2\text{-day}$ (33 gal/sfd) at a TMP of 69 kPa (10 psi) and 21°C . Determine if a significant change in specific flux has occurred, and what implications the number may have with respect to the operation of the facility.

Solution The flux for the spring measurement is normalized to a standard temperature of 25°C using Eq. 11-56.

$$\text{TCF}_{1.63 \text{ m}^3/\text{m}^2\text{-day}} = \left(1.63 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day}} \right) (1.026)^{(25^{\circ}\text{C}-9^{\circ}\text{C})} = 2.458 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day}} \left(64.2 \frac{\text{gal}}{\text{sfd}} \right)$$

The specific flux is the flux at standard temperature divided by the TMP.

$$J_{\text{specific}} = \frac{2.458 \frac{\text{m}^3}{\text{m}^2\text{-day}}}{89 \text{ kPa}} = 0.02792 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day} \cdot \text{kPa}} \cdot \left(4.9 \frac{\text{gal}}{\text{sfd} \cdot \text{psi}} \right)$$

Accounting for the temperature change one month later,

$$\text{TCF}_{1.34 \text{ m}^3/\text{m}^2\text{-day}} = \left(1.34 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day}} \right) (1.026)^{(25^{\circ}\text{C}-21^{\circ}\text{C})} = 1.485 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day}} \left(37.1 \frac{\text{gal}}{\text{sfd}} \right)$$

And the specific flux was

$$J_{\text{specific}} = \frac{1.485 \frac{\text{m}^3}{\text{m}^2\text{-day}}}{69 \text{ kPa}} = 0.02152 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day} \cdot \text{kPa}} \cdot \left(3.7 \frac{\text{gal}}{\text{sfd} \cdot \text{psi}} \right)$$

The percent reduction can be calculated as

$$\left[\frac{0.02792 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day} \cdot \text{kPa}} - 0.02152 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day} \cdot \text{kPa}}}{0.02792 \frac{\text{m}^3}{\text{m}^2 \cdot \text{day} \cdot \text{kPa}}} \right] \times 100 = 23\%$$

This is a 23 percent reduction, indicating that a significant loss in performance has occurred and the membranes should be chemically cleaned to remove the foulants that have caused the loss in productivity. ▲

INTEGRATED MF AND UF PROCESS APPLICATIONS AND PROCESS DESIGN

Membrane processes are considered for integration into water treatment plants for a variety of reasons. Because MF and UF processes do not effectively remove dissolved organic and inorganic constituents from water, the use of pretreatment processes such as powdered activated carbon (PAC), coagulation, lime addition, and/or oxidation are often integrated into the treatment scheme. It has been recognized that UF is limited in removing disinfection by-product precursors as a stand-alone process (Jacangelo, 1991). MF and UF processes are often integrated with other water treatment processes for application on ground and surface waters, and function as integrated membrane systems. There is a variety of flexibility for integrating MF and UF with other treatment processes (Pressdee et al., 2006). According to a survey conducted by the U.S. Environmental Protection Agency (USEPA, 2001) the principal reasons for integrating MF and UF membranes are

1. Complying with existing and future regulations (with compliance being facilitated by using membrane filtration)
2. Providing a barrier to protozoan cysts and bacteria
3. Improving operating efficiency through automation and ability to treat water of variable quality
4. Using a smaller land area for the plant in comparison with a conventional filtration system
5. Providing an additional barrier against hazards to public health
6. Having lower capital, operation, and maintenance costs in comparison to other technologies
7. Providing a barrier for unfiltered systems that may lose unfiltered status
8. Providing pretreatment before NF or RO
9. Bolstering consumer confidence in water quality

The most common reason for implementing membrane filtration has been to meet or exceed current and identified future regulatory requirements, and for MF and UF particularly the removals of pathogens, organics, and particles. However, certain types of conventional processes should not be considered for integration. For example, the use of polymers (e.g., cationic polymer) that are upstream of membranes can result in excessive fouling. This was observed during pilot studies in Appleton, Wisconsin, when cationic polymer use during upstream lime softening resulting in 10-day cleaning intervals (Roquebart et al., 2002). Also the use of some polymeric coagulants (e.g., chitosan) has been determined to cause significant fouling for hollow fiber UF membranes (Machenback et al., 2002). The

following section describes the various types of MF- and UF-integrated membrane systems that are employed to address specific contaminants not associated with simple particle removal and microbial removal.

MF and UF Integrated with Either Lime or Coagulation, Flocculation, and Sedimentation (CFS) with or without Powdered Activated Carbon (PAC)

Many surface water supplies contain elevated levels of TOC (natural organic matter [NOM]) and variable turbidity requiring the use of excessive coagulant dosing to produce sweep floc or addition of polymers to aid floc formation, settling, and filtration. Hard-surface water supplies often use lime softening for pretreatment ahead of filtration. UF has been integrated successfully into lime-softening facilities for surface- and groundwater treatment (Duranceau, 2000; Kweon and Lawler, 2002; Brown et al., 2004). Also, it has been shown that the use of CSF prior to membrane filtration produces higher-quality water for significantly variable turbidity loadings and the UF process can operate more efficiently. Sedimentation is incorporated to reduce the solids loading to the membranes; however, MF and UF processes are able to operate at increased flux rates and reduced cleaning frequencies, thereby reducing overall cost. However, pressurized UF processes operated at instantaneous flux rates over $1.83 \text{ m}^3/\text{m}^2\text{-day}$ ($45 \text{ gal}/\text{ft}^2\text{-day}$) required frequent cleaning events and suffered damage due to excessive backwash regimes when the same water was treated without the use of CSF pretreatment. Figure 11-21 provides a simplified process flow schematic for MF or

FIGURE 11-21 Process flow diagram for a MF or UF process integrated with CSF pretreatment. (Courtesy of the American Water Works Association *Manual of Water Supply Practices M53 Microfiltration and Ultrafiltration Membranes for Drinking Water*.)

UF membrane processes integrated with conventional CSF treatment. PAC has been used for treatment of organics from water supplies. (Adham, 1991, 1993) PAC has been used to remove pesticide contaminants in the Seine River in Paris, where PAC was added ahead of a cellulose triacetate UF membrane (Anselme, 1991). However, PAC has been reported to decrease filtration run times and productivity, especially at higher operating flux (Huey et al., 1999). Longer backwash intervals improved PAC effectiveness for removal of tastes and odors, and membrane fouling was shown to be independent of PAC dose for a low-turbidity, cold-lake-water supply (Schideman et al., 2001). Preclarification was shown to increase the operating flux in piloted systems in Texas by 19 to 50 percent (Braghetta, Price, and Kolkhorst, 2001). PAC was believed to have reduced the fouling rates due to PAC adsorption of NOM. Presedimentation was shown to only marginally improve the operating flux of a submerged UF system by less than $0.204 \text{ m}^3/\text{m}^2\text{-day}$ ($5 \text{ gal}/\text{ft}^2\text{-day}$), most likely because these immersed systems operate in basins with higher solid loadings than their forward pressure counterpart (Crawford and Bach, 2001).

FIGURE 11-22 Process flow diagram for a MF or UF process integrated as direct filtration. (Courtesy of the American Water Works Association Manual of Water Supply Practices M53 Microfiltration and Ultrafiltration Membranes for Drinking Water.)

MF and UF Integrated with Coagulation

Water supplies with low turbidity, less than 5 ntu and having no other water quality contaminants (e.g., iron, manganese, low NOM, or other metal foulants) can be fed directly to a MF or UF membrane process, as shown in Fig. 11-22. This is analogous to direct filtration with conventional media filters. Prestrainers are incorporated into the flow stream to serve as a bulk protection strainer and can be automated for backwashing. The applicability of direct membrane filtration is limited by the amount of coagulant the membrane can reliably process without excessive decline in production or clarification will have to be incorporated into the design. Studies have shown that the addition of coagulant prior to MF and UF reduces membrane fouling by organic matter (Lahoussine-Tourcaud et al., 1990; Carroll et al., 2000).

MF and UF Integrated with Coagulation, Flocculation, and Clarification as Pretreatment to NF, RO, and EDR for Surface Water Supplies

As shown in Fig. 11-23, NF, RO, and EDR can be integrated with MF, UF, and CSF for treatment of surface water supplies. Although MF and UF pretreatment of surface water supplies is of benefit for downstream NF and RO processes, fouling is of concern, and most surface water NF or RO membranes will require more frequent cleaning intervals than when NF or RO is used for treatment of ground-, brackish-, or seawater supplies (Taylor et al., 1989a, 2000; Duranceau 2001) even if MF or UF is used in combination with the RO and NF process. This is because aerobic biofouling will impact the NF and RO processes

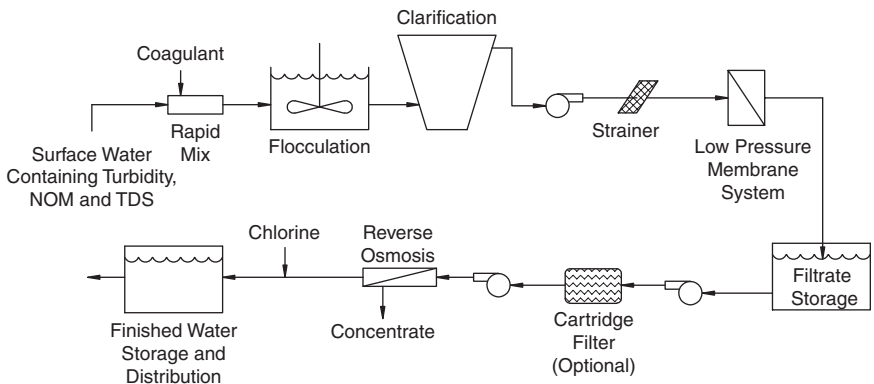

FIGURE 11-23 Process flow diagram for MF or UF process integrated with CSF pretreatment prior to NF, RO or EDR for surface water treatment. (Courtesy of the American Water Works Association Manual of Water Supply Practices M53 Microfiltration and Ultrafiltration Membranes for Drinking Water.)

as disinfectant is not available for pretreatment downstream of MF and UF processes else damage will occur in the NF and RO membranes as NF and RO processes are tolerant to only 2000 ppm-hours of chlorine contact. Although NF and RO membranes are somewhat more tolerant to monochloramine on the order of 20,000 ppm-hours of monochloramine contact time, the NF and RO membranes will eventually be damaged. Monochloramine in incremental or low-level treatment can help to reduce biofouling impacts on NF and RO processes. EDR facilities are unique in that they can be disassembled for fouling control if needed unlike the synthetic membrane processes (MF, UF, NF and RO) that are of a fixed membrane construction. EDR does require additional stack maintenance due to the configuration and design of the process (it is an electrically driven process and not pressure driven). Similar chemicals are used in EDR, RO and NF for the removal of organics, scale and bacteria; however, EDR membranes, if severely fouled, can be individually removed and cleaned by disassembling the stack and placing the flat sheet membranes in chemical baths. Severely fouled RO and NF membranes cannot be treated in this same method. Silica when present in sufficient quantities could limit the recovery of RO or NF but does not impact EDR as silica remains uncharged and does not concentrate and potentially scale in the EDR process. Consequently, EDR may have an advantage over RO and NF offering a lower present worth when silica is predominant in brackish surface water (Duranceau, 2006). RO and NF membranes operating as a surface water integrated membrane system will typically require monthly cleaning frequencies, which compares to conventional groundwater RO and NF treatment that experience cleaning frequencies on the order of once or twice per year.

MF and UF Integrated with Oxidation Processes for Removal of Iron and Manganese from Groundwater

There are many options for removing iron and manganese from groundwater. Typically a two-step process is used. First, addition of an oxidant (air, permanganate, or chlorine) reacts with the dissolved Fe and Mn. This is followed by granular media filtration to remove oxidized iron and manganese particulates that remain after the chemical reaction has been completed. Chapter 7 discusses principles of iron and manganese removal; the reader should consult this chapter for more detail. Note that strong oxidants, such as chlorine, can damage membranes that are not oxidant resistant and should not be used without quenching the chlorine or use oxidant-resistant membranes. Figure 11-24 presents a basic process flow diagram for the oxidant integrated

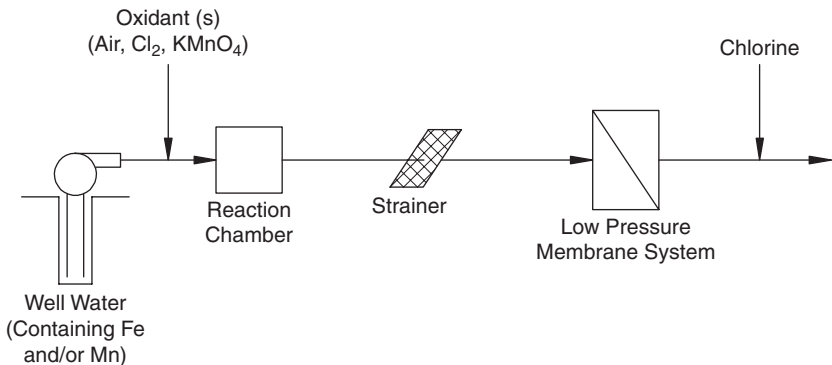

FIGURE 11-24 Process flow diagram for a MF or UF process integrated with oxidation processes for removal of iron and manganese from groundwater. (Courtesy of the American Water Works Association *Manual of Water Supply Practices M53 Microfiltration and Ultrafiltration Membranes for Drinking Water*.)

membrane system. Schneider et al. (2001) demonstrated that chlorine dioxide reduced manganese from 0.094 mg/L in an MF feed stream to 0.001 mg/L in the permeate after a 20 min upstream MF detention time. Permanganate reduced manganese to 0.03 mg/L in MF permeate (from a feed concentration of 0.099 mg/L), also after 20 min of detention time upstream of MF. Of the facilities that use oxidant-resistant membranes, permanganate is the preferred oxidizing chemical. For nonoxidant resistant membranes, designs must be evaluated for compatibility with oxidation pretreatments, as some membranes are not tolerant to oxidizing chemicals (e.g., chlorine and other strong oxidants) and may weaken or change in pore size and permeability.

MF and UF Integrated with Coagulant for Arsenic Removal from Groundwater

Integrated membrane systems (IMSS) using coagulant and MF or UF processes have been shown to be effective at reducing arsenic levels from as high as 100 µg/L to an arsenic concentration of 2 µg/L (Amy et al., 2000, Chwirka et al., 2000). Figure 11-25 presents a process flow diagram of an integrated membrane system that could be used for arsenic removal. Included in the process flow is acidification, which is required to reduce the pH to between 6.8 and 7.0 to maximize arsenic adsorption. Also, because arsenic (V) is better adsorbed and co-precipitated during coagulation than is arsenic (III), an addition of an oxidizing chemical upstream of coagulant may be required if As(III) is the predominant arsenic species. Regarding the coagulant feed, ferric salts are preferred over aluminum salts because they provide better arsenic removal on a molar basis.

MF and UF Integrated with Seawater RO

The integration of MF and UF as membrane pretreatment for seawater desalination is an integrated membrane system and has been demonstrated at the pilot scale (Rosberg, 1997; Van Hoof, 2001; Vial, 2003; Duranceau and Henthorne, 2004). However, operation of an open intake system caused poor UF performance and presented operational challenges because of fouling (Henthorne, 2005). It was found that MF and UF production could be maintained with the use of additional pretreatment using disc filters. Similar results were obtained at another MF and UF facility when disc filters were used for additional pretreatment to resolve membrane failure from sharp and serrated debris present in UF feedwater (Jew et al., 2003). Disc filters were shown to reduce MF and UF fouling rates during pilot-scale testing at the Naval Facilities Engineering Service Center in Port Hueneme, California (Huehmer et al., 2005).

There are many water quality parameters that can influence the choice of pretreatment, such as dissolved organic carbon, silt density index (SDI), turbidity, algae content (that may vary depending on the season and other factors), temperature, oil and grease, and suspended

FIGURE 11-25 Process flow diagram for a MF or UF process integrated with coagulant for removal of Arsenic from groundwater. (Courtesy of the American Water Works Association Manual of Water Supply Practices M53 Microfiltration and Ultrafiltration Membranes for Drinking Water.)

solids content. As a result, required pretreatment can comprise different technologies, and may include the coupling of an advanced technology such as UF with a conventional process such as coagulation, ballasted sedimentation, dissolved air flotation (DAF), dual media filtration, and the like. Regarding UF, studies have shown that the principal cause of severe fouling in seawater RO is organic matter including algae (Chua et al., 2003; Ma et al. 2007); however, UF pretreatment was found as an effective pretreatment to seawater RO.

MF and UF Process Design

MF and UF membranes are designed primarily as particle removal processes. Additionally, MF and UF design concepts are changing rapidly with this relatively new technology, which presents unique challenges during engineering design. Currently, MF and UF systems are available as modular systems from several manufacturers. MF and UF systems are typically offered as packaged systems that contain the required filtration equipment and appurtenances and vary greatly among manufacturers. Consequently, MF and UF system design should involve direct communication with manufacturers and ancillary supporting system vendors that are familiar with individual products, as many of these systems have proprietary design features that the process design engineer must know. Typically, MF and UF processes require prescreening of the raw water and pumping it under pressure onto a membrane in either a direct or crossflow operation mode. For the direct filtration mode, the transmembrane pressure (TMP) can be calculated as the difference between the pressure of the inlet and the permeate pressure as follows:

$$p_{\text{tmp}} = p_i - p_p \quad (11-59)$$

where p_{tmp} is the transmembrane pressure kPa (psi), p_i the pressure at the inlet to the MF or UF module kPa (psi), and p_p the pressure of permeate kPa (psi).

For the crossflow operation scenario, the average TMP is defined as the average of the difference between the pressure at the inlet and outlet of the process less the permeate pressure.

$$p_{\text{tmp}} = \left[\frac{(p_i + p_o)}{2} \right] - p_p \quad (11-60)$$

where p_o is the pressure at the outlet to the MF or UF module kPa (psi).

When the MF or UF process is operated in the crossflow mode, there is an accompanying pressure drop across the module where Δp is the pressure drop across the module in kPa (psi).

$$\Delta p = p_i - p_o \quad (11-61)$$

Application of transmembrane pressure (TMP) in an MF and UF process will produce a filtrate or permeate, with TMPs typically ranging from 0.2 bar (3 psi) to 1 bar (15 psi). The total production flow of permeate from a MF or UF process can be determined by

$$Q_p = (J_m)(S) \quad (11-62)$$

where Q_p is the process permeate flow in L/hr (gal/min), J_m the transmembrane flux in L/hr/m² (gal/day/ft²), and S the total effective membrane surface area.

The flux is directly proportional to TMP, and for a given membrane area, the filtrate or permeate flow rate is also directly proportional to the TMP. The flux is inversely proportional

to the water viscosity. Hence, temperature will affect the required driving pressure for membrane processes because of changes in the feedwater viscosity. Therefore, as the water temperature decreases, MF and UF systems must increase the TMP to maintain production. About 50 percent more TMP is needed to maintain a constant flux at 5°C than at 20°C. Assuming a constant TMP and membrane area, the filtrate flow at 5°C would be about 35 percent less than at 20°C. Therefore, designers must account for temperature impacts on sizing of the membrane facilities and must define the desired production rate at a specified temperature. Typical flux rates for MF and UF membranes vary widely, depending on membrane material and specific application, and range from 0.815 m³/m²-day to 4.07 m³/m²-day (20 to 100 gpd/ft²).

In MF and UF processes, a frequent backwash (every 15 min to 1 hour or more frequently) removes the cake formed on the membrane surface. Some MF and UF systems incorporate a chemical enhancement routine in backwash events, referred to as chemically enhanced backwashing. However, over time, as the MF and UF membrane ages, backwashing will not completely remove components of the foulant layer, and the process will be unable to achieve its original operating transmembrane pressure.

Figure 11-26 illustrates correlating a backwashing event to operating transmembrane pressure, where at some point in time the MF or UF system will require a chemical clean in place (CIP) to maintain productivity without exceeding some maximum allowable transmembrane pressure (else the membrane become damaged). CIP is typically required when the TMP reaches 207 to 172 kPa (30 to 25 psi). A typical CIP would be implemented in a two-step process that uses (1) caustic chlorine solution to remove organic and microbial foulants and (2) an acid solution to remove inorganic mineral foulants.

FIGURE 11-26 Transmembrane pressure development over time indicating a chemical cleaning was performed after backwashing illustrating concept of irreversible fouling.

Example 11-5 Ultrafiltration Plant Concept Design

An ultrafiltration treatment plant is to be designed to produce 19,000 m³/d of treated water. Piloting demonstrates that a UF membrane system can operate at a flux of 100 L/m²-h at 20°C with a filter run length of 75 min. The selected UF manufacturer offers the following full-scale system:

Item description	Quantity
Number of modules per rack	90
Membrane area per module (m ²)	15
Backwash duration (min)	1
Backwash flux (L/m ² -h)	2810

Develop design criteria for the following:

1. Membrane area required to achieve the design flow
2. Number of membrane racks
3. Total number of UF modules
4. UF permeate flux
5. Water volume produced per filtration cycle
6. Water volume wasted per backwash cycle
7. System recovery

Solution

1. Convert the given design flow rate into L/h, then calculate membrane area.

$$Q = \left(\frac{19,000 \text{ m}^3}{\text{day}} \right) \left(\frac{1000 \text{ L}}{\text{m}^3} \right) \left(\frac{\text{day}}{24 \text{ h}} \right) = 791,667 \frac{\text{L}}{\text{h}}$$

$$\text{Area}_{\min} = \frac{Q}{J} = \frac{791,666.67 \text{ L/h}}{100 \text{ L/m}^2 \cdot \text{h}} = 7916.667 \text{ m}^2$$

2. Calculate the minimum number of modules, then determine rack quantity.

$$N_{\text{modules},\min} = \frac{7916.67 \text{ m}^2}{(15 \text{ m}^2/\text{modules})} = 527.78 \text{ modules} = 528 \text{ modules}$$

$$N_{\text{racks},\min} = \frac{528 \text{ modules}}{(90 \text{ modules/rack})} = 5.86 \text{ racks} = 6 \text{ racks}$$

3. Calculate the total number of UF modules.

$$N_{\text{modules},\text{total}} = (6 \text{ racks}) \left(90 \frac{\text{modules}}{\text{rack}} \right) = 540 \text{ modules}$$

4. Calculate the design membrane area, then the UF permeate flux.

$$\text{Area}_{\text{actual}} = (540 \text{ modules}) \left(\frac{15 \text{ m}^2}{\text{modules}} \right) = 8100 \text{ m}^2$$

$$J = \frac{Q}{A_{\text{actual}}} = \frac{791,667 \text{ L/h}}{8100 \text{ m}^2} = 97.74 \frac{\text{L}}{\text{m}^2 \cdot \text{h}}$$

5. Calculate the water produced during one filtration cycle per rack.

$$V_F = \left(\frac{97.748}{\text{m}^2 \cdot \text{h}} \right) \left(\frac{15 \text{ m}^2}{\text{modules}} \right) \left(\frac{90 \text{ modules}}{\text{rack}} \right) (75 \text{ min}) \left(\frac{1 \text{ h}}{60 \text{ min}} \right) = 164,931 \frac{\text{L}}{\text{rack}}$$

6. Calculate the water consumed during one backwash cycle per rack.

$$V_{BW} = \left(\frac{280 \text{ L}}{\text{m}^2 \cdot \text{h}} \right) \left(\frac{15 \text{ m}^2}{\text{modules}} \right) \left(\frac{90 \text{ modules}}{\text{rack}} \right) (1 \text{ min}) \left(\frac{1 \text{ hr}}{60 \text{ min}} \right) = 6300 \frac{\text{L}}{\text{rack}}$$

7. Calculate the design water recovery

$$r = \left(\frac{V_F - V_{BW}}{V_F} \right) = \left(\frac{(164.931 \text{ L/rack}) - (6300 \text{ L/rack})}{(166.931 \text{ L/rack})} \right) = 0.96$$

Thus, recovery is 96 percent. ▲

NF AND RO PROCESS CONCEPTS AND DESIGN CRITERIA

RO and NF Processes

This section introduces priorities for NF and RO design and associated material. A conventional RO or NF treatment system includes pretreatment, membrane process, posttreatment, and concentrated residuals, as shown in Fig. 11-27. As can be seen in Fig. 11.27, the overall process can be rationally separated into advanced pretreatment, conventional pretreatment, membrane process, and posttreatment subsections. Any raw-water stream used as a feed stream to a membrane process must undergo either conventional or advanced pretreatment. Conventional pretreatment includes acid or scale inhibitor addition to prevent precipitation of salts during membrane processing. Advanced pretreatment is required before conventional pretreatment when the raw water contains excessive fouling materials. Membrane treatment is the passage of the pretreated water through an active RO/NF membrane surface with a pore size 0.001–0.0001 μm . Posttreatment includes many unit operations common to drinking water treatment such as aeration, disinfection, and corrosion control.

In a typical membrane process, one stream enters the membrane element and two streams exit. The entering stream is the feed stream. The streams exiting the membrane are referred to as *concentrate* and *permeate streams*. A portion of the concentrate stream is sometimes recycled back to the feed stream to increase crossflow velocity and recovery. The different configurations for softening NF, brackish RO, and seawater RO processes are shown in Fig. 11-28. In multistaged systems the number of pressure vessels decreases in each succeeding stage to maintain sufficient velocity in the feed-concentrate channel and is referred to as *concentrate-staged arrays*. In this type of system, the concentrate stream

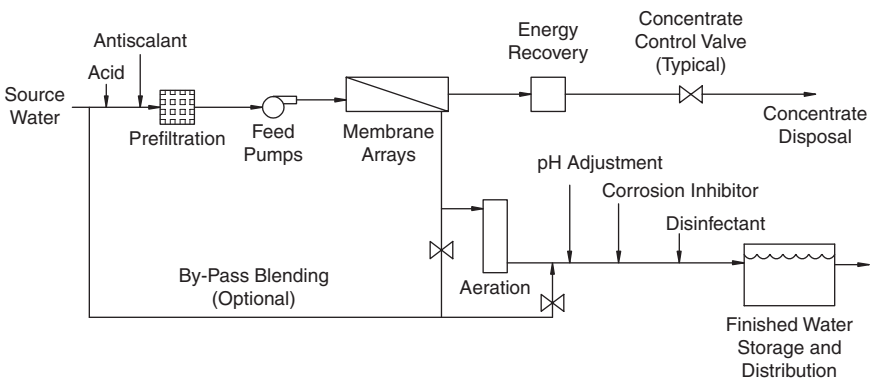

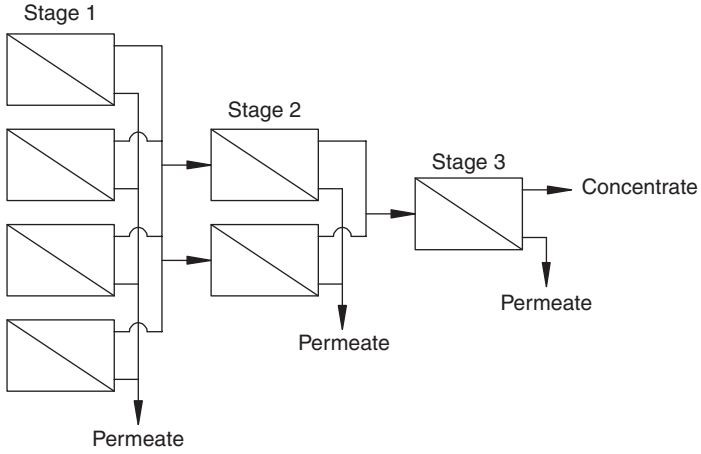

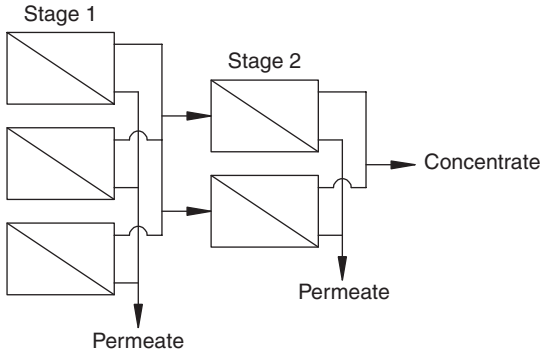

FIGURE 11-27 Process flow diagram for a conventional RO or NF membrane process that incorporates energy recovery and by-pass.

(a)

(b)

(c)

FIGURE 11-28 Configuration of reverse osmosis facilities. (a) A concentrate-staged $4 \times 2 \times 1$ NF softening array, (b) A concentrate-stage 3×2 RO brackish desalting array, and (c) A two-pass permeate-staged RO seawater array.

produced in the first stage serves as the feed stream for the second stage while the permeate produced in all stages is taken for subsequent unit operations or processes. However, for seawater applications, the permeate from the first bank of membrane trains is fed to the second bank of membrane trains and is referred to as *permeate-staged arrays*.

Fouling Indexes

Membrane fouling is a widespread problem limiting the performance and application of synthetic membrane processes and, as such, is an important consideration in the design and operation of a membrane system. Cleaning frequency, pretreatment requirements, operating conditions, cost, and performance are affected by membrane fouling. Fouling indexes are estimates of the fouling and pretreatment requirements for RO or NF systems. The silt density index (SDI) and the *modified fouling index (MFI)* are the most common fouling indexes. SDI and the MFI are defined using the basic resistance model as quantitative indicators of water quality and potential for membrane fouling.

Fouling indexes are determined from simple membrane tests. These values resemble mass transfer coefficients for membranes used to produce drinking water. Although similar data are collected for each index, significant differences separate them. Because of the effects of different filtration equipment, only a Millipore filter apparatus can be used to generate accurate index measurements.

Silt Density Index. The SDI is the most widely used fouling index and is calculated as shown in Eq. 11-63. The SDI is a timed filtration test using three time intervals whereby water flows through a laboratory-grade membrane Millipore filter. The water is passed through a 0.45 μm Millipore filter having a 47 mm internal diameter at 207 kPag (30 psig) to determine the SDI (ASTM, 2001). The time required to complete data collection for such a test varies from 15 min to 2 hours depending on the character of the water. The Millipore test apparatus is used to determine three time intervals for calculation of the SDI. The first two intervals are the times to collect initial and final 500 mL samples. The third time interval—5, 10, or 15 min—is the time between the collection of the initial and final samples. The 15 min interval is used unless the water has such extreme fouling potential that the filter plugs before that period expires. The interval between the initial and final sample collection is decreased until a final 500 mL sample can be collected.

$$\text{SDI} = \frac{100[1 - (t_i/t_f)]}{t} \quad (11-63)$$

where t_i is the time to collect initial 500 mL of sample, t_f the time to collect final 500 mL of sample, and t the total running time of the test.

The SDI value is a static measurement of resistance determined by samples taken at the beginning and the end of the test. The SDI does not measure the rate of change of resistance during the test, and it is the least sensitive of the fouling indexes. The SDI is not dynamic, is not measured in a crossflow mode, does not use the same material or pore size as a membrane element, measures only static resistance, and is not reflective of a continuously operated membrane process.

Modified Fouling Index. The MFI is determined using the same equipment and procedure as for the SDI, except that the volume is recorded every 30 sec over a 15 min filtration period (Schippers and Verdouw, 1980). The flow rate is determined from volume and time data, and the inverse of the flow rate is plotted as a function of volume filtered. The development of the MFI is consistent with Darcy's law, in that the thickness of the cake layer

FIGURE 11-29 Typical MFI curve.

formed on the membrane surface is directly proportional to the filtrate volume. The total resistance is the sum of the filter and cake resistance. The MFI is derived in Eqs. 11-64 to 11-66 and is defined graphically as the slope of a curve relating inverse flow to cumulative volume (Fig. 11-29).

$$\frac{dV}{dt} = \frac{\Delta P}{\mu} \frac{A}{(R_f + R_k)} \quad (11-64)$$

$$t = \frac{\mu VR_f}{\Delta PA} + \frac{\mu V^2 \zeta}{2\Delta PA^2} \quad (11-65)$$

$$\frac{1}{Q} = a + MFI \times V \quad (11-66)$$

where R_f = resistance of the filter (L^{-1})
 R_k = resistance of the cake (L^{-1})
 ζ = measure of fouling potential (L^2t)
 Q = average flow (v/t^{-1})
 a, b = constants

On the basis of the work of Schippers and Verdouw, Morris (1990) determined an instantaneous MFI by calculating the ratio of flow over volume in 30 sec increments to increase sensitivity. An MFI plot is shown in Fig. 11-29. Typically the formation, buildup, and compaction or failure of the cake can be seen in three distinct regions on a MFI plot. The regions corresponding to blocking filtration and cake filtration represent productive operation, whereas compaction indicates the end of a productive cycle.

Index Guidelines. The SDI and MFI serve as general guidelines for acceptable feedwater quality, and a maximum value of 3 to 4 is typically specified by membrane manufacturers when the SDI and MFI are expressed in units of reciprocal minutes and s/L^2 , respectively. Some approximations for index values required prior to conventional membrane treatment are given in Table 11-9. The indexes apply to the raw or advanced pretreated water before conventional pretreatment processes. These numbers are only approximations and do not eliminate the need for pilot plant studies. Pretreatment requirements cannot be determined

TABLE 11-9 Fouling index approximations for RO and NF

Fouling index	Range (s/L ²)	Application
MFI	0–2	Reverse osmosis
	0–10	Nanofiltration
SDI	0–2	Reverse osmosis
	0–3	Nanofiltration
	0–10	Electrodialysis reversal

Source: Morris (1990); Sung (1994); Duranceau (2006).

for most installations without pilot plant studies unless actual plant operating data can be obtained on similar waters. Pilot plant studies have been omitted in the design of some reverse osmosis plants for treatment of raw waters with TOC and SDI values less than 1 unit. EDR can handle feedwaters with SDI₅ values of less than 12, whereas RO requires feed waters to have a 15 min SDI (SDI₁₅) less than 2. Colloidal fouling of EDR has not been experienced below a feedwater 5 min SDI (SDI₅) of 12, while fouling is likely if the SDI₅ is above 16; RO membranes could not operate under similar conditions. NF can process feed waters with a SDI₅ of 3.0, but suffers from biological and organic fouling which are not predicted by the SDI.

Example 11-6 SDI Problem

A municipal utility is considering using a membrane process as an alternative treatment method for its newly developed well field. The following information is collected using a SDI testing apparatus on an unfiltered raw water sample. Determine the 15 min SDI value.

Test time (min)	Water volume collected (mL)	Time to collect 500 mL (sec)
0	500	9
5	500	11
10	500	12
15	500	14

Solution Using Eq. 11-63,

$$SDI = \frac{100[1 - (t_i/t_f)]}{t}$$

$$SDI = \frac{100[1 - \frac{9\text{sec}}{14\text{sec}}]}{15\text{min}}$$

$$SDI = 2.4 \text{ unit}$$

Since the SDI is less than 3 units, this specific water evaluated would be considered acceptable feed water for a reverse osmosis process. ▲

Pretreatment

As mentioned, membrane operations require some feedwater pretreatment upstream of the process. First, however, it is important to realize that pretreatment is specific for individual processes and feedwaters. Needs differ from application to application and site to site.

Control of Fouling. Pretreatment is the first step in controlling membrane fouling, and it can be quite involved. In its simplest form, pretreatment involves microstraining with no chemical addition. However, when a surface water is treated, the pretreatment procedure may be much more involved and include pH adjustment, chlorination, addition of coagulants (e.g., alum, polyelectrolytes), sedimentation, DAF, dechlorination (e.g., addition of sodium bisulphite), adsorption onto activated carbon, addition of complexing agents [e.g., EDTA, sodium hexametaphosphate (SHMP)], and final polishing. Note that when oxidants are used for pretreatment prior to polyamide membranes or other nonoxidant resistant materials, precautions must be made to prevent the oxidant from contacting these types of membranes else irreversible damage will occur. Several important factors must be considered in contemplating pretreatment.

1. Material of membrane construction (asymmetric cellulose or noncellulose membranes, thin-film ether, or amide composite membranes)
2. Module configuration (spiral wrap, hollow fine fiber, tubular)
3. Feedwater quality
4. Recovery ratio
5. Final water quality

A listing of substances potentially harmful to membranes has been compiled (Rautenbach and Albrecht, 1989) and they have been categorized as either those damaging (acids, bases, pH, free chlorine, bacteria, and free oxygen) or those blocking, which include foulants (metal oxides, colloids, inorganic, NOM, and biological substances) and scalents (CaCO_3 , CaSO_4 , CaF_2 , BaSO_4 , and silica). Concentrations and/or presence of these components in the feedwaters must be controlled (Taylor and Jacobs, 1996). Biological substances can include bacteria, such as slime forming, iron, and sulfur bacteria, and other microorganisms will impact membrane process performance if not controlled (Duranceau, 2005). Several researchers have identified the characteristics and nature of the foulants using different autopsy procedures and found that humic acids were not as fouling as other organic compounds (Mosqueda-Jimenez, Huck and Basu, 2008) for UF, as an example.

Turbidity levels stipulated by membrane manufacturers are normally attained by conventional clarification techniques such as coagulation followed by sedimentation and sand filtration. In seawaters that are rich in suspended nutrients and for treating surface waters with high TOC, ultrafiltration has been advocated as a viable pretreatment option capable of reducing the suspended solids concentration to acceptable standards to feed finer membrane processes (Strohwalld and Jacobs, 1992; Metcalf et al., 1992; Taylor et al., 1989a). The minimum pretreatment processes for RO or NF consist of scale inhibitor and/or acid addition and microfiltration. These pretreatment processes help to control scaling and to protect the membrane elements. Such precautions are required for conventional reverse osmosis or nanofiltration systems.

Advanced Pretreatment. Advanced pretreatment operations precede scaling control and static microfiltration. These processes might include coagulation, dissolved air flotation (DAF), oxidation followed by green-sand filtration, groundwater recharge, continuous microfiltration, and granular activated carbon (GAC) filtration. Any other processes upstream of conventional pretreatment would also be advanced pretreatment by definition. In some pretreatment processes, such as alum coagulation, the feedwater is saturated with a salt, such as alum hydroxide. The solubility of such salts must be accounted for in the feedwater stream to avoid precipitation in the membrane. Several other types of pretreatment may form part of RO or NF membrane systems.

The majority of RO plants operating on surface water and many operating on groundwater have reported fouling problems (Goosen et al., 2004). Fouling controls productivity

and directly impacts cleaning and operating costs in many surface water RO applications (Duranceau 2005, 2006). Membrane fouling is not a well-understood phenomenon, and many different pretreatment processes can be used to control different types of fouling mechanisms. For example, to prevent problems with biological fouling, a bactericide that is not harmful to the membranes might be introduced. To treat for biodegradable foulants, biologically activated carbon would be a feasible option. Microfiltration or ultrafiltration would also be useful for removing some fouling contaminants. Many processes could be combined with membranes for specific applications.

The most serious fouling problems often involve treatment of highly organic surface waters by NF or RO for TOC or DBP control. Such applications may require cleaning frequencies of less than 1 month, a period not typical for conventional RO or NF processes. However membrane applications for organic control are not typically used and new methods will have to be developed with time. One method for controlling fouling is to highly automate the membrane-cleaning process. Currently, conventional RO plants treat nonfouling groundwaters, averaging cleaning frequencies of 6 months or more. Consequently, the cleaning operation is not automated, and it disrupts normal operation. Development of non-damaging membrane cleaning agents and automation of the cleaning process offer potential answers to fouling control.

Impact of Hydrocarbons on RO and EDR. Organic fouling in RO has been studied using model hydrocarbons such as hexane and diesel (Owadally, 2002). A large number of countries that use RO to obtain drinking water also are producers and exporters of hydrocarbons. This makes seawater RO units particularly susceptible to damage from oil spills. Lower molecular weight hydrocarbons are typically present in contaminated seawater feed as it can be safely assumed that organics of higher molecular weight will have already been dealt by passage through the RO pretreatment processes.

Diesel (a likely constituent arising from spillages) and hexane (chosen as a model low-molecular-weight hydrocarbon) were found to be present in oil spills, and the presence of these contaminants in both water-soluble and emulsion form can impact RO performance. Brackish-water membranes and seawater membranes of different structures were tested in saline water under different environmental conditions such as salinity and pressure of feedwaters and duration.

The performance of the RO unit, in terms of salt passage and permeate flux through the membranes, was assessed before and after fouling. It was determined that the polyamide-based membranes exhibit a decrease in permeate flux and an increase in salt passage after a short exposure to the foulants and a catastrophic drop in performance if exposure was prolonged. Although EDR membranes are tolerant to many different chemical conditions, continued exposure to solvents would affect the membrane process (including membranes, spacers, gaskets, and electrode tape). However, EDR would be more tolerant to short-term exposure than RO because of the fact that the anion and cation membranes are hydrophobic, unlike many RO membrane formulations that are hydrophilic.

Scaling Control. Scaling control is essential in RO/NF membrane processes. Control of precipitation or scaling within the membrane element involves identifying the limiting salt and determining an acid and/or inhibitor treatment that will prevent precipitation at the desired recovery.

Limiting Salt

The required dosage of scale inhibitor or acid is determined by the limiting salt. A diffusion-controlled membrane process naturally concentrates salts on the feed side of the membrane. If excessive water is passed through the membrane, this concentration process continues

until a salt precipitates and scaling occurs. Scaling reduces membrane productivity and limits recovery to the allowable recovery just before the limiting salt precipitates.

The limiting salt can be determined from the solubility products of potential limiting salts and the actual feed stream water quality, as shown Eq. (11-67).

$$\begin{aligned}
 A_n B_m &\leftrightarrow nA^{+J} + mB^{-K} \\
 K_{s0} &= (A^{+J})^n (B^{-K})^m \\
 K_c &= \left(a \frac{A^{+J}}{x} \right)^n \left(b \frac{B^{-K}}{x} \right)^m
 \end{aligned}
 \tag{11-67}$$

where a is the fraction of cation retained and b the fraction of anion retained.

Ionic strength must also be considered in these calculations, because the natural concentration of the feed stream during the membrane process increases the ionic strength which affects solubility and recovery. Calcium carbonate scaling is commonly controlled by sulfuric acid addition; however, sulfate salts are often the limiting salt. Commercially available scale inhibitors can prevent scaling by complexing metal ions and preventing precipitation. Specific scale inhibitor formulas are proprietary, but phosphates, silicates, and other materials commonly used for corrosion control also help with scaling control. Scale inhibitors are not toxic, but they can add significant nutrients for biogrowth in the feed stream and in the concentrate stream after discharge. Equilibrium constants for these scale inhibitors are not available, preventing direct calculations. However, some manufacturers provide computer programs for estimating the required scale inhibitor doses for given recovery, water quality, and membrane parameters. General formulas for the ionic strength and activity coefficient approximations are given in Eqs. 11-68 and 11-69; see Chap. 3 for additional coverage of ionic strength.

$$I = 0.5 \sum C_i Z_i^2 \approx (2.5 \times 10^{-5})(\text{TDS}) \tag{11-68}$$

where I is the ionic strength, C in moles/L, Z the ion charge, and TDS in mg/L.

$$\log \gamma \approx -0.5Z^2 \frac{\sqrt{I}}{1 + \sqrt{I}} \tag{11-69}$$

where γ is the activity coefficient.

Example 11-7 Limiting Salt

A limiting salt calculation is provided in Table 11-10. Rejection of ions varies by operating conditions, membrane type, molecular weight, and charge. The solubility product has been modified by a and b coefficients, as shown in Eq. 11-67, for consideration of less-than-complete rejection. A 0.90 rejection is assumed for divalent ions. A more exact estimate of the fraction rejected can be obtained from the manufacturer's literature or pilot studies. A raw-water quality is given with the solubility products of limiting salts at 25°C. The limiting salt is identified by determining which salt allows the least recovery or minimizes $1 - x$. The solubility levels of all possible salts are considered here. The first calculations demonstrate supersaturation of both CaCO_3 and BaSO_4 . This conclusion is suggested by the negative decimal fraction for r ; a positive r would indicate the fraction of the feed stream that could be recovered. Although recovery seems impossible, when ionic strength is considered, the allowable recovery rises to 60 percent. CaCO_3 precipitation will be controlled by acid addition.

Solution Using Eq. 11-67,

if $\text{Ca}^{2+} = 8 \text{ mg/L} = 0.0002 \text{ M}$

$$\text{CO}_3^{2-} = \text{HCO}_3^- \frac{\alpha_2}{\alpha_1} = \text{HCO}_3^- \frac{K_2}{H^+} = 0.00005 \text{ M} = 3 \text{ mg/L}$$

then $\left[\frac{0.0002}{X} \right] \left[\frac{0.00005}{X} \right] = 10^{-8.3}$

$$X = 1.41 \text{ L}$$

$$r = 1 - X = -0.41 \text{ L}$$

Using Eq. 11-67,

if $\text{Ba}^{2+} = 0.04 \text{ mg/L} = 3 \times 10^{-7} \text{ M}$

$$\text{SO}_4^{2-} = 79 \text{ mg/L} = 0.0008 \text{ M}$$

then $\left(\frac{3 \times 10^{-7}}{X} \right) \left(\frac{0.0008}{X} \right) = 10^{-9.7}$

$$X = 1.09 \text{ L}$$

$$r = 1 - X = -0.09 \text{ L}$$

The following calculations demonstrate the effect of ionic strength on recovery for the BaSO_4 example, approximated for brevity. Recovery increases because the increasing TDS boosts the ionic strength, which increases the solubility of the limiting salt at equilibrium. Iteration using the adjusted solubility product allows convergence of the recovery calculation, as illustrated in the example. The recovery is observed to increase from 0 to 72 percent when ionic strength is used following iteration.

$$\text{TDS} = \left(\frac{0.8}{0.4} \right) 2200 = 4400 \text{ mg/L}$$

Using Eq. 11-68,

$$I = (2.5 \times 10^{-5}) \text{TDS} = 0.11$$

Using Eq. (11-69),

$$\log \gamma = -0.5(2)^2 \frac{\sqrt{0.11}}{1 + \sqrt{0.11}} \log \gamma = pk_{s0} - (m)p\gamma - (n)p\gamma = 9.77 - (2)0.50 - (1)0.50 = 8.7$$

Recalculate x from Eq. (11-67).

$$K_c = \left[a \left(\frac{A^{+m}}{X} \right) \right] n \left[b \left(\frac{B^{-n}}{X} \right) \right] m = \left[(0.9) \frac{3 \times 10^{-7}}{X} \right] \left[(0.9) \frac{0.0008}{X} \right] = 10^{-8.7}$$

$$X = 0.31 \text{ L}$$

$$r = 1 - X = 0.69 \text{ L or } 69\%$$

Iterate calculations from the beginning but use 0.31 for X in place of 0.4 to determine new TDS concentration in concentrate stream. After two iterations the recovery converges at 72 percent. ▲

TABLE 11-10 Limiting Salt Example

Raw water quality used for example 11-7				Salts to consider	
Parameter	Conc. (mg/L)	Parameter	Conc. (mg/L)	Salt	pK_{s0} @ 25°C
pH	8.0	Cl ⁻	730	CaCO ₃	8.3
Na ⁺	695	NO ₃ ⁻	0	Ca ₃ (PO) ₄	6.8
K ⁺	8	F ⁻	1.1	CaF ₂	10.3
Ca ⁺²	8	SO ₄ ⁻²	79	CaSO ₄	4.7
Mg ⁺²	2	O-PO ₄	0.7	BaSO ₄	11.7
Fe ⁺²	0.5	HCO ₃ ⁻	631	SrSO ₄	6.2
Mn ⁺²	0.02	SiO ₂	24	SiO ₂	2.7
Cu ⁺²	0	TDS	2200		
Ba ⁺²	0.04				

Example 11-8 Acid Addition

Acid is usually added to allow CaCO₃ recovery to the limiting salt recovery, as illustrated in the example. The equilibrium constants for the carbonate system, alkalinity, pH, calcium, and recovery are required to make these calculations. In the example, pH 7.18 was required to avoid scaling by CaCO₃. Addition of 162 mg/L H₂SO₄ produces this pH. The additional sulfate from acid addition should be considered for calculating the limiting salt recovery.

Solution

1. Determine the pH required on the feed side of membrane.

Given

$$\text{Ca}^{2+} = 8 \text{ mg/L} \quad \text{HCO}_3^- = 631 \text{ mg/L} \quad \text{pH} = 8.0$$

$$R = 75\% \quad I = 0.12 \text{ M}$$

$$K_{s0} = [\text{Ca}^{2+}][\text{CO}_3^{2-}] = 10^{-8.3}$$

$$\log \gamma = -0.5(1)^2 \frac{\sqrt{0.12}}{1 + \sqrt{0.12}} = -0.13$$

$$p\gamma_{+f-1} = 0.13$$

$$p\gamma_{+f-2} = 0.51$$

$$pK_c = pK_{s0} - (m+n)p\gamma = 8.3 - 1(0.51) - 1(0.51) = 7.31$$

$$K_c = \left(a \frac{(A^{+m})}{x} \right) n \left(b \frac{(B^{-n})}{x} \right) m = \left((0.9) \frac{[\text{Ca}^{2+}]}{x} \right) \left((0.9) \frac{[\text{CO}_3^{2-}]}{x} \right) = 10^{-7.31}$$

$$\text{Ca}^{2+} = \frac{8}{40000} = 0.00002 \text{ M}$$

$$K_2 = \frac{[H^+][CO_3^{2-}]}{[HCO_3^-]} = 10^{-10.3}$$

$$K_2 = \frac{[H^+][\gamma_2 CO_3^{2-}]}{[\gamma_1 HCO_3^-]} pK_{c2} = pK_2 + p\gamma_1 - p\gamma_2 = 10.3 + 0.13 - 0.51 = 9.92$$

$$CO_3^{2-} = \frac{[K_{c2}][HCO_3^-]}{[H^+]} = \frac{[10^{-9.92}][631 / 61000]}{[H^+]} = \frac{10^{-11.9}}{[H^+]}$$

Going back to the preceding equation for K_c ,

$$K_c = \left(a \frac{(A^{+m})}{x} \right) n \left(b \frac{(B^{-n})}{x} \right) m = \left((0.9) \frac{[Ca^{2+}]}{x} \right) \left((0.9) \frac{[CO_3^{2-}]}{x} \right) = 10^{-7.31}$$

$$K_c = \left((0.9) \frac{[Ca^{2+}]}{0.225} \right) \left((0.9) \frac{[CO_3^{2-}]}{0.25} \right)$$

$$K_c = \left((0.9) \frac{[0.0002]}{0.03} \right) \left((0.9) \frac{[10^{-11.9}]}{[H^+]} \right) = \left(\frac{0.9}{0.03} \right)^2 (0.0002) \frac{10^{-11.9}}{[H^+]} = 10^{-7.31}$$

$$[H^+] = 10^{-7.78}$$

$$pH = 7.18$$

The calculations determined the pH that will not scale calcium carbonate at 75 percent recovery. The example assumed 90 percent rejection of calcium and carbonate ions. This calculation is approximate, but it does illustrate the effect of ionic strength and the control of calcium carbonate solubility by adjusting pH. Control of calcium carbonate solubility is required in almost every RO/NF plant that treats groundwater. Once the required pH has been determined for calcium carbonate scaling, the required acid dose can be calculated.

- Determine the dose of H_2SO_4 required to achieve pH 7.18.

$$K_1 = \frac{[H^+][\gamma HCO_3^-]}{[H_2CO_3]} = 10^{-6.3}$$

$$pK_{c1} = pK_1 - p\gamma$$

$$\log \gamma = -0.5(1)^2 \frac{\sqrt{0.12}}{1 + \sqrt{0.12}} = -0.13$$

$$p\gamma = 0.13$$

$$pK_{c1} = pK_1 - p\gamma = 6.3 - 0.13 = 6.17$$

$$K_{c1} = \frac{[H^+][HCO_3^-]}{[H_2CO_3]} = 10^{-6.17} = \frac{[10^{-7.18}][(0.9/0.25)(631/61000) - X]}{[0 + XX]}$$

where X is the H^+ needed to react with HCO_3^- .

$$10^{-6.17} X = 10^{-7.18} X + 10^{-8.61}$$

solve for X and convert to an equivalent amount of sulfuric acid.

$$X = 0.0033 \frac{M}{L} H^+ = \frac{(0.0033 \times 98000)}{2} = 162 \text{ mg/L } H_2SO_4$$

This is the H_2SO_4 that needs to be added in the last element of the last element of the last stage. Consequently, this concentration is reduced by $(0.25)(162) = 40.5 \text{ mg/L}$ to determine feed stream H_2SO_4 addition. ▲

Scale Inhibitor Manufacturers' Programs. Scale inhibitors can also be used to determine allowable recovery. Manufacturers provide computer programs to help with estimating recovery. Most scale inhibitors work by complexing or dispersing metal cations, making them unavailable for precipitation. Polyacrylic acid (PAA), one common scale inhibitor, interferes with nucleation and crystal growth. Unfortunately, the equilibrium constants are not available, and the predicted recoveries cannot be checked. However, scale inhibitors certainly work, as they are used worldwide in membrane plants to increase recovery. Many membrane plants combine sulfuric acid and scale inhibitor pretreatment. For example, even though BaSO_4 can be 608 percent oversaturated in a feedwater, a computer evaluation will render a recommended inhibitor dose of 4.2 mg/L to control scaling. These manufacturer programs can be used to predict the saturation percentages of selected salts and the doses required to control scaling, but they do not give the exact requirements for a particular membrane. That judgment reflects a design choice, as all scaling could possibly be controlled by scale inhibitor addition, and often requires site-specific investigations to confirm design and operation criteria. Scale inhibitors are typically more costly than acid based on mass, but they cost less than acid in use. Scale inhibitors commonly lose effectiveness if they react preferentially with metals other than the limiting salt metals. High iron concentrations sometimes greatly decrease the effectiveness of certain scale inhibitors, and dispersant formulations are then often recommended. These factors and others point out the need for pilot studies.

Static Microfiltration. Static microfilters typically used for RO/NF pretreatment are sieving filters made of polypropylene with pore diameters of 5 to $20 \mu\text{m}$. The pretreatment microfilters have larger pores than the continuous MF membranes. The pressure drop through a microfilter does not usually exceed 34.5 kPa (5 psi) in nanofiltration applications and 68.9 kPa (10 psi) in reverse osmosis applications. Microfiltration upstream of a nanofiltration or reverse osmosis process protects only against foulants or materials in the solid phase. The technology offers no protection against scaling. Also, microfiltration alone cannot remove foulants from a feed stream with a high turbidity or suspended solids concentration. Generally, the size distribution of the foulants removed in this way includes particles with diameters smaller than the microfilter pore sizes. Consequently, a maximum value for the feed-stream fouling indexes is specified prior to microfiltration. A microfilter in a reverse osmosis or nanofiltration process should be thought of as a means of protecting the membrane elements against periodic upsets from failure of solids removal processes or sand entrainment from well pumping.

Array Models

This section describes different models and design techniques used to size arrays of membrane elements. A linear solution diffusion model, a film theory solution diffusion model, and a coupling model are described. Single and multistaged array equations for predicting permeate water quality are developed, and a simple design example is presented.

Linear Solution Diffusion Model. Many different theories and models attempt to describe mass transfer in diffusion-controlled membrane processes. However, a few basic principles or theories are used to develop most of these models: convection, diffusion, film theory, and electroneutrality. These principles or theories could be used to group models

FIGURE 11-30 Basic diagram of mass transport in a membrane.

into linear diffusion models, exponential diffusion models, and coupling models. Most of the modeling efforts have been developed using very small test cells. Also, they have not incorporated product recovery, limiting their practical use. The basic equations used to develop these models are shown in Eqs. 11-70 through 11-74. The standard membrane element configuration is shown in Fig. 11-30.

$$J = k_w (\Delta P - \Delta \Pi) = \frac{Q_p}{A} \quad (11-70)$$

$$J_i = k_i \Delta C = \frac{Q_p C_p}{A} \quad (11-71)$$

$$r = \frac{Q_p}{Q_f} \quad (11-72)$$

$$Q_f = Q_c + Q_p \quad (11-73)$$

$$Q_f C_f = Q_c C_c + Q_p C_p \quad (11-74)$$

where

J = water flux (L^3/L^2t)

J_i = solute flux (M/L^2t)

k_w = solvent mass transfer coefficient (L^2t/M)

k_i = solute mass transfer coefficient (L/t)

r = recovery

Q_f, Q_p = feed flow rate, permeate flow rate (L/t) (respectively)

$C_f, C_p,$ and C_c = feed concentration, permeate concentration and concentrate concentration (M) (respectively)

If ΔC is defined as the difference of the average feed and brine stream concentrations and the permeate stream concentration, then Eq. 11-75 can be derived from Eqs. 11-70 and 11-74. This model can be described as a linear homogenous solution-diffusion model in that it predicts diffusion-controlled solute flow and pressure-(convection)-controlled solvent flow. Eq. 11-75 can be simplified by including a Z term that incorporates the effects of the mass transfer coefficients, pressure, and recovery into a single term.

$$C_p = \frac{k_i C_f}{k_w (\Delta P - \Delta \Pi) \left(\frac{2-r}{2-r} \right) + k_i} = Z_i C_f \quad (11-75)$$

where Z is the combined mass transfer term and r the recovery.

This is the simplest model, but it does incorporate the effects of five independent variables on permeate water quality, as shown in Fig. 11-31. If pressure increases and

REVERSE OSMOSIS AND NANOFILTRATION

FIGURE 11-31 Sodium permeate concentration for varying pressure and recovery. (Source: Duranceau, 1990.)

all other variables are held constant, then the permeate concentration will decrease. If recovery is increased and all other variables are held constant, then the permeate concentration increases. These effects may be hard to realize if an existing membrane array is considered. It is impossible in such an environment to increase pressure without increasing recovery. However, array designs can increase pressure without varying recovery. Decreasing feed stream concentration may identify pretreatment as an option for decreasing the permeate stream concentration. Different membranes may have different mass transfer characteristics. Using a membrane with a lower molecular weight cutoff would probably decrease the permeate concentration, although the solvent and solute MTCs must be considered before such a result can be expected.

Film Theory Model. The linear model for array design can be modified by the incorporation of film theory, which assumes that the solute concentration exponentially increases from the center of the feed stream channel toward the surface of the membrane and diffuses

back into the bulk stream. Mathematically, this is shown in Eq. 11-76, and the back diffusion constant is introduced in Eq. 11-77.

$$J_i = -D_s \frac{dC}{dx} + C_i J \quad (11-76)$$

$$\left(\frac{C_s - C_p}{C_b - C_p} \right) = \exp \left(\frac{J}{k_b} \right) \quad (11-77)$$

where x is the path length or film thickness, $k_b = D_s/x$ is the diffusion coefficient from the surface to the bulk.

Incorporation of Eq. 11-77 into Eqs. 11-70 through 11-74 results in Eq. 11-78, which is a development of the homogenous solution diffusion model using concentration-polarization. This model predicts a higher concentration at the membrane surface than in the bulk of the feed stream. Such an effect is documented in the literature (Sung, 1993; Hofman, 1995), and the model in Eq. 11-78 accounts for this phenomenon. The back-diffusion coefficient k_b represents solute diffusion from the membrane surface to bulk in the feed stream which is different than the mass transfer coefficient k_w , which represents solute diffusion through the membrane to the permeate stream.

$$C_p = \frac{C_f k_i e^{jk}}{k_w (\Delta P - \Delta \Pi) \left(\frac{2-2r}{2-r} \right) + k_i \exp \left(\frac{J}{k_b} \right)} \quad (11-78)$$

Solutions are electrically neutral according to the principles laid out in Chap. 3. Therefore, solutes do not pass through a membrane in a charged state but in a coupled state. Such electroneutrality is observed in diffusion-controlled membrane processes when the permeate streams become more concentrated than the feed streams. Relatively high concentrations of sulfates have been observed to increase rejection of calcium and decrease rejection of chlorides. One interpretation of such observations suggests that the strong calcium sulfate couple is retained in the feed stream and the weaker sodium chloride couple is forced to pass through the membrane to maintain equilibrium.

Coupling. The coupling effect on mass transfer through membranes has been modeled using a statistical modification of free energy for single-solute systems as shown in Eq. 11-79 (Rangarajan, 1976; Sung, 1993). The free-energy term is assumed to be different in the bulk solution and at the membrane surface because of a difference of ion concentration. Consequently, the energy required to bring the ions to the surface, shown in Eq. 11-80, is the difference of the free energy in bulk and surface solutions. The $\Delta \Delta G$ value for each ion is determined by experiment.

$$\frac{1}{\Delta G} = -\frac{1}{E} r - \frac{\Delta}{E} \quad (11-79)$$

$$\Delta \Delta G = \Delta G_I - \Delta G_B \quad (11-80)$$

where ΔG is the free energy of coupled ion, E a solution-dependent constant, a a coupled ion radius, Δ a statistical constant, and $\Delta \Delta G$ a difference of coupled ion free energy at interface (I) and bulk (B).

Membrane-specific solute mass transfer coefficients for single-solute systems have been determined by experiment. They are related to free energy as indicated by Eq. 11-81. Once the membrane specific constant $\ln(C^*)$ has been determined for a reference solute (e.g., NaCl), it is possible to determine k_s for any given solute in a single-solute system.

Once k_s is known, the mass transport of any single solute in a diffusion-controlled membrane can be predicted.

$$\ln(k_i) = \ln(C^*) + \sum \left(-\frac{\Delta\Delta G}{RT} \right) \quad (11-81)$$

where C^* is the membrane specific constant.

Coupling can be used to model mass transport in a multisolute system. As with the single-solute system, electroneutrality is assumed in all phases (bulk, surface, permeate, film). A coupling model can incorporate either a homogenous or an exponential solution-diffusion model with the free-energy model. The model requires the mass transfer coefficients for water and a reference couple, the back-transfer coefficient and the $\Delta\Delta G$ values for all ions to predict flux, and the concentration of the permeate stream. The mass transfer models shown in Eqs. 11-39 and 11-40 can both be used as coupling models as long as the k_i term is determined using $\Delta\Delta G$ or feed stream solute composition. However, this term is membrane-specific and must be determined for a given product. No model accounts for the effects of the membrane surface on a fundamental basis.

The determination of $\Delta\Delta G$ is based on free energy and is therefore affected by feed stream composition. The determination of free energy for any given reaction is a good method of determining the likelihood that the reaction will proceed, but this method relies on consideration of all the free energies for the major chemical interactions. As the solutes and free energies are not known for many of the constituents in natural waters, a basic free-energy model has not been developed for practical membrane design.

Array Modeling. The design process for membrane element arrays will be illustrated using the linear model for simplicity and to take advantage of a membrane manufacturer's computer program. The mass transfer coefficients for the linear model can be developed from field criteria, and the model can easily be used to predict permeate water quality for given changes in operation. Variations in sodium permeate concentration are shown in Fig. 11-31 for varying pressures and recoveries. Reverse osmosis and nanofiltration processes allow considerable flexibility in permeate water quality. Designers can vary flux and recovery to achieve water quality goals. Anyone involved in the design or operation of a membrane facility should be aware of the coupling phenomena and concentration-polarization. The mass transfer coefficients for the film theory model are more difficult to develop, but they have been shown to increase accuracy of pilot plant data. However, the best design criteria would come from site-specific pilot studies. Pilot studies may not be required for systems to desalinate some brackish waters with low organic concentration and no potential foulants, but many physical, chemical, and biological factors not initially recognized can cause serious operational problems. The only way to avoid these types of unrealized problems in design is to conduct a pilot study.

Modeling a Linear Array. Equations 11-75 and 11-78 are useful tools for determining the effect of pressure gradient (ΔP), feed concentrate (C_f), recovery (r), osmotic pressure ($\Delta\Pi$), k_w , and k_i on permeate stream solute concentration (C_p) without experimentation if the six variables are known. The first four can be accurately assumed by the user. However, k_w and k_i should be measured experimentally for a given membrane and source; they can be taken from the literature if reports describe a given membrane and a similar source. In Eq. 11-82, Z_i states a modified MTC, which represents the effect of solvent mass transfer, solute mass transfer, recovery, and pressure on permeate stream concentration for any single membrane element. In this way, the expression simplifies Eq. 11-75. If Eq. 11-78 were used, the modified MTC would be represented by Z_{cpi} , which would include consideration of back-diffusion.

$$C_{p,i} = \frac{k_{i,i} C_{f,i}}{k_{w,i} \Delta P_i \left(\frac{2-2r_i}{2-r_i} \right) + k_{i,i}} = Z_i C_{f,i} \quad (11-82)$$

where Z_i is the modified mass transfer coefficient, and $\Delta P_i = \Delta P - \Delta \Pi =$ net average driving pressure including hydraulic losses.

The subscript i in Eq. 11-82 denotes any stage in a multistage membrane array. Membrane systems are configured in arrays that consist of stages. Consequently, Eq. 11-82 can be expanded to describe an entire membrane system. The configuration for a typical two-stage membrane system is shown in Fig. 11-32. The first stage consists of two pressure vessels, each of which typically contains six membrane elements. The second stage consists of one pressure vessel, also typically with six elements. The combination of these two stages is a 2-1 array. The model can be used to predict the system's permeate concentration or the effects of any of the six independent variables on permeate concentration if MTCs, pressures, and recoveries for each stage are known.

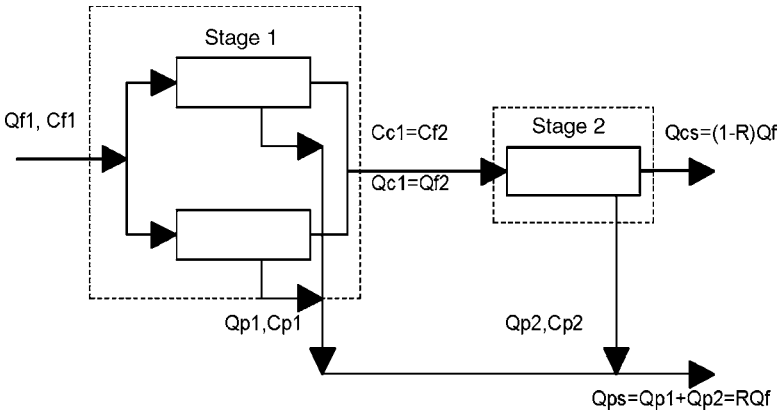

FIGURE 11-32 One array (two-stage) membrane system.

As noted in Fig. 11-32, the Stage 2 feed stream flow and concentration always equals the Stage 1 concentrate stream flow and concentration in a high-recovery system for potable water treatment. The interstage flow and solute concentration in a multiple-array membrane system can be related by an interstage mass balance, as shown in Eqs. 11-83 through 11-86. The resulting X_i term is used in Eq. 11-86 to determine the feed stream concentration for any stage from the initial feed stream concentration. It can be considered a concentration factor of Stage i .

$$C_{c,i} = \frac{Q_{f,i} C_{f,i} - Q_{p,i} C_{p,i}}{Q_{c,i}} = \frac{C_{f,i} - r_i C_{p,i}}{1 - r_i} \quad (11-83)$$

$$C_{c,i} = C_{f,i+1} = C_{f,i} \left(\frac{1 - Z_i r_i}{1 - r_i} \right) \quad (11-84)$$

$$C_{c,i} = X_i C_{f,i} \quad (11-85)$$

$$X_i = \frac{1 - Z_i r_i}{1 - r_i}; \quad \text{Define } X_0 \equiv 1 \quad (11-86)$$

Consequently an interstage equation for permeate concentration can be developed by interrelating all stages in any diffusion-controlled membrane system. Equation 11-87 interrelates

all stages in a simple, flow-weighted concentration equation that represents the total solute mass from the permeate stream in each stage, shown in the numerator of Equation 11-87, and the total volume of solvent from the permeate stream in each stage, shown in the denominator. Equation 11-88 is less complex than an expression incorporating the full Z_i and X_j terms, as shown in Eq. 11-87. This equation can be used to describe membrane system performance with as much versatility as Eq. 11-75 or Eq. 11-78, which describes a single stage or element. The subscripts j and i denote the stage number in a multistage membrane array as shown in Eq. 11-88.

$$C_{p,\text{system}} = \frac{C_f \sum_{i=1}^n \left[A_i k_{i,i} \Delta P_i \frac{k_{i,i}}{k_{w,i} \Delta P_i \left(\frac{2-2r_i}{2-r_i} \right) + k_{i,i}} \prod_{j=0}^{i-1} \frac{1 - \frac{k_{i,j} r_j}{k_{w,j} \Delta P_j \left(\frac{2-2r_j}{2-r_j} \right) + k_{i,j}}}{1 - r_j} \right]}{\sum_{i=1}^n A_i k_{w,i} \Delta P_i} \quad (11-87)$$

$$C_{p,\text{system}} = \frac{C_f \sum_{i=1}^n \left(A_i k_{i,i} \Delta P_i Z_i \prod_{j=0}^{i-1} X_j \right)}{\sum_{i=1}^n A_i k_i \Delta P} \quad (11-88)$$

In Eq. 11-88, the term $\prod_{j=0}^{i-1} X_j$ is the product of the concentration factors of all stages

before Stage i . The concentration factor is therefore mathematically defined as 1 before Stage 1 ($X_0 = 1$) (Duranceau, 1992).

The exponent J/k_b used in the film theory model, as shown in Eq. 11-77, can be approximated by a constant times the ratio of the flow through the membrane to the flow across the membrane, as shown in Eq. 11-89. This expression approximates the compensation for the effects of multisolute solutions in a high-recovery or plant application.

$$\frac{J}{k_b} = k \left(\frac{r_e}{1 - r_e} \right) \quad (11-89)$$

where k_b is a statistically derived coefficient, and r_e the average membrane recovery per element.

The system permeate equation can also be modified to incorporate the film theory model, as shown in Eqs. 11-90 and 11-91.

$$C_p = \frac{k_i e^{\frac{J}{k_b}} C_f}{k_w (\Delta P - \Delta \Pi) \left(\frac{2-2r}{2-r} \right) + k_i e^{\frac{J}{k_b}}} = Z_{i,cp} C_f \quad (11-90)$$

$$C_{p,\text{system}} = \frac{C_f \sum_{i=1}^n \left(A_i k_{w,i} \Delta P_i Z_{i,cp} \prod_{j=0}^{i-1} X_{j,cp} \right)}{\sum_{i=1}^n A_i k_{w,i} \Delta P_i} \quad (11-91)$$

where $Z_{i,cp}$ is the modified film theory feedstream mass transfer coefficient, and $X_{j,cp}$ the modified film theory concentrate stream concentration factor.

Practical Array Design

Membranes are typically incorporated in elements, as mentioned early in the chapter. Unfortunately, the terms in Table 11-1 are not universally accepted, and meanings vary. For example, a membrane *array* can be defined as Stage 1, or as the total of Stages 1, 2, and 3. Care must be taken to ensure that parties discussing membrane systems are using the same terminology.

Example 11-9 Simple Sizing

This example assumes a simplistic 4-2-1 array to illustrate design concepts for membrane configurations. Basic assumptions in this design are 20 cm (8 in.) diameter membrane elements with 32.5 m² (350 ft²) surface areas operating at a flux of 0.6 m³/m²/day (15 gsf/d) and a 75 percent recovery. One element produces 19.9 m³/d (5250 gpd). As seven elements are in each pressure vessel, and seven pressure vessels are in one array, an array will produce approximately 946.4 m³/d (250,000 gpd). Four such arrays provide 3785 m³/d (1 mgd) of permeate and 1249 m³/d (0.33 mgd) of concentrate. Note that osmotic pressure, not illustrated, would continuously decrease the recovery in each succeeding element.

Assumptions

1. Membrane element flux = 0.6 m³/m²/day (15 gal/ft²-day)
2. Design for a 4-2-1 array
3. Each pressure vessel can contain 6 to 8 elements
4. Element surface area = 32.5 m² (350 ft²)
5. Recovery = 75 percent

Solution Water 1 element can produce

$$Q_p = JA = \left(0.6 \frac{\text{m}^3}{\text{m}^2 \text{day}}\right) \left(32.5 \frac{\text{m}^2}{\text{element}}\right) = 19.5 \frac{\text{m}^3}{\text{day element}} \left(5150 \frac{\text{gal}}{\text{day element}}\right)$$

Number of elements on one array

$$\left(7 \frac{PV}{\text{array}}\right) \left(7 \frac{\text{elements}}{PV}\right) = 49 \frac{\text{elements}}{\text{array}}$$

Gallons per day produced per array

$$\left(19.5 \frac{\text{m}^3}{\text{day element}}\right) \left(49 \frac{\text{elements}}{\text{array}}\right) = 955.5 \frac{\text{m}^3}{\text{array day}} \left(252,400 \frac{\text{gal}}{\text{array day}}\right)$$

Trains needed to supply 3786 m³/day (1 mgd)

$$\left(3786 \frac{\text{m}^3}{\text{day}}\right) \left(\frac{\text{array day}}{955.5 \text{ m}^3}\right) = 3.96 \text{ arrays}$$

Total number of elements needed

$$(4 \text{ arrays}) \left(49 \frac{\text{elements}}{\text{array}}\right) = 196 \text{ elements}$$

Flow in and out of one array

$$Q_f = \frac{Q_p}{r} = \frac{3786 \text{ m}^3/\text{day}}{0.75} = 5048 \text{ m}^3/\text{day}$$

Flow in per array

$$\frac{5048 \text{ m}^3/\text{day}}{4} = 0.88 \text{ m}^3/\text{min}$$

Flow out per array

$$\frac{3786 \text{ m}^3/\text{day}}{4} = 0.66 \text{ m}^3/\text{min} \quad \blacktriangle$$

The film theory model can be used to estimate permeate water quality. In the following example, MTCs were determined from a pilot study or given by the membrane manufacturer. The concentration-polarization factor is also given. The example calculation shows the chloride concentrate in the permeate stream from each stage and the array (Hofman et al., 1993).

Example 11-10 Predicting RO Permeate Concentration

The film theory model can be used to estimate permeate water quality. In this example, mass transfer coefficients were determined from a pilot study or given by the membrane manufacturer. The concentration-polarization factor is also given. The example calculation shows the chloride concentrate in the permeate stream from each stage and the array (Hofman et al., 1993).

This example assumes a simplistic 2-1 array to illustrate design concepts for membrane configurations. Basic assumptions in this design are six elements per pressure vessel with an element surface area (SA) of 30 m^2 (323 ft^2). There are five bars of driving force. The feed concentration C_f is 100 mg/L . For this particular system, pilot studies have shown that the mass transfer coefficient of water k_w is equal to $1.46 \times 10^{-6} \text{ m/s-bar}$ (0.2135 gsfd/psi), and the mass transfer coefficient of the solute k_i is equal to $1.87 \times 10^{-6} \text{ m/s}$ (0.53 ft/day). The concentration-polarization factor or mass transport coefficient k is equal to 0.75 . The recovery of the system r is 0.5 , and the average membrane recovery per element r_e is equal to 0.083 per element.

Given

1. 2-1 array with six elements/vessel
2. Element SA = 30 m^2 (323 ft^2)
3. $P =$ five bars
4. $k_w = 1.46 \times 10^{-6} \text{ m/s-bar}$ (0.2135 gsfd/psi)
5. $k_i = 1.87 \times 10^{-6} \text{ m/s}$ (0.53 ft/day)
6. $k = 0.75$
7. $r = 0.5$
8. $r_e = 0.083/\text{element}$

Solution Using the array film theory model, Eq. 11-91,

$$C_{p,\text{system}} = \frac{C_f \sum_{i=1}^n \left(A_i k_{w,i} \Delta P_i Z_{i,cp} \prod_{j=0}^{i-1} X_{j,cp} \right)}{\sum_{i=1}^n A_i k_{w,i} \Delta P_i}$$

First calculate the stage permeate flow given as $A_i k_{w,i} \Delta P_i$.

$$\begin{aligned} \sum_{i=1}^2 A_i k_{w,i} \Delta P_i &= (\text{Stage 1}) \left(\frac{2 \text{ vessels}}{\text{Stage 1}} \right) \left(\frac{66 \text{ elements}}{\text{vessel}} \right) \left(\frac{30 \text{ m}^2}{\text{element}} \right) \left(\frac{1.46 \times 10^6 \text{ m}}{\text{s-bar}} \right) (5 \text{ bar}) \\ &+ (\text{Stage 2}) \left(\frac{1 \text{ vessels}}{\text{Stage 2}} \right) \left(\frac{6 \text{ elements}}{\text{vessel}} \right) \left(\frac{30 \text{ m}^2}{\text{element}} \right) \left(\frac{1.46 \times 10^6 \text{ m}}{\text{s-bar}} \right) (5 \text{ bar}) \\ &= 2.628 \times 10^{-3} \frac{\text{m}^3}{\text{s}} + 11.314 \times 10^{-3} \frac{\text{m}^3}{\text{s}} = 3.942 \times 10^{-3} \frac{\text{m}^3}{\text{s}} (89999 \text{ gal/day}) \end{aligned}$$

Next, calculate the modified film theory feed stream mass transfer coefficient, $Z_{i,cp}$, using Eq. 11-90,

$$C_p = \frac{k_i e^{k_b} C_f}{k_w (\Delta P - \Delta \Pi) \left(\frac{2-2r}{2-r} \right) + k_i e^{k_b}} = Z_{i,cp} C_f$$

According to Eq. 11-89,

$$\frac{J}{k_b} = k \left(\frac{r_e}{1-r_e} \right)$$

Assume $(\Delta P - \Delta \Pi)$ is equal to the given pressure (five bars). Plugging in Eq. 11-89 into Eq. 11-90 and solving for $Z_{i,cp}$, you obtain

$$\begin{aligned} Z_{i,cp} &= \frac{k_{s,i} e^{k \left(\frac{r_e}{1-r_e} \right)}}{k_{w,i} \Delta P_i \left(\frac{2-2r_i}{2-r_i} \right) + e^{k \left(\frac{r_e}{1-r_e} \right)} k_{s,i}} = Z_1 = Z_2 \\ Z_1 = Z_2 &= \left(\frac{\left(1.87 \times 10^{-6} \frac{\text{m}}{\text{s}} \right) e^{0.75 \left(\frac{0.083}{1-0.083} \right)}}{\left(1.46 \times 10^{-6} \frac{\text{m}}{\text{s bar}} \right) (5 \text{ bar}) \left(\frac{2-2(0.5)}{2-0.5} \right) + \left(11.8 \times 10^{-6} \frac{\text{m}}{\text{s}} \right) e^{0.75 \left(\frac{0.083}{1-0.083} \right)}} \right) = 0.29 \end{aligned}$$

Equation 11-86 can be used to solve for the concentration factor $X_{j,cp}$.

$$\prod_{j=0}^1 X_j = (1) \left(\frac{1-Z_1 r}{1-r} \right) = (1) \left(\frac{1-(0.29)(0.50)}{1-0.5} \right) = 1.71$$

Plug in the values obtained for stage permeate flow, modified film theory feed stream mass transfer coefficient, and concentration factor, as well as the feed stream concentration into Eq. 11-91.

$$\begin{aligned} C_{p,\text{system}} &= \frac{100 \frac{\text{mg}}{\text{L}} \left(2.628 \times 10^{-3} \frac{\text{m}^3}{\text{s}} \right) (0.29) + 100 \frac{\text{mg}}{\text{L}} \left(1.3114 \times 10^{-3} \frac{\text{m}^3}{\text{s}} \right) (0.29) (1.71)}{3.942 \times 10^{-3} \frac{\text{m}^3}{\text{s}}} \\ &= 19.33 \frac{\text{mg}}{\text{L}} + 16.53 \frac{\text{mg}}{\text{L}} = 35.86 \frac{\text{mg}}{\text{L}} \quad \blacktriangle \end{aligned}$$

Some comments will clarify this model application. The 5-bar feed stream pressure gradient through each stage has been assumed to include the effects of osmotic pressure and hydraulic losses. These effects can be estimated by assuming that 1 mg/L TDS produces 0.070 kPa (0.01 psi) of osmotic pressure, a 20.0 kPa (2.9 psi) pressure loss across each element, and a 34 kPa (4.93 psi) stage entrance loss. The hydraulic effects on pressure gradient are accounted for during design and typically controlled by high-pressure pumps and flow restrictors. The first stage and second stage Z terms are identical, because stage recovery, pressure gradient, and membranes are identical. The Z_1 term is used to calculate the X_2 term, as the Stage 1 concentrate stream is the Stage 2 feed stream. The denominator of Eq. 11-91 is the permeate flow produced by the two-stage system and is shown as the first calculation in the example application. The final calculation gives the system's permeate chloride concentration, estimated at 35.8 mg/L. The Stage 1 and Stage 2 chloride concentrations are 29.0 and 49.6 mg/L, respectively shown in the calculation of the flow-weighted system concentration. Since recovery, pressure, and membranes are identical from Stage 1 to Stage 2, the second stage permeate stream chloride concentration will always be higher than that in the first stage, because the feed stream chloride concentration is higher in Stage 2 (171 mg/L) than in Stage 1 (100 mg/L).

Membrane Manufacturers' Programs. Manufacturers such as Hydranautics, Toray, Koch (Fluid Systems), Dow-Filmtec, GE-Osmonics, and GE-Ionics provide computer programs for developing RO plant design criteria. These programs do not yield final design specifications, and no manufacturer accepts responsibility for their use by anyone not specifically authorized. These programs are only tools for developing and testing various system configurations, and their output should not be regarded as completed designs. The software can be used to project the performance of a specific membrane over a period of time, and are often used to guarantee performance warranties. The programs do provide a means of estimating water production and quality for given parameters. Feed flow rate, TDS concentration, feed temperature, recovery, array type (i.e., 4-2-1 array), number of elements per pressure vessel, and element type are typically required program inputs. Other process inputs could include permeate back-pressure or interstage booster pumping which will affect system design and performance. The program outputs typically include pressure, flux, flow, and water quality for all process streams by stage and element for each array. Scaling calculations are provided for calcium sulfate.

Posttreatment

The Need for Posttreatment. Posttreatment consists of several different unit operations for RO and NF membrane systems and are summarized in Table 11-11. A recent overview of the current state of 62 full-scale RO/NF plants conducted for plants greater than 3785 m³/day (1.0 MGD) of capacity, used for either seawater desalination, brackish-water desalination (including groundwater, surface water, and agricultural runoff), or wastewater reclamation provides an insight into posttreatment practices (Burbano 2007). All of the surveyed facilities reported using at least one posttreatment method for permeate conditioning and corrosion control. These included such methods as caustic addition (31 percent), blending with raw, semitreated, or finished water (29 percent), degasification–decarbonation (25 percent), and addition of corrosion inhibitor (14 percent). Most of the brackish-water RO plants responding to the survey reported using degasification–decarbonation and caustic addition, with the majority blending permeate with groundwater. Permeate disinfection was reported to be used by 85 percent of the surveyed facilities that responded, most of which used chlorine. Other reported disinfection methods included the use of chloramine (24 percent) and ultraviolet irradiation (4 percent).

TABLE 11-11 Typical Posttreatment Processes Based on Source Water

Supply type	Membrane process type(s)	Examples of applicable posttreatment processes
Seawater	RO	Recarbonation Lime addition Calcite bed filtration pH and/or alkalinity adjustment Addition of corrosion inhibitors Primary and secondary disinfection Blending with freshwater supplies
Brackish water (surface)	RO, NF, EDR	pH and/or alkalinity adjustment Addition of corrosion inhibitors Primary and secondary disinfection Blending with freshwater supplies
Brackish water (ground)	RO, NF, EDR	Decarbonation (degasification) Hydrogen sulfide stripping pH and/or alkalinity adjustment Addition of corrosion inhibitors Primary and secondary disinfection Blending with freshwater supplies Bypass blending with raw water supply
Fresh water (ground)	NF, EDR	Decarbonation Hydrogen sulfide stripping pH and/or alkalinity adjustment Addition of corrosion inhibitors Primary and secondary disinfection Blending with fresh water supplies Bypass blending with raw water supply

Desalinated waters are commonly blended with small volumes of more mineral-rich waters to improve their acceptability and particularly to reduce their aggressive attack on materials (WHO, 2004). Blending water should be fully potable; where seawater is used for this purpose, the major ions added are sodium and chloride. This does not contribute to improving hardness or ion balance, and only a small amount, no more than 3 percent, can be added without leading to problems of acceptability. Blended waters from coastal and estuarine areas may be more susceptible to contamination with petroleum hydrocarbons or algal toxins, which could give rise to taste and odor problems. Some groundwaters or surface waters, after suitable treatment, may be employed for blending in higher proportions and may improve hardness and ion balance. As noted by Fritzmann (2007), untreated permeate from sea- or brackish-water RO plants does not conform to the drinking water standards such as WHO Guidelines for Drinking Water Quality. Due to the low TDS values, RO permeate water can be unpalatable, corrosive, and unhealthy. Permeate must be rehardened in order to prevent corrosion of pipes in the distribution network, pH value and carbon dioxide content need to be adjusted for scaling prevention, and permeate water needs further disinfection.

Alkalinity depends mainly on the bicarbonate concentration, and for waters with $\text{pH} > 9$, it also depends on the carbonate, and hydroxide concentrations; see Chap. 3 for a presentation on alkalinity. According to Lahav and Birnhack (2007) for a given pH, the higher the alkalinity, the water has a greater acid-neutralizing capacity. Also, higher-alkalinity water means a higher dissolved inorganic carbon (DIC) concentration. However, too high an alkalinity at higher pH levels may accelerate lead and copper metal release (Duranceau

and Henthorne, 2004). Ruggieri and coworkers developed limestone selection criteria for EDR water remineralization (Ruggieri, 2008). Five commercially available limestones were characterized by mineralogical, chemical, and surface methods, including *scanning electron microscopy (SEM)*. The main criteria in selecting a limestone for EDR water remineralization are its compositional purity in terms of both mineralogy and chemistry, and its textural characteristics. The dominant mineral phase in the uncontacted limestones was calcite (CaCO_3), and included small amounts of dolomite ($\text{CaMg}(\text{CO}_3)_2$) and quartz (SiO_2) and trace levels of clay matter. In relation to mineralogical purity, it was recommended that the occurrence other than calcite should be avoided and that the use of SEM was a useful tool in evaluating surface texture influence on suspended particulate matter generation on consumption of the bed (calcite). Recarbonation refers to the process used to introduce inorganic carbon and alkalinity to produce a positive Langelier Saturation Index (LSI) to prevent corrosion in pipes; see Chap. 20 for discussion of corrosion and corrosion indices. Remineralization is a means of increasing the mineral content by addition to those which increase the bicarbonate or carbonate alkalinity of the desalinated water as stated by Withers (2005).

The steps chosen and their sequence depend on the designer's preferences and water-quality goals. The primary posttreatment unit operations are aeration, disinfection, and stabilization. Additional posttreatment operations of concern are removal of hydrogen sulfide, if present, and alkalinity recovery. A systems view of posttreatment can help a designer to realize important goals. The membrane process removes essentially all pathogens and the majority of the DBP precursors, salts, and other solutes in the feed stream. Solute removal eliminates inorganic carbonate alkalinity, but all dissolved gases including carbon dioxide and hydrogen sulfide pass through the membrane (Lovins, 2004). The designer must produce finished water after posttreatment with an appropriate alkalinity profile and disinfection without significant sulfur turbidity. Posttreatment water quality changes by unit operation are provided in Table 11-12 and are based on using the permeate stream water quality illustrated in the previous membrane section. The water quality resulting from each posttreatment unit operation is illustrated in the table.

TABLE 11-12 Posttreatment Water Quality Changes by Unit Operation

	Permeate, mg/L	Alkalinity recovery, mg/L	Aeration/stabilization, mg/L
pH	5.5	7.6	7.6
H_2CO_3	129 mg/L	6 mg/L	0.6 mg/L
HCO_3^-	0.8	122	122
H_2S as S	1	0	0
SO_4^{2-}	1.7	4.7	4.7
Cl^-	19.7	30.1	30.1
Ca^{+2}	4.1	50.9	50.9
TDS	34	79	79
DO	0	0	8.24 (25°C)
Cl_2	0	3	3

The changes in water quality will be discussed in the following sections. The sequence of unit operations assumed here are H_2S removal, alkalinity recovery, and aeration/stabilization. There are different sequences of posttreatment, but this sequence has the advantage of minimizing equipment, as H_2S removal, alkalinity recovery and aeration/stabilization are conducted simultaneously in separate unit operations.

Hydrogen Sulfide Removal. Many of the groundwaters used for feed streams to RO or NF plants contain hydrogen sulfide. Acid addition in the feed stream is common to avoid

calcium carbonate scaling in the permeate stream, and permeate pH is commonly between 5.5 and 6.5. While this measure prevents scaling, the acid addition converts dissolved sulfide to gaseous hydrogen sulfide. Neither the conventional pretreatment process (micro-filtration, acid, or antiscalant addition) nor the membrane process will remove hydrogen sulfide. Aeration and oxidation are the two primary means of removing hydrogen sulfide; however, the involved chemical reactions are not well defined. An often-neglected problem in the hydrogen sulfide removal processes is the formation of elemental sulfur. Elemental sulfur has been shown not to form during the chlorination of hydrogen sulfide if the reaction pH is less than 3.7; sulfate is the predominant reaction product at this pH. However, both entrained oxygen and chlorine will react with hydrogen sulfide to form elemental sulfur at pH levels above 4.0, as shown here.

The pK for hydrogen sulfide is 7, and H_2S gas can essentially be removed at pHs below 6.5 without turbidity formation in an air-stripping, packed tower process. Aeration using tray aerators is less efficient at hydrogen sulfide removal because there is less available surface area for air stripping, so that residual sulfide remains in the water allowing elemental sulfur to form due to oxygen oxidation. While the air-stripping, packed tower process generally will avoid sulfur formation, the CO_2 is also lost during the volatilization process. Consequently, unless a carbonate salt is added or a significant amount of alkalinity passes through the membrane, there will be no carbonate buffering in the finished water. The final pH can be increased by the addition of sodium hydroxide but the finished water will have very low buffering capacity and will be corrosive. A better application would be to increase the pH to 6.3 prior to packed tower, air stripping with calcium hydroxide or sodium hydroxide to recover 1 to 2 meq/L of alkalinity with minimal elemental sulfur formation. Ultimately, most plants rely heavily on air stripping with packed towers for H_2S removal rather than using chlorination for H_2S destruction.

Alkalinity Recovery. Alkalinity recovery becomes a consideration during scaling control. The addition of acid to the feed stream prior to membrane treatment will prevent scaling, but because of the decrease in pH, alkalinity in the form of bicarbonate (HCO_3^-) will be converted to carbon dioxide, and this will pass through the membrane. Membranes are a closed system, and the carbon dioxide will remain under pressure until exposed to an open system. Exposure to an open system occurs in the removal of hydrogen sulfide using aeration. Unless the pH is increased prior to aeration, the excess CO_2 will leave the system along with hydrogen sulfide and the alkalinity will be lost. In an alkalinity recovery system, the excess dissolved CO_2 is converted to alkalinity in the form of HCO_3^- by adding caustic downstream of permeate prior to air stripping with packed towers. Figure 11-33 depicts an alkalinity recovery process flow diagram that further illustrates this concept. Normally, finished waters with 1 to 3 meq/L of bicarbonate alkalinity are considered highly desirable for corrosion control. The reader is referred to Chap. 3 for principles dealing with inorganic carbon and alkalinity. Table 11-12 illustrates how pH increases and alkalinity and hydrogen sulfide concentrations change following the unit operations discussed.

Aeration and Stabilization. These unit processes can be discussed simultaneously in membrane processes because they will be accomplished simultaneously. Chlorination could also be done here if desired. If calcium and bicarbonate are present, the pH following

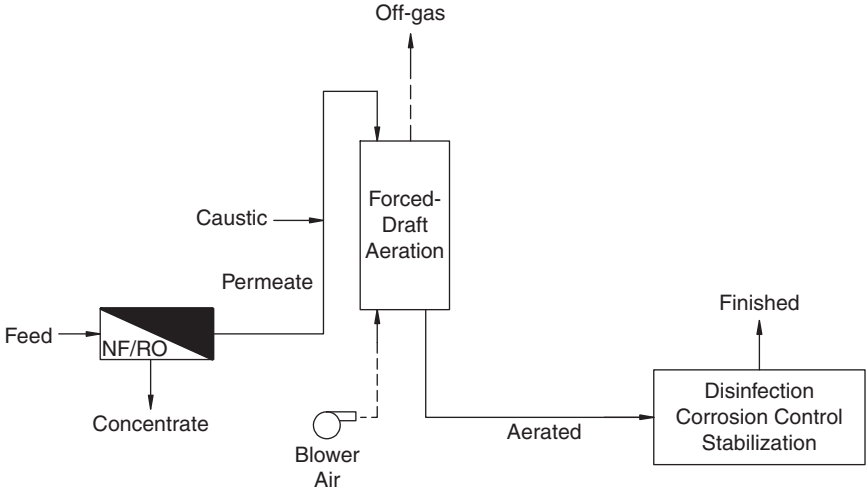

FIGURE 11-33 Alkalinity recovery process flow diagram.

aeration is controlled by $\text{CaCO}_3(\text{s})$ buffering and can be estimated by assuming CaCO_3 equilibrium. Equation 11-96 shows the calculation made to determine the pH following aeration.

$$\text{pH}_s = \text{pK}_2 - \text{pK}_{s0} + p[\text{Ca}^{2+}] + p[\text{HCO}_3^-] \quad (11-96)$$

Example 11-11 Stabilization pH Following Aeration

The pH calculation following aeration is determined by equilibrium with CaCO_3 and can be determined by the pH_s calculation shown as follows. Table 11-12 gives the permeate stream pH and concentrations of different species following alkalinity recovery. The following equations, along with Eq. 11-96, are referenced and used for calculations:

Given

$$\text{Ca}^{+2} = 50.9 \text{ mg/L}$$

$$\text{HCO}_3^- = 122 \text{ mg/L}$$

Solution Convert the concentration of calcium to mol/L.

$$[\text{Ca}^{+2}] = \left(50.9 \frac{\text{mg}}{\text{L}} \text{Ca}^{2+} \right) \left(\frac{1 \text{ mmol Ca}^{2+}}{40 \text{ mg Ca}^{2+}} \right) = 1.27 \text{ mM Ca}^{+2}$$

Calculate $p[\text{Ca}^{2+}]$.

$$p[\text{Ca}^{+2}] = -\log[\text{Ca}^{+2}] = -\log[1.27 \times 10^{-3}] = 2.90$$

Convert the concentration of bicarbonate to mol/L.

$$[\text{HCO}_3^-] = \left(122 \frac{\text{mg}}{\text{L}} \text{HCO}_3^-\right) \left(\frac{1 \text{ mmol} \cdot \text{HCO}_3^-}{61 \text{ mg} \cdot \text{HCO}_3^-}\right) = 2.0 \text{ mM} \cdot \text{HCO}_3^-$$

Calculate $p[\text{HCO}_3^-]$.

$$p[\text{HCO}_3^-] = -\log[\text{HCO}_3^-] = -\log[2.0 \times 10^{-3}] = 2.70$$

Using Eq.11-96, calculate the stabilization pH.

$$pH_s = pK_2 - pK_{s0} + p[\text{Ca}^{2+}] + p[\text{HCO}_3^-]$$

$$\text{Eq.11-98 gives} \quad pK_2 = 10.3$$

$$\text{Eq.11-97 gives} \quad pK_{s0} = 8.3$$

$$p[\text{Ca}^{2+}] = 2.90$$

$$p[\text{HCO}_3^-] = 2.70$$

Plug in these values into Eq. 11-96 to obtain the stabilization pH.

$$pH_s = pK_2 - pK_{s0} + p[\text{Ca}^{2+}] + p[\text{HCO}_3^-]$$

$$pH_s = 10.3 + 8.3 + 2.9 + 2.7 = 7.6 \quad \blacktriangle$$

RESIDUALS DISPOSAL AND CONCENTRATE MANAGEMENT

Waste disposal is a more significant problem for any membrane plant than for a conventional water treatment plant because concentrate disposal is highly regulated by government agencies. A membrane plant collects significant amounts of waste with a high TDS concentration.

MF and UF Process Residuals

MF and UF process residuals result from the wastes generated during backwashing and chemical cleaning. Chemical-cleaning wastes include residuals generated from either *clean in place (CIP)* or *chemically enhanced backwash (CEB)* operations. Monthly CIP wastes are normally less than one percent of the plant flow, and the volume of chemical-cleaning wastes generated from CEB operations are typically less than 0.5 percent of the plant flow. Chlorine residuals in CIP or CEB wastes may range from 1 to 1000 mg/L as chlorine. The pH of the chemical-cleaning-waste streams may vary from acidic ($\text{pH} < 6$) to basic ($\text{pH} > 9$) depending on the type of cleaning performed. If citric acid is used in the CIP, the biological oxygen demand of the spent cleaning solution may be high. In addition, if citric acid is used in the process cleaning regimen, then the ability to recirculate combined backwash and CIP solutions is limited if the MF or UF process is integrated into a coagulation process due to chemical reactions between the citric acid and coagulant that will impact process operations and result in loss of operating flux.

MF and UF membranes produce a similar backwash stream of approximately the same quantity of materials as would a conventional water treatment plant. However, MF and UF membrane processes do not contain residual polymers that are sometimes used in conventional treatment facilities as polymers are incompatible with membranes. In many cases

considerable coagulant or other pretreatment residuals (such as PAC or potassium permanganate) may not be used in combination with MF and UF. So, the amount of solids removed from a water stream is less than a conventional process. Also, MF and UF processes are backwashed more frequently than a conventional filter. The typical membrane process backwash occurs every 15 to 60 min, with a backwash duration of 1 to 4 min. Although the backwashes are more frequent, the total water lost during MF and UF backwash operations is typically only 2 to 12 percent of the plant flow rate for systems operating at 85 to 98 percent recovery. Backwash flows represent 95 to 98 percent of the total volume of residual wastes from a MF or UF system. The remaining 1 to 5 percent of MF and UF membrane residuals originates from cleaning procedures.

Consequently, the disposal of MF and UF solid residual streams are handled in a similar fashion as a conventional water treatment plant residual stream. The backwash solution may require dechlorination (or pH adjustment) prior to discharge. Dechlorination, if used, is generally designed to match the backwash frequency and typically performed as a batch operation where the backwash water is collected, neutralized, and discharged. Backwash wastes are commonly disposed of by discharging into sewers or surface water. Sewers are used as the predominant method of disposal for cleaning wastes. However, some form of pH adjustment will occur prior to discharge. Some MF and UF facilities may be able to settle solids out of the spent backwash stream and recycle the supernatant to increase the overall system recovery or to further treat the backwash stream using additional unit operations to develop a zero discharge backwash residual operation.

Disposal of MF and UF process residuals is generally regulated by the same guidelines governing water treatment plant residuals. Although the USEPA has not established specific regulations for the disposal of MF and UF water treatment plant residuals, there are federal requirements that apply to membrane residuals as industrial waste streams. Most states have been delegated by the USEPA to administer established regulations that will meet the requirements of the federal regulations. It is important to note that although the recycling of backwash and other recycled flows in conventional treatment plants is regulated by the Filter Backwash Recycling Rule (see Chap. 10), this rule does not apply to membrane residuals recycling unless membrane wastes are mixed with other conventional process wastes prior to recycling.

Spent Cleaning Solutions

Membrane systems require periodic cleaning with chemicals to control fouling and maintain productivity. If a membrane process is suspect of forming mineral scale on the membrane surface, then most often it will be cleaned with an *acid cleaner such as citric acid*. In addition, most membrane processes will be cleaned with a base cleaner, such as sodium hydroxide, to remove organic foulants. Spent chemical-cleaning solutions may be handled and disposed of either separately from the concentrate discharge or, if neutralized, may be blended in with the concentrate prior to disposal. Several waste discharges are generated during membrane cleaning procedures. The concentrated waste cleaning system is the actual spent membrane cleaning chemical; however, permeate (or filtrate) flush water is used to displace the spent cleaning residual remaining in the membrane unit or system and must be disposed of after use. The flush water removed from the concentrate lines of membrane systems must also be accounted for in determining residual quantities and flow.

The various streams typically are routed to a spent cleaning solution scavenger tank for holding and treatment (neutralization) prior to discharge. A survey of 49 NF and RO facilities and 27 MF and UF facilities was conducted to evaluate the disposal methods for spent cleaning solutions (Kenna and Zander, 2001). It was found that the two most common methods for disposal of cleaning solution residuals from NF and RO plants were sewer

discharge and mixing with concentrate after the cleaning solution had been neutralized. The most common method for disposal of MF and UF residuals was sewer discharge.

NF and RO Membrane Concentrate

The quality and quantity of concentrate streams from RO/NF/ED plants can be easily estimated using simple recovery and rejection calculations. A 37,855 m³/d (10 mgd) plant operating at 90 percent recovery will produce a concentrate stream of 4165 m³/d (1.11 mgd), which is determined by dividing the permeate flow, 37,855 m³/d (10 mgd), by the recovery, 0.11. The quality of the concentrate stream can be determined by dividing the decimal fraction solute rejection into the feed stream recovery. The same plant producing 37,855 m³/d (10 mgd) at 90 percent recovery and rejecting 80 percent of 100 mg/L of the feed stream chlorides would produce 20 mg/L of chlorides in the permeate stream and 820 mg/L of chlorides in the concentrate stream. Rejection and recovery are sometimes confused. The calculations are illustrated below. For the purposes of these calculations, r will represent the fraction recovered and R will represent the fraction rejected.

$$Q_c = \frac{Q_p(1-R)}{R} = \frac{37,855 \text{ m}^3/\text{day} (1.0-0.9)}{0.9} = \frac{3785.5}{0.9} = 4200 \frac{\text{m}^3}{\text{day}} (1.11 \text{ mgd})$$

$$C_p = (1-R)(C_f) = (1-0.8) \left(100 \frac{\text{mg Cl}^-}{\text{L}} \right) = 20 \frac{\text{mg Cl}^-}{\text{L}}$$

$$C_p = \frac{Q_f C_f Q_p C_p}{Q_c} = \frac{(1 \text{ L}) \left(100 \frac{\text{mg Cl}^-}{\text{L}} \right) - (0.9 \text{ L}) \left(20 \frac{\text{mg Cl}^-}{\text{L}} \right)}{0.1 \text{ L}} = 820 \frac{\text{mg Cl}^-}{\text{L}}$$

Table 11-13 lists techniques used for concentrate disposal in the United States by plant size and number (Mickley, 1993). Mickley identified five basic techniques used by 137 plants surveyed in an AWWARF study of concentrate disposal. Other surveys of concentrate disposal methods are available (Kenna and Zander, 2001; Truesdall, Mickley and Hamilton, 1995). Surface discharge is the most common technique, accounting for nearly half of the techniques surveyed. Land application was not planned for any proposed new plant. However, land application of NF concentrates is possible in some locations because of their low TDS concentrations, typically 1000 to 2000 mg/L, relative to RO concentrates. Sewer discharge, usually an option only for very small plants, was

TABLE 11-13 Concentration Disposal Technique Distribution by Plants and Flow

Technique or method	Plant size (mgd)				Total
	<0.3	0.3-1	1-3	>3	
Surface	34	12	9	11	66
Land application*	14	2	0	1	17
Sewer	18	8	3	3	32
Deep-well injection	3	1	5	5	14
Evaporation pond	8	0	0	0	8
Total	77	23	17	20	137

*None planned in future.

the second most common technique for plants under 1100 m³/d (0.3 mgd). Deep-well injection was more common in Florida than any other states because of differences in regulatory environments.

Concentrate discharge is regulated through programs in the Clean Water Act (CWA) National Pollutant Discharge Elimination System (NPDES) program, Dredge and Fill program and Resource Conservation Recovery Act, and the Safe Drinking Water Act (SDWA) Underground Injection Control (UIC) program. Surface waters fall under NPDES whereas groundwaters fall under the UIC program. Regulatory environments for concentrate disposal are controlled by states or by USEPA, depending on primacy. Although these programs have existed since the 1970s, the regulatory environment is becoming more stringent. Bioassay testing is required now in many states, is common in Florida and California, and can be used to require additional treatment or stop planned disposal of concentrate streams. An overview and summary of regulation and current practices has been documented elsewhere (Mickley, 2001; AWWA 2004).

PILOT PLANT TESTING

Pilot plant testing offers the best method for evaluating the feasibility of a membrane application for a specific water supply, especially since fouling cannot be quantitatively predicted from water-quality measurements alone. Fouling indices do provide an estimate of the potential for fouling, but unlike pilot-scale testing, are not predictive of long-term performance. In many states, pilot testing is required for membrane processes prior to receiving regulatory approvals and applicable permits. There are many reasons for pilot plant testing, some of which include

1. Pilot testing is mandated by state or local primacy regulatory agencies.
2. Collect baseline raw-water-quality profiles that can be used to establish a basis of design.
3. Collect operating membrane process data for cost and performance evaluations.
4. Confirm that the permeate water quality meets the contractual, regulatory, and site-specific needs of the owner and engineer.
5. Provide hands-on training for plant operations personnel.
6. Demonstrate operation protocols and procedures.
7. Allow for continued long-term investigations on process operations.
8. Allow for research and development.

Two of the most critical needs to the design of an UF treatment plant are delineating the quality of the feedwaters going into the system and predicting the desired quality of the water being produced by the system. Additional considerations for design include pretreatment, process feed pumping requirements, process monitoring and flow control, backwash and cleaning cycles, chemical feed equipment, posttreatment, and residuals disposal. These components are necessary to provide an estimate of the cost and allow a cost-benefit evaluation to be conducted. Different membranes can produce different permeate water qualities depending on the feedwater quality. Because most applications are unique, a site-specific understanding is necessary for the proper design of the membrane system. However, the operation of MF and UF processes are different from NF, RO, and ED/EDR membrane processes, requiring that system-specific testing for different manufacturers' membranes and systems be addressed accordingly.

MF and UF Piloting

Important considerations for evaluating MF and UF performance include specific flux, water temperature and associated TMP, backwash and bleed interval impact on productivity and run time, cleaning frequency and interval, and other system-specific operation, such as chemical-enhanced backwashes. Instrument verification and calibration are required for flowmeters, pressure and temperature transmitters, online particle counters, and turbidimeters. Test duration is also critical to obtaining pertinent and applicable information from the pilot operation regarding cost and performance of the projected full-scale facility. If the feedwater supply is subject to seasonal impacts, then the number of applicable testing periods for each season should be conducted. During testing, a minimum of 30 days of run time should be required prior to altering the test conditions or pilot operation set points for any given feedwater. If multiple feedwaters are to be blended or varied during full-scale operating conditions, then worst-case blending scenarios with regard to temperature and water-quality impacts (particularly those related to fouling) must be considered and studied at the pilot scale.

Additional consideration should be given to specific study components of a pilot program, such as challenge tests, integrity testing, and module repair procedures. Fouling impacts on process productivity are best assessed by pilot testing. Evaluation of chemical cleaning is a significant component of MF and UF piloting, and longer run times may be required in order to fully evaluate CIP procedures. Also, if CEB is incorporated into the process operation, then impact on backwash recycle operations with regard to DBP formation potential must be evaluated. If recirculation is to be practiced in the full-scale plant then the pilot-testing program should incorporate the recirculation. Should citric acid be incorporated into the cleaning regimen, then resultant residuals should be disposed of in an acceptable fashion and not be recycled back to the front of the process stream, particularly if coagulant is used as part of the pretreatment process train. Citric acid will interfere with coagulant pretreatment, especially when an iron base is used. They should not be allowed to come into contact with coagulant upstream of the membrane.

It is important that any problems related to scalability, such as membrane packing density, and analogous pretreatment be incorporated into the testing. The MF and UF modules tested must be comparable to anticipated full-scale module configurations. If packing density differences exist between pilot-scale and full-scale systems then inaccuracies in operation evaluations will occur. For MF and UF, the owner and engineer are thus reliant on the manufacturer to provide a pilot system that mimics full-scale operation, and so must be involved in the technical aspects of the pilot test.

NF, RO, and ED/EDR Piloting

The demonstrated benefits of performing bench-, pilot- and demonstration-scale testing of NF, RO, and ED/EDR processes has continued over the years. Brackish groundwater RO and EDR plants have been successfully designed, effectively constructed, and successfully operated over the years. Typically, approximately 2000 hours of run time are required to operate a pilot and obtain quality performance data. Piloting could be considered a method to reduce the risk of unknown potential problems related to operating a membrane process with a specific raw water and does provide hands-on experience for plant operations personnel. Problems related to long-term fouling experienced in nonbrackish ground- and surface water remain with NF, RO, and ED/EDR, and should be assessed with pilot testing. In these cases longer testing intervals should be considered to capture seasonal variations and allow for the development of long-term fouling assessments, particularly if biological and organic fouling are predicted.

Today most RO and NF elements in use are 20.3 cm (8 in.) in diameter, and it is common that piloting be performed using 10.2 cm (4 in.) diameter elements as they tend to mimic full-scale operating conditions (e.g., feed channel hydraulics). However, 6.35 cm (2.5 in.) diameter elements, although available for testing, should not be used to evaluate RO full-scale operating conditions, as these elements do not mimic larger-element manufacture. On the other hand, for 10.2 cm (4 in.) NF pilot studies requiring a third stage, the use of 6.35 cm (2.5 in.) diameter elements are often used because the need to control velocity in the third stage, despite the inherent limitations of the smaller-diameter element. With the advent of 406.4 mm (16 in.) diameter elements entering the market, the use of 10.2 cm (4 in.) membranes for analogous testing conditions would be in question for this application. Demonstration-scale testing (on the order of 1900 m³/d (0.5 mgd)) using the large-diameter membrane would be recommended for these cases, as these larger diameter elements can be mounted on pilot-scale skids. Instrument verification and calibration of flowmeters, pressure and temperature transmitters, and online pH and conductivity meters, and similar, are required for NF, RO, and EDR pilot facilities.

ABBREVIATIONS

BAT	Best available technology
CaCO ₃	Calcite
CTA	Cellulose triacetate
CEB	Chemically enhanced backwash
CWA	Clean Water Act
CIP	Clean in place
CFS	Coagulation, flocculation, and sedimentation
m ³ /d	Cubic meters per day
DC	Direct current
DBP	Disinfection by-product
DBPFP	Disinfection by-product formation potential
DAF	Dissolved air flotation
DIC	Dissolved inorganic carbon
DOC	Dissolved organic carbon
CaMg(CO ₃) ₂	Dolomite
ED/EDR	Electrodialysis/electrodialysis reversal

OVERVIEW

In the first part of this chapter, the fundamentals of ion exchange (IX) and adsorption processes are explained, with the goal of demonstrating how these principles influence process design for inorganic contaminant removal. In the second part, ion exchange and adsorption processes that have been proven effective at bench, pilot, and full scale are described for the removal of hardness, barium, radium, nitrate, fluoride, arsenic, dissolved organic carbon (DOC), uranium, and perchlorate. For each contaminant, the factors that influence the choice and design of a process, for example, pH, total dissolved solids (TDS), contaminant speciation, competing ions, resins, adsorbents, foulants, regenerants, and column flow patterns, are discussed. In the third and final part of the chapter, ion exchange modeling using equilibrium multicomponent chromatographic theory (EMCT) with constant separation factors (CSFs) is covered. Summary tables for cation and anion contaminants are included at the end of the chapter to aid the reader in process selection. The basic features, advantages, and disadvantages of the ion exchange and metal oxide/hydroxide packed bed processes covered in this chapter are summarized in Table 12-1.

INTRODUCTION AND THEORY OF ION EXCHANGE

Contaminant cations such as calcium, magnesium, radium, barium, and strontium and anions such as fluoride, nitrate, fulvates, humates, arsenate, selenate, chromate, perchlorate, and anionic complexes of uranium can be removed from water using ion exchange

TABLE 12-1 Advantages and Disadvantages of Packed Bed Inorganic Contaminant-Removal Processes

Ion exchange

Advantages

- Operates on demand.
- Relatively insensitive to flow variations, short contact time required.
- Relatively insensitive to trace level contaminant concentration.
- Essentially zero level of effluent contaminant possible.
- Large variety of “tailored” resins available for specific target ions.
- Beneficial selectivity reversal commonly occurs on regeneration.
- In some applications, spent regenerant may be reused without contaminant removal.

Disadvantages

- Potential for chromatographic effluent peaking when using single beds.
- Variable effluent quality with respect to background ions when using single beds.
- Usually not feasible at high levels of sulfate or total dissolved solids.
- Large volume/mass of regenerant must be used and disposed of.

Metal oxide/hydroxide adsorption

Advantages

- Operates on demand.
- Relatively insensitive to total dissolved solids and sulfate levels.
- Low effluent contaminant level possible.
- Highly selective for fluoride and arsenic.

Disadvantages

- Both acid and base are required for regeneration when regeneration is possible.
 - Relatively sensitive to trace level contaminant concentration.
 - Media tend to dissolve, producing fine particles.
 - Slow adsorption kinetics and relatively long contact time required.
 - Significant volume/mass of spent regenerant to neutralize and dispose of.
-

with resins or adsorption onto granular hydrous metal oxides/hydroxides such as activated alumina (AA), granular ferric oxide (GFO), and granular ferric hydroxide (GFH) or coagulated Fe(II), Fe(III), Al(III), Ti(III), Ti(IV), Zr(III), Zr(IV), and Mn(IV) surfaces. This chapter deals only with the theory and practice of IX with resins and adsorption with granular media including GFH, GFO, and AA. The reader interested in cation and anion adsorption onto hydrous metal oxides in general is referred to Schindler's and Stumm's publications on the solid-water interface (Schindler, 1981; Stumm, 1992) as a starting point.

IX with synthetic resins and adsorption onto hydrous metal oxides/hydroxides are water treatment processes in which a presaturant ion on the solid phase, the *adsorbent*, is exchanged for an unwanted ion in the water. In order to accomplish the exchange reaction, a packed bed of IX resin beads or metal oxide/hydroxide granules is used. Source water is continually passed through the bed in a downflow or upflow mode until the adsorbent is exhausted, as evidenced by the appearance (*breakthrough*) of the unwanted contaminant at an unacceptable concentration in the effluent.

The most useful IX reactions are reversible. In the simplest cases, the exhausted bed is regenerated using an excess of the presaturant ion. Ideally, no permanent structural change takes place during the exhaustion/regeneration cycle. (Resins do swell and shrink, however, and the metal oxides/hydroxides may be slightly dissolved during regeneration.) When the reactions are reversible, the medium can be reused many times before it must be replaced because of irreversible fouling or, in the case of metal oxides/hydroxides, excessive attrition. In a typical water supply application, from 300 to as many as 300,000 bed volumes (BV) of contaminated water may be treated before the medium is exhausted. Regeneration typically requires from 1 to 5 BV of regenerant followed by 2 to 20 BV of rinse water. These wastewaters generally amount to less than 2 percent of the product water; nevertheless, their ultimate disposal is a major consideration in IX and adsorption design practice. Disposal of the spent medium also may present a problem if it contains toxic or radioactive substances such as nitrate, arsenic, perchlorate, uranium, and/or radium.

Uses of IX in Water Treatment

By far the largest application of IX to drinking water treatment is water softening, that is, the removal of calcium, magnesium, and other polyvalent cations, including Ra^{2+} , Ba^{2+} , Sr^{2+} , Fe^{2+} , and Mn^{2+} , in exchange for sodium. The IX softening process is applied to residential, industrial, and municipal water treatment. In residential use, IX can be applied for whole-house [*point-of-entry* (POE)] softening or for softening only the water that enters the hot water heater. For industrial use, generally all the water is passed through the resin to lower the hardness to zero, whereas in municipal water treatment some of the water is bypassed around the softener because some hardness is desirable in the treated water. Radium and barium are ions more preferred by the resin than calcium and magnesium; thus the former are also removed effectively during IX softening. Resins beds containing chloride-form anion exchange resins can be used to remove nitrate, arsenate, perchlorate, chromate, selenate, natural organic matter (NOM)/color, uranium, perchlorate, and other contaminant anions. GFO, GFH, and zirconium and titanium oxides/hydroxides are being used to remove arsenate, whereas AA is being used to remove fluoride. These adsorption processes are especially useful for groundwater treatment in small systems and for residential *point-of-use* (POU) and POE systems.

The choice between IX and metal oxide/hydroxide adsorption, for example, to remove arsenic from water, is largely determined by (1) the background water quality including TDS level, competing ions, alkalinity, and contaminant concentration and (2) the resin or adsorbent medium affinity for the contaminant ion in comparison with competing ions. The affinity sequence determines the run length, chromatographic peaking (if any), and process costs. As mentioned previously, process selection is affected by spent regenerant and spent

medium disposal requirements and regenerant reuse possibilities, particularly if hazardous contaminants are involved. Each of these requirements is dealt with in some detail in the upcoming design sections for the specific processes.

Past and Future of IX

Natural zeolites, which are crystalline aluminosilicate minerals, were the first ion exchangers, and they were used to soften water on an industrial scale. Later, zeolites were completely replaced with synthetic resins because of the latter's faster exchange rates, higher capacity, greater resilience, and longer life. Aside from softening, the use of IX and inorganic adsorption for removal of specific contaminants from municipal water supplies has been limited owing to the perceived expense involved in removing what have been seen as minimal health risks resulting from contaminants such as fluoride and nitrate. The production of pure and ultrapure water by IX demineralization (DM) is the largest use of IX resins on an industrial scale. The complete removal of contaminants, which occurs in DM processes, is not necessary for drinking water treatment, however. Furthermore, treatment costs are high compared with membrane processes (reverse osmosis and electro dialysis) for desalting water (see Chap. 11).

Adherence to governmentally mandated maximum contaminant level (MCL) goals for inorganic chemicals (IOCs) will result in more use of IX and adsorption systems for small community water treatment to remove barium, radium, cadmium, chromium, mercury, lead, fluoride, arsenic, nitrate, perchlorate, uranium, and other IOCs.

IX Materials and Reactions

An IX resin consists of a cross-linked polymer matrix to which charged functional groups are attached by covalent bonding. The usual matrix is polystyrene cross-linked for structural stability with 3 to 8 percent divinylbenzene (abbreviated STY-DVB or simply polystyrene). The common functional groups fall into four categories: strongly acidic (e.g., sulfonate, $-\text{SO}_3^-$), weakly acidic (e.g., carboxylate, $-\text{COO}^-$), strongly basic [e.g., quaternary amine, $-\text{N}(\text{CH}_3)_3^+$], and weakly basic [e.g., tertiary amine, $-\text{N}(\text{CH}_3)_2$] (Helfferich, 1962).

A schematic presentation illustrating resin matrix cross-linking and functionality is shown in Fig. 12-1a. The schematic depicts a three-dimensional bead (sphere) made up of many polystyrene polymer chains held together by divinylbenzene cross-linking. The negatively charged IX sites ($-\text{SO}_3^-$) in a cation exchanger and the positively charged sites [$-\text{N}(\text{CH}_3)_3^+$] in an anion exchanger are shown in Fig. 12-1b fixed to the resin backbone, or *matrix* as it is called. Mobile positively charged counterions (positive charges in Fig. 12-1a) are associated by electrostatic attraction with each negative IX site on a cation exchange resin. The resin exchange *capacity* is measured as the number of fixed charge sites per unit volume or weight of resin. *Functionality* is the term used to identify the chemical composition of the fixed charge site, for example, sulfonate ($-\text{SO}_3^-$) or quaternary ammonium [$-\text{N}(\text{CH}_3)_3^+$]. *Porosity*, expressed by the terms *microporous/gel*, *porous*, and *macroporous*, is the resin characterization referring to the degree of openness of the polymer structure. An actual resin bead is much tighter than on the schematic, which is shown as fairly open for purposes of illustration only. The water (40–60% by weight) present in a typical resin bead is not shown. This resin-bound water is an extremely important characteristic of ion exchangers because it strongly influences both the exchange kinetics and thermodynamics.

Strong- and Weak-Acid Cation Exchangers. *Strong-acid cation* (SAC) exchangers operate over a wide pH range because the sulfonate group, being strongly acidic, is ionized

FIGURE 12-1 (a) Organic cation exchanger bead comprising polystyrene polymer crosslinked with divinylbenzene with fixed negatively charged co-ions (minus charges) balanced by mobile positively charged counterions (plus charges). (b) Strong-acid cation exchanger (*left*) in the hydrogen form and strong-base anion exchanger (*right*) in the chloride form.

throughout the 1 to 14 pH range. Three typical SAC exchange reactions are shown below. In Eq. 12-1, the neutral CaCl₂ salt, representing noncarbonate hardness, is said to be *split* by the resin, and hydrogen ions are exchanged for calcium, even though the equilibrium liquid phase is acidic because of HCl production. Equations 12-2 and 12-3 are the standard IX softening reactions in which sodium ions are exchanged for the typical hardness ions: Ca²⁺, Mg²⁺, Fe²⁺, Ba²⁺, Sr²⁺, and/or Mn²⁺, either as noncarbonate hardness (Eq. 12-2) or as carbonate hardness (Eq. 12-3). In all these reactions, R denotes the resin matrix, and the overbar indicates the solid (resin) phase.

Regeneration of the spent resin is accomplished using an excess of concentrated (0.5–3 M) HCl or NaCl, and amounts to the reversal of Eqs. 12-1 through 12-3. *Weak-acid cation* (WAC) resins can exchange ions only in the neutral to alkaline pH range because the functional group, typically carboxylate ($\text{p}K_a = 4.8$), is not ionized at low pH. Thus WAC resins

can be used for carbonate hardness removal (Eq. 12-4) but fail to remove noncarbonate hardness, as is evident in Eq. 12-5.

If Eq. 12-5 proceeded to the right, the HCl produced would be so completely ionized that it would protonate, that is, add a hydrogen ion to the resin's weakly acidic carboxylate functional group and prevent exchange of H^+ ions for Ca^{2+} ions. Another way of expressing the fact that Eq. 12-5 does not proceed to the right is to say that WAC resins will not *split neutral salts*; that is, they cannot remove noncarbonate hardness. This is not the case in Eq. 12-4, in which the *basic salt* $\text{Ca}(\text{HCO}_3)_2$ is *split* because a weak acid, H_2CO_3 ($\text{p}K_1 = 6.3$), is produced.

In summary, SAC resins split basic and neutral salts (remove carbonate and noncarbonate hardness), whereas WAC resins split only basic salts (remove only carbonate hardness). Nevertheless, WAC resins have some distinct advantages for softening, namely, TDS reduction, no increase in sodium, and very efficient regeneration resulting from the carboxylate's high affinity for the regenerant H^+ ion.

Strong- and Weak-Base Anion Exchangers. The use of *strong-base anion* (SBA) exchange resins for nitrate removal is a fairly recent application of IX for drinking water treatment (Clifford and Weber, 1978; Guter, 1981), although anion resins have been used in water demineralization for more than 50 years. In anion exchange reactions with SBA resins, the quaternary amine functional group [$-\text{N}(\text{CH}_3)_3^+$] is so strongly basic that it is ionized, and therefore useful as an ion exchanger, over the pH range of 0 to 13 (Helferich, 1962). This is shown in Eqs. 12-6 and 12-7, in which nitrate is removed from water by using hydroxide- or chloride-form SBA resins. Note that R_4N^+ is another way to write the quaternary exchange site $-\text{N}(\text{CH}_3)_3^+$.

In Eq. 12-6, the NaOH produced is completely ionized, but the quaternary ammonium functional group has such a small affinity for OH^- ions that the reaction proceeds to the right. Eq. 12-7 is a simple ion-exchange reaction without a pH change. Fortunately, all SBA resins have a higher affinity for nitrate than chloride (Clifford and Weber, 1978) and Eq. (12-7) proceeds to the right at near-neutral pH values.

Weak-base anion (WBA) exchange resins are useful only in the acidic pH region, where the primary, secondary, or tertiary amine functional groups (Lewis bases) are protonated, and can act as positively charged exchange sites for anions. In Eq. 12-8, chloride is, in effect, being adsorbed by the WBA resin as hydrochloric acid, and the TDS level of the solution is being reduced. In this case, a positively charged Lewis acid-base adduct (R_3NH^+) is formed that can act as an anion exchange site. As long as the solution in contact with the resin remains acidic (just how acidic depends on the basicity of the R_3N ; sometimes $\text{pH} \leq 6$ is adequate), IX can take place, as is indicated in Eq. 12-9—the exchange of chloride for nitrate by a WBA resin in acidic solution. If the solution is neutral or basic, no adsorption or exchange can take place, as indicated by Eq. 12-10. In all these reactions, R represents either the resin matrix or a functional group, such as $-\text{CH}_3$ or $-\text{C}_2\text{H}_5$, and the overbars represent the resin phase.

Although WBA resins are not used commonly for drinking water treatment, such processes are possible as long as the exchange pH is in the 4 to 6 range, which can be costly because this requires neutralization of most of the alkalinity present. Furthermore, activated alumina, when used for fluoride and/or arsenic removal, acts as if it were a WBA exchanger, and the same general rules regarding pH behavior can be applied. Another advantage of weak-base resins in water supply applications is the ease with which they can be regenerated with bases. Even weak bases such as ammonium hydroxide (NH_4OH) and lime ($\text{Ca}(\text{OH})_2$) can be used, and regardless of the base used, only a small stoichiometric excess (<20 percent) normally is required for complete regeneration.

Granular Media Adsorption. Packed beds of AA, titanium and zirconium oxides/hydroxides, GFO and GFH, and iron oxides coated onto or incorporated into various media, including anion resins (Cumbal and Sengupta, 2005), diatomaceous earth (NSF International, 2005), and sand (Benjamin et al., 1996), can be used to remove contaminant anions, including fluoride, arsenic, selenium, silica, phosphate, vanadate, and natural organic matter (fulvate) anions from water. A simple schematic of the contaminant adsorption process is shown in Fig. 12-2, where the contaminant (Adsorbate-A) attaches to an

FIGURE 12-2 Schematic of the contaminant adsorption process on a porous adsorbent with internal surface area containing adsorbent sites. Adsorbate (A) + Adsorbent Site (S) react to form Adsorbate · Site complex (A · S) on adsorbent surface.

adsorption site (Sorbent-S) to form A·S a site with contaminant attached. Coagulated Fe(II) and Fe(III) oxides/hydroxides (McNeill and Edwards, 1995; Scott et al., 1985; Lakshmanan et al., 2008) also can be employed to remove these anions, but coagulation processes are not covered in this chapter. The mechanism, which is one of exchange of contaminant anions for surface hydroxides on the alumina or iron oxides/hydroxides, generally is called *sorption* or *adsorption*, although *ligand exchange* is a more appropriate term for the highly specific surface reactions involved (Stumm, 1992). Figure 12-3 depicts the ligand exchange of arsenate for hydroxide on the surface of ferric oxide/hydroxide (FeOOH). Similar reactions can occur on the surfaces of activated alumina (AlOOH) and metal oxides/hydroxides (MeOOH), including zirconium and titanium.

The typical activated aluminas used for fluoride removal in water treatment are 28×48 mesh (0.3–0.6 mm diameter) mixtures of amorphous and gamma aluminum oxide ($\gamma\text{-Al}_2\text{O}_3$) prepared by low-temperature (300°C–600°C) dehydration of precipitated $\text{Al}(\text{OH})_3$. These highly porous materials have surface areas of 50 to 300 m^2/g . The granular ferric oxides/hydroxides (GFO and GFH) used for arsenate removal are prepared by similar methods and also have surface areas in the 50 to 300 m^2/g range. Using the model of a hydroxylated alumina surface subject to protonation and deprotonation, the following ligand (fluoride) exchange reaction (Eq. 12-11) can be written for fluoride adsorption in acid solution (alumina exhaustion), in which AlO represents the alumina surface and an

FIGURE 12-3 Schematic of ligand exchange of hydroxide for arsenate on ferric oxide/hydroxide surface. Similar reactions may occur for other metal oxides/hydroxides (MeOOH).

overbar denotes the solid phase. FeOOH surfaces undergo similar reactions with arsenate ($H_2AsO_4^-$) as the ligand (see Fig 12-2).

The equation for fluoride desorption by hydroxide (alumina regeneration) is presented in Eq. 12-12.

Metal oxide/hydroxide surfaces, including AA, GFH, GFO, and etc., are sensitive to pH, and anions are best adsorbed below the *zero point of charge* (ZPC), where the metal oxide surface has a net positive charge, and excess protons are available to fuel Eq. 12-11. Above the ZPC (pH 8.2), alumina is predominantly a cation exchanger, but its use for cation exchange is relatively rare in water treatment. An exception is encountered in the removal of radium by plain and treated activated alumina (Clifford et al., 1988; Garg and Clifford, 1992).

Ligand exchange, as indicated in Eqs. 12-11 and 12-12, occurs chemically at the internal and external surfaces of activated alumina, GFH, and GFO. A more useful model for process design, however, is one that assumes that the adsorption of fluoride or arsenic onto a metal oxide/hydroxide surface at the optimal pH of 5.5 to 6 is analogous to weak-base anion exchange. For example, the uptake of F^- or $H_2AsO_4^-$ requires the protonation of the metal oxide/hydroxide surface, which is sometimes accomplished by preacidification of the medium with HCl or H_2SO_4 and/or reducing the feed water pH into the 5.5 to 6.0 region. The positive charge caused by excess surface protons then may be viewed as being balanced by exchanging anions, that is, ligands such as hydroxide, fluoride, and arsenate. To reverse the adsorption process and remove the adsorbed fluoride or arsenate, an excess of strong base, for example, NaOH, must be applied. The following series of reactions (Eqs. 12-13 through 12-17) is presented as a model of the adsorption/regeneration cycle that is useful for design purposes. Although less common, these reactions also may be applied to GFH and GFO processes.

The first step in the cycle is acidification, in which neutral (water-washed) alumina (alumina·HOH) is treated with acid, for example, HCl, and protonated (acidic) alumina is formed as follows:

When HCl-acidified alumina is contacted with fluoride ions, the chloride ions are strongly displaced, provided that the alumina surface remains acidic (pH 5.5–6). This displacement of chloride by fluoride, analogous to ion exchange, is shown as

To regenerate the fluoride-contaminated adsorbent, a dilute solution of alkali (0.25–0.5 N NaOH) is used. Because alumina is both a cation and an anion exchanger, Na⁺ is exchanged for H⁺, which immediately combines with OH⁻ to form HOH in the alkaline regenerant solution. The regeneration reaction of fluoride-spent alumina is

Recent experiments have suggested that Eq. 12-15 can be carried out using fresh or recycled NaOH from a previous regeneration. This suggestion is based on the field studies of Clifford and colleagues (1998) in which arsenic-spent alumina was regenerated with equally good results using fresh or once-used 1.0 M NaOH. Probably the spent regenerant, fortified with NaOH to maintain its hydroxide concentration at 1.0 M, could have been used many times, but the optimal number of spent-regenerant reuse cycles was not determined in the field study.

To restore the *fluoride-removal capacity*, the basic alumina is acidified by contacting it with an excess of dilute acid, typically 0.5 N HCl or H₂SO₄:

The acidic alumina, alumina·HCl, is now ready for another fluoride (or arsenate or selenite) ligand exchange cycle, as summarized by Eq. 12-14. Alternatively, the feed water may be acidified prior to contact with the basic alumina, thereby combining acidification and adsorption into one step, as summarized by Eq. 12-17.

The modeling of the alumina/GFH/GFO adsorption-regeneration cycle as being analogous to weak-base anion exchange fails in regard to regeneration efficiency, which is excellent for weak-base resins but quite poor on metal oxides/hydroxides. This is caused by the need for excess acid and base to partially overcome the poor kinetics of the metal oxide/hydroxide granules, which exhibit very low solid-phase diffusion coefficients compared with resins that are well hydrated flexible gels, offering little resistance to the movement of hydrated ions. A further reason for poor regeneration efficiency on metal oxides/hydroxides is that they are amphoteric and react with (consume) excess acid and base to partly dissolve in acidic and basic regenerant solutions. Resins are totally inert in this regard; that is, they are not dissolved by regenerants.

Special-Purpose Resins. Resins are practically without limit in their variety because polymer matrices, functional groups, capacity, and porosity are controllable during manufacture. Thus numerous special-purpose resins have been made for water treatment applications. For example, bacterial growth can be a major problem with anion resins used in some water supply applications because the positively charged resins tend to absorb the negatively charged bacteria

that metabolize the adsorbed organic material—negatively charged humate and fulvate anions. To correct this problem, special resins have been developed that contain bacteriostatic long-chain *quaternary amine functional groups* (quats) on the resin surface. These immobilized quats kill bacteria on contact with the resin surface (Janauer et al., 1981).

The strong attraction of polyvalent humate and fulvate anions [components of natural organic matter (NOM)] for anion resins has been used as the basis for removal these compounds and total organic carbon (TOC) from water by using special highly porous resins. Both weak- and strong-base macroporous anion exchangers have been manufactured to remove these large anions from water. The extremely porous resins, originally thought to be necessary for adsorption of the large organic anions, tended to be structurally weak and break down easily. However, it has been shown that both gel and standard macroporous resins, which are well hydrated, highly cross-linked, and physically very strong, can be used to remove NOM (Fu and Symons, 1990). Regeneration of resins used to remove NOM is often a problem because of the strong attraction of the aromatic portion of the anions for the aromatic resin matrix. This problem has been solved at least partially using hydrophilic, well-hydrated, acrylic-matrix SBA resins. More detail on the use of IX resins to remove NOM is given later in this chapter.

Special-purpose SBA resins with large, hydrophobic, widely space functional groups have been developed for nitrate and perchlorate removal applications. These resins are discussed in more detail later in the sections on nitrate and perchlorate removal.

Resins with chelating functional groups such as iminodiacetate (Calmon, 1979), aminophosphonate, and ethylenamine (Matejka and Zirkova, 1997) have been manufactured that have extremely high affinities for hardness ions and troublesome metals such as Cu^{2+} , Zn^{2+} , Cr^{3+} , Pb^{2+} , and Ni^{2+} . These resins are used in special applications such as trace metal removal and metals recovery operations (Brooks et al., 1991). Table 12-2 summarizes the

TABLE 12-2 Special Ion Exchangers Available Commercially

Type of resin	Functional group	Typical applications
Chelating	Iminodiacetic	Selective removal of heavy metals and transition metals
Chelating	Aminophosphonic	Decalcification of brine and removal of cations of low atomic mass
Chelating	Thiouonium	Selective removal of heavy metals, especially mercury
Chelating	Polyamine	Removal of trace heavy metals and heavy-metal complex anions
Chelating	Amidoxime	Removal of copper and iron from low pH water
Boron-specific	<i>N</i> -Methylglucamine	Removal of boron from water
NSS, nitrate-over-sulfate-selective (sulfate/divalent rejecting)	Triethyl and tripropyl quaternary amines	Nitrate removal in high sulfate water
Perchlorate-selective	Tripropyl or ethylhexyl quaternary amines	Perchlorate removal from water, often applied in single-use (nonregenerated resin) applications
Silver-impregnated SAC	Sulfonic	Softening resins with bacteriostatic properties
Iodine-releasing	Quaternary amine in triiodide form— $\text{R}_4\text{N}^+\text{I}_3^-$	Portable disinfection units

features of some of the special ion exchangers available commercially from a variety of sources (Purolite, 2009).

IX Equilibrium

Selectivity Coefficients and Separation Factors. IX resins do not prefer all ions equally. This variability in preference is often expressed semiquantitatively as a position in a selectivity sequence or quantitatively as a separation factor α_{ij} or a selectivity coefficient K_{ij} for binary exchange. The selectivity, in turn, determines the run length to breakthrough for the contaminant ion; the higher the selectivity, the longer is the run length. Consider, for example, Eq. 12-18, the simple exchange of Cl^- for NO_3^- on an anion exchanger with an equilibrium constant, as expressed numerically in Eq. 12-19 and graphically in Fig. 12-4a.

$$K = \frac{\{\overline{\text{NO}_3^-}\}\{\text{Cl}^-\}}{\{\text{Cl}^-\}\{\text{NO}_3\}} \quad (12-19)$$

In Eqs. 12-18 to 12-20, overbars denote the resin phase, and the matrix designation R has been removed for simplicity, K is the thermodynamic equilibrium constant, and braces denote ionic activity. Concentrations are used in practice because they are measured more easily than activities. In this case, Eq. 12-20 based on concentration, the selectivity coefficient $K_{\text{N/Cl}}$ describes the exchange. Note that $K_{\text{N/Cl}}$ includes activity-coefficient terms that are functions of ionic strength and thus is not a true constant; that is, it varies somewhat with different ionic strengths.

$$K_{\text{N/Cl}} = \frac{[\overline{\text{NO}_3^-}][\text{Cl}^-]}{[\text{Cl}^-][\overline{\text{NO}_3^-}]} = \frac{q_{\text{N}}C_{\text{Cl}}}{q_{\text{Cl}}C_{\text{N}}} \quad (12-20)$$

where q_{N} = resin-phase equivalent concentration (normality) of nitrate, eq/L
 C_{N} = aqueous-phase equivalent concentration (normality), eq/L

and the brackets represent concentration (mol/L).

FIGURE 12-4 (a) Favorable isotherm for nitrate-chloride exchange according to Reaction 12-18 with constant separation factor $\alpha_{\text{NO}_3/\text{Cl}} > 1.0$. (b) Unfavorable isotherm for bicarbonate-chloride exchange with constant separation factor $\alpha_{\text{HCO}_3/\text{Cl}} < 1.0$.

The binary separation factor $\alpha_{N/Cl}$, used throughout the literature on separation practice, is a useful description of the exchange equilibria because of its simplicity and intuitive nature:

$$\alpha_{ij} = \frac{\text{distribution of ion } i \text{ between phases}}{\text{distribution of ion } j \text{ between phases}} = \frac{y_i/x_i}{y_j/x_j} \quad (12-21)$$

$$\alpha_{N/Cl} = \frac{y_N/x_N}{y_{Cl}/x_{Cl}} = \frac{y_N/x_{Cl}}{x_N/y_{Cl}} = \frac{(q_N/q)(C_{Cl}/C)}{(C_N/C)(q_{Cl}/q)} \quad (12-22)$$

where y_i = equivalent fraction of ion i in resin, q_i/q
 y_N = equivalent fraction of nitrate in resin, q_N/q
 x_i = equivalent fraction of ion i in water, C_N/C
 x_N = equivalent fraction of nitrate in water, C_N/C
 q_N = concentration of nitrate on resin, eq/L
 q = total exchange capacity of resin, eq/L
 C_N = nitrate concentration in water, eq/L
 C = total ionic concentration of water, eq/L

Equations 12-20 and 12-22 show that for homovalent exchange, where the exchanging ions have the same charge (i.e., monovalent/monovalent ion and divalent/divalent ion exchange), the separation factor α_{ij} and the selectivity coefficient K_{ij} are equal. This is expressed for nitrate/chloride exchange as

$$K_{N/Cl} = \alpha_{N/Cl} = \frac{q_N C_{Cl}}{C_N q_{Cl}} \quad (12-23)$$

For exchanging ions of unequal charge, that is, heterovalent exchange, the separation factor is not the same as the selectivity coefficient. Consider, for example, the case of sodium IX softening, as represented by Eq. 12-24, the simplified form of Eq. 12-2.

$$K_{Ca/Na} = \frac{q_{Ca} C_{Na}^2}{C_{Ca} q_{Na}^2} \quad (12-25)$$

Using a combination of Eqs. 12-21 and 12-25, we obtain

$$\alpha_{\text{divalent/monovalent}} \text{ or } \alpha_{Ca/Na} = K_{Ca/Na} \frac{q_{Na}}{C_{Na}} \quad (12-26)$$

The implication from these equations is that the intuitive separation factor for divalent/monovalent exchange depends inversely on solution concentration C and directly on the distribution ratio (y_{Na}/x_{Na}) between the resin and the water, with constant resin capacity q . The higher the solution concentration C , the lower is the divalent/monovalent separation factor; that is, selectivity tends to reverse in favor of the monovalent ion as ionic strength I (which is a function of C) increases. This reversal of selectivity is discussed in detail below.

Selectivity Sequences for Resins. A selectivity sequence describes the order in which ions are preferred by a particular resin or by a solid porous oxide surface such as AlOOH (activated alumina granules or hydrated aluminum oxide precipitate), FeOOH (hydrous iron oxide), or MnOOH (hydrous manganese oxide). Although special-purpose resins such as chelating resins can have unique selectivity sequences, the commercially available cation and anion resins exhibit similar selectivity sequences. These are presented in Table 12-3,

TABLE 12-3 Relative Affinities of Ions for Resins^a

Strong-acid cation resins ^b		Strong-base anion resins ^c	
Cation _i	α_{i/Na^+}^d	Anion _i	α_{i/Cl^-}
Ra ²⁺	13.0	UO ₂ (CO ₃) ₃ ⁴⁻	3200
Ba ²⁺	5.8	ClO ₄ ^{-e}	150
Pb ²⁺	5.0	CrO ₄ ²⁻	100
Sr ²⁺	4.8	SeO ₄ ²⁻	17
Cu ²⁺	2.6	SO ₄ ²⁻	9.1
Ca ²⁺	1.9	HAsO ₄ ²⁻	4.5
Zn ²⁺	1.8	HSO ₄ ⁻	4.1
Fe ²⁺	1.7	NO ₃ ⁻	3.2
Mg ²⁺	1.67	Br ⁻	2.3
K ⁺	1.67	SeO ₃ ²⁻	1.3
Mn ²⁺	1.6	HSO ₃ ⁻	1.2
NH ₄ ⁺	1.3	NO ₂ ⁻	1.1
Na ⁺	1.0	Cl ⁻	1.0
H ⁺	0.67	BrO ₃ ⁻	0.9
		HCO ₃ ⁻	0.27
		CH ₃ COO ⁻	0.14
		F ⁻	0.07

^aValues are approximate separation factors for 0.005 to 0.010 N solution (TDS = 250–500 mg/L as CaCO₃).

^bSAC is polystyrene divinylbenzene matrix with sulfonate functional groups.

^cSBA resin is polystyrene divinylbenzene matrix with —N⁺(CH₃)₃ functional groups (i.e., a type 1 resin).

^dSeparation factors are approximate and are based on various literature sources and on experiments performed at the University of Houston.

^eClO₄⁻/Cl⁻ separation factor is for polystyrene SBA resins; on polyacrylic SBA resins, the ClO₄⁻/Cl⁻ separation factor is approximately 5.0.

where the most preferred ions, that is, those with the highest separation factors, are listed at the top of the table and the least preferred ions at the bottom. For example, the $\alpha_{Ca/Na}$ value of 1.9 means that, at equal concentrations (eq/L) in the aqueous phase, calcium is preferred by the resin 1.9/1.0 over sodium. Weak-acid cation (WAC) resins with carboxylic functional groups exhibit the same selectivity sequence as SAC resins except that hydrogen is the most preferred cation, and the magnitude of the separation factors differs from that in Table 12-3. Similarly, WBA and SBA resins exhibit the same selectivity sequence except that hydroxide is most preferred by WBA resins, and the WBA separation factors differ in magnitude but have the same trend as those in Table 12-3.

Some general rules govern selectivity sequences. In dilute solution, for example, in the TDS range of natural waters, the resin prefers the ion with the highest charge and lowest degree of hydration.

Selectivity is affected by the nature of the ion. Hydrophobic ions, for example, nitrate, chromate, and perchlorate, prefer hydrophobic resins, that is, highly cross-linked macroporous resins without polar matrices and/or functional groups, whereas hydrophilic ions, for example, bicarbonate and acetate, prefer moderately cross-linked (gel) resins with polar matrices and/or functional groups. Divalent ions, for example, sulfate and calcium, prefer resins with closely spaced exchange sites, where their need for two charges can be satisfied (Clifford and Weber, 1983; Sengupta and Clifford, 1986; Subramonian and Clifford, 1998; Horg and Clifford, 1997).

Selectivity Sequences for Alumina- and Iron-Based Adsorbents. Activated alumina (AlOOH) and GFH/GFO (FeOOH) operated in the acidic to neutral pH range for anion adsorption exhibit selectivity sequences that differ markedly from anion exchange resins. Fortunately, some of the ions, such as fluoride and arsenate, that are least preferred by resins (and therefore are not amenable to removal by resins) are highly preferred by the aluminum and iron oxides/hydroxides. Based on research by the authors and their coworkers, as well as other investigators (Trussell et al., 1980; Sing and Clifford, 1981; Rosenblum and Clifford, 1984; Schmitt and Pietrzyk, 1985), activated alumina operated in the pH range of 5.5 to 8.5 prefers anions in the following order:

NOM including humic and fulvic acid anions are more preferred than sulfate, but because of their widely differing molecular weights and structures and the different pore size distributions of commercial aluminas, no exact position in the selectivity sequence can be assigned. Reliable separation factors for ions in the preceding selectivity sequence such as fluoride, arsenate, silicate, and biselenite are not available in the literature, but this is not particularly detrimental to the design effort because alumina, GFH, and GFO have an extreme preference for these ions. For example, when fluoride or arsenate is removed from water, the presence of the usual competing ions—bicarbonate and chloride—is nearly irrelevant in establishing run length to contaminant ion breakthrough (Singh and Clifford, 1981; Rosenblum and Clifford, 1984; Amy, 2005). Sulfate, however, does offer measurable (up to 20% capacity reduction) competition for adsorption sites. The problem with the extremely preferred ions is that they are difficult to remove from the alumina during regeneration, which necessitates the use of hazardous and potentially destructive (of the medium) regenerants (e.g., NaOH and H₂SO₄).

Iron-based oxide/hydroxide (GFO/GFH) adsorbents are similar in their high affinity for anions such as arsenate, phosphate, and silicate and exhibit the following selectivity sequence, which is based on bench-, pilot-, and full-scale studies (Amy et al., 2005; Lakshmanan et al., 2008):

Isotherm Plots. The values of α_{ij} and K_{ij} can be determined from a constant-temperature equilibrium plot of resin-phase concentration versus aqueous-phase concentration, that is, the IX isotherm. Favorable and unfavorable isotherms are depicted in Fig. 12-4a and b, where each curve depicts a constant separation factor $\alpha_{\text{NO}_3/\text{Cl}}$ for Fig. 12-4a and $\alpha_{\text{HCO}_3/\text{Cl}}$ for Fig. 12-4b.

A favorable isotherm (convex to x axis) means that species i (NO₃⁻ in Fig. 12-4a), which is plotted on each axis, is preferred to species j (Cl⁻ in Fig. 12-4a), the exchanging species. An unfavorable isotherm (concave to the x axis) indicates that species i (HCO₃⁻ in Fig. 12-4b) is less preferred than j (Cl⁻ in Fig. 12-4b). During column exhaustion processes, favorable isotherms result in sharp breakthroughs when i is in the feed and j is on the resin, whereas unfavorable isotherms lead to gradual breakthroughs under these conditions. (This is discussed in detail in the section “Column Processes and Calculations.”) In viewing these binary isotherms, note that

$$x_i + x_j = 1.0 \quad (12-28)$$

$$C_i + C_j = C \quad (12-29)$$

$$y_i + y_j = 1.0 \quad (12-30)$$

$$q_i + q_j = q \quad (12-31)$$

Therefore, the concentration or equivalent fraction of either ion can be obtained directly from the plot, which in Fig. 12-4a and b is a *unit* isotherm because equivalent fractions (x_i, y_j) rather than concentrations have been plotted in the range 0.0 to 1.0. Figure 12-4a represents the favorable isotherm for nitrate-chloride exchange, and Fig. 12-4b represents the unfavorable isotherm for bicarbonate-chloride exchange.

For nonconstant separation factors, for example, the divalent/monovalent ($\text{Ca}^{2+}/\text{Na}^+$) exchange case described by Eqs. 12-24 and 12-26, a separate isotherm exists for every total solution concentration C . As the solution concentration or TDS level decreases, the resin exhibits a greater preference for the divalent ion, as evidenced by a progressively higher and more convex isotherm. The phenomenon can be explained by solution theory: As the solution concentration increases, the aqueous phase becomes more ordered. This results in polyvalent ion activity coefficients that are significantly less than 1.0; that is, the tendency for polyvalent ions to escape from the water into the resin is greatly diminished, leading to a reduction in the height and convexity of the isotherm. This phenomenon of diminishing preference for higher-valent (di- and trivalent) ions with increasing ionic strength I of the solution has been labeled *electroselectivity* and eventually can lead to selectivity reversal, whereupon the isotherm becomes concave (Helfferich, 1962). This trend is shown in Fig. 12-5, where the sulfate-chloride isotherm is favorable in ≤ 0.06 N solution and unfavorable in ≥ 0.6 N solution.

FIGURE 12-5 Electroselectivity of a typical type 1 strong-base anion exchange resin used for divalent-monovalent ($\text{SO}_4^{2-}/\text{Cl}^-$) anion exchange.

The exact ionic strength at which electroselectivity reversal occurs depends on the ionic makeup of the solution and highly depends on the resin structure (Boari et al., 1974) and its inherent affinity for polyvalent ions. Electroselectivity reversal is beneficial to the sodium IX softening process in that it causes the divalent hardness ions to be highly preferred in dilute solution ($I \leq 0.020$ M) during resin exhaustion and highly nonpreferred, that is, easily rejected, during regeneration with relatively concentrated (0.50–2.0 M) salt solution.

Example 12-1 Isotherm Data

The following problem briefly describes the experimental technique necessary to obtain isotherm data and illustrates the calculations required to construct a nitrate-chloride isotherm for an SBA exchange resin. By using the isotherm data or the plot, the individual and average separation factors α_{ij} can be calculated. Only minor changes are necessary to apply the technique to weak-base resins or to cation resins. For example, acids (HCl and HNO_3) rather than sodium salts would be used for equilibration of weak-base resins.

To obtain the data for this example, weighted amounts of air-dried chloride-form resin of known exchange capacity were placed into capped bottles containing 100 mL of 0.005 N (5.0 meq/L) NaNO_3 and equilibrated by tumbling for 16 hours. Following equilibration, the resins were settled, and the nitrate and chloride concentrations of the supernatant water were determined for each bottle. The nitrate/chloride equilibrium data are listed in Table 12-4. The total capacity q of the resin is 3.63 meq/g. Note that the units of resin capacity used here are milliequivalents per gram rather than equivalents per liter because, for precise laboratory work, a mass rather than a volume of resin must be used.

Outline of Solution

1. Verify that, within the expected limits of experimental error, the total concentration C of the aqueous phase at equilibrium is 0.005 N. Large deviations from this value usually indicate that concentrated salts were absorbed in the resin and leached out during the equilibration procedure. This problem can be avoided by extensive prewashing of the resin with the same normality of salt, in this case 0.005 N NaCl, as is used for equilibration.
2. Calculate the equivalent fractions $x_{\text{N}} = C_{\text{N}}/C$ and $x_{\text{Cl}} = C_{\text{Cl}}/C$ of nitrate and chloride in the water at equilibrium.
3. Using the known total capacity of the resin q , calculate the milliequivalents of chloride remaining on the resin q_{Cl} at equilibrium by subtracting the milliequivalents of chloride found in the water.
4. Calculate the milliequivalents of nitrate on the resin q_{N} by assuming that all the nitrate removed from solution is taken up by the resin.
5. Calculate the equivalent fractions $y_{\text{N}} = q_{\text{N}}/q$ and $y_{\text{Cl}} = q_{\text{Cl}}/q$ of nitrate and chloride in the resin phase at equilibrium.
6. Calculate the separation factor $\alpha_{\text{N/Cl}} = (y_{\text{N}}/x_{\text{N}})/(y_{\text{Cl}}/x_{\text{Cl}})$, which is equal to the selectivity coefficient K_{ij} for homovalent exchange.
7. Repeat steps 1 through 6 for all equilibrium data points, and plot the isotherm.

Solution The equilibrium data point for 0.2 g of resin is chosen as an example:

1. $C = C_{\text{N}} + C_{\text{Cl}} = 1.17 + 3.78 = 4.95$ meq/L (This is within the expected ± 5 percent limits of experimental error $(5.00 - 4.95)/5.00 = 1.0$ percent error).

$$2. \quad x_{\text{N}} = \frac{C_{\text{N}}}{C} = \frac{1.17 \text{ meq/L}}{4.95 \text{ meq/L}} = 0.236$$

$$x_{\text{Cl}} = \frac{C_{\text{Cl}}}{C} = \frac{3.78 \text{ meq/L}}{4.95 \text{ meq/L}} = 0.764$$

Checking: $x_{\text{N}} + x_{\text{Cl}} = 0.236 + 0.764 = 1.00$

3. Calculate chloride remaining on the resin at equilibrium q_{Cl} :

$$q_{\text{Cl}} = q_{\text{Cl, initial}} - \text{chloride lost to water per gram of resin}$$

$$q_{\text{Cl, initial}} = q = 3.63 \text{ meq/g}$$

$$q_{\text{Cl}} = 3.63 \text{ meq/g} - 3.78 \text{ meq/L} \left(\frac{0.100 \text{ L}}{0.200 \text{ g}} \right) = 1.74 \text{ meq/g}$$

4. Calculate nitrate on resin at equilibrium:

$$q_N = q_{N, \text{initial}} + \text{nitrate lost from water per gram of resin}$$

$$q_N = 0 + [(5.00 - 1.17) \text{ meq/L}] \left(\frac{0.100 \text{ L}}{0.200 \text{ g}} \right) = 1.91 \text{ meq/g}$$

Checking: $q_N + q_{Cl} = 1.74 + 1.91 = 3.65 \text{ meq/g}$ (within 5 percent of 3.63)

5. Calculate the resin-phase equivalent fractions y_N and y_{Cl} at equilibrium:

$$y_N = \frac{1.91 \text{ meq/g}}{3.65 \text{ meq/g}} = 0.523$$

$$y_{Cl} = \frac{1.74 \text{ meq/g}}{3.65 \text{ meq/g}} = 0.477$$

6. Calculate the separation factor α_{ij} :

$$\alpha_{ij} = \frac{y_N x_{Cl}}{x_N y_{Cl}} = \frac{0.523 \times 0.764}{0.236 \times 0.477} = 3.55$$

Note: Each data point will have an associated α_{ij} value. These α_{ij} values can be averaged, but it is preferable to plot the isotherm data, construct the best-fit curve, and use the curve at $x_N = 0.5$ to obtain an average α_{ij} value. The bad data points will be evident in the plot and can be ignored. Owing to mathematical sensitivity, resin inhomogeneity, and imprecise experimental data, the calculated α_{ij} values are not constant, as can be seen in Table 12-4. The α_{ij} values at the ends of the isotherm may not be representative.

7. Plot the isotherm of y_N versus x_N . The nitrate versus chloride isotherm plot should appear similar to Fig. 12-4a. ▲

TABLE 12-4 Example 12-1 Data for Plot of Nitrate/Chloride Isotherm

g resin/ 100 mL	C_N , meq/L	C_{Cl} , meq/L	C , meq/L	x_N	x_{Cl}	y_N	y_{Cl}	α_{ij}
0.020	4.24	0.722	4.96	0.854	0.146	0.980	0.020	8.6
0.040	3.56	1.32	4.88	0.730	0.270	0.920	0.091	4.25

Note: The first three columns represent experimental data. The remaining columns were obtained by calculation as described in the example.

IX and Adsorption Kinetics

Pure IX Rates. As is usual with interphase mass transfer involving solid particles, IX kinetics is governed by liquid- and solid-phase resistances to mass transfer (film and particle diffusion processes). It has long been accepted that ion diffusion processes rather than the actual exchange reactions determine IX kinetics. The IX rates depend on solution (ion) concentration, resin particle size, degree of resin cross-linking and hydration, solution-phase turbulence, ion diffusion coefficients in the aqueous and resin phases, and temperature (Kunin, 1958). In early IX kinetic research on the rates of film and particle diffusion measured in batch experiments, Boyd and colleagues (1947) demonstrated that for sodium-potassium exchange, film diffusion controlled at 0.001 N solution concentration,

whereas particle diffusion controlled at 1.0 N. In the range between 0.001 and 1.0 N solution concentration, where most IX reactions occur, both phases controlled. Thus IX kinetics are difficult to describe mathematically.

The liquid-phase resistance, modeled as the stagnant thin film, can be minimized by providing turbulence around the particle such as that resulting from fluid velocity in packed beds or mechanical mixing in batch operations. The speed of pure IX reactions, that is, reactions not involving (1) WAC resins in the RCOOH form or (2) free-base forms of weak-base resins, can be attributed to the inherently low mass transfer resistance of the resin phase that is caused by its well-hydrated gelular nature. Resins beads typically contain 40 to 60 percent water within their boundaries, and this water can be considered as a continuous extension of the aqueous phase within the flexible polymer network. This pseudocontinuous aqueous phase in conjunction with the flexibility of the resin phase can result in rapid kinetics for "pure IX" reactions, that is, IX of typical inorganic ions using fully hydrated strong resins.

IX and Adsorption Kinetics Compared. Unlike adsorption onto granular activated carbon (GAC), activated alumina, or granular iron oxides/hydroxides requiring on the order of hours to days to reach equilibrium, pure IX using strong-acid or strong-base resins is a rapid process at near-ambient temperature. For example, the half-time to equilibrium for adsorption of arsenate onto granular 28 × 48 mesh (0.29–59 mm diameter) activated alumina was found to be approximately 2 days (Rosenblum and Clifford, 1984), whereas the half-time to equilibrium during the exchange of arsenate for chloride on a strong-base resin was only 5 minutes (Horng, 1983; Horng and Clifford, 1997). This is in general agreement with early observations (Kunin, 1958) that the time for 90 percent attainment of sodium-calcium exchange on strong-acid (sufonic) cation resins (pure IX) was less than 2 minutes.

Rates Involving Tight Resin Forms. In contrast to pure IX, IX with WAC and WBA resins can be slow because of the tight, nonswollen nature of the acid form ($\overline{\text{RCOOH}}$) of WAC resins or free-base forms, for example, $\overline{\text{R}_3\text{N}^-}$, of WBA resins. In reactions involving these tight forms, the average solid-phase diffusion coefficients change drastically during the course of the exchange, which is often described using the progressive-shell, shrinking-core model (Helfferich, 1965, 1966) depicted in Fig. 12-6. In these reactions, which are effectively neutralization reactions, either the shell or the core can be the swollen (more hydrated) portion, and a rather sharp line of demarcation exists between the tight and swollen zones. Consider, for example, the practical case of softening with WAC resins in the H^+ form (Eq. 12-4). As the reaction proceeds, the hydrated calcium-form shell comprising $\overline{(\text{RCOO}^-)_2\text{Ca}^{2+}}$ expands inward and replaces the shrinking, poorly hydrated core of $\overline{\text{RCOOH}}$. The entire process is reversed on regeneration with acid, and the tight shell of $\overline{\text{RCOOH}}$ thickens as it proceeds inward and replaces the porous, disappearing core of $\overline{(\text{RCOO}^-)_2\text{Ca}^{2+}}$.

In some cases, pure IX with weak resins is possible, however, and proceeds as rapidly as pure IX with strong resins. For example, the pure exchange of sodium for calcium on a WAC resin (Eq. 12-32) does not involve conversion of the resin RCOOH, in contrast to Eq. 12-4, and would take place in a matter of minutes as with SAC resins (Eq. 12-3).

Although weak resins involving $\overline{\text{RCOOH}}$ and $\overline{\text{R}_3\text{N}^-}$ may require several hours to attain equilibrium in a typical batch exchange, they still may be used effectively in column processes

FIGURE 12-6 Progressive shell model of IX with weak resins.

where the contact time between the water and the resin is only 1 to 5 minutes. There are two reasons for the column advantage: (1) An overwhelming amount of unspent resin capacity (eq/L) is present relative to the number of ions (eq/L) in the water in the column, and (2) the resin is typically exposed to the feed water for periods in excess of 24 hours before it is exhausted. Prior to exhaustion, the overwhelming ratio of resin exchange sites present in the column to exchanging ions present in the column water nearly guarantees that an ion will be removed by the resin before the water carrying the ion exits the column. The actual contaminant removal takes place in the *adsorption* or *ion exchange* or *mass transfer zone* (Fig. 12-7) that characterizes the breakthrough curve of interest.

FIGURE 12-7 Resin concentration profile for binary IX of sodium for calcium.

In summary, IX of small inorganic ions (e.g., Na^+ , Ca^{2+} , Cl^- , NO_3^- , SO_4^{2-}) using strong resins is fundamentally a fast interphase transfer process because strong resins are well-hydrated gels exhibiting large solid-phase diffusion coefficients and little resistance to mass transfer. This is not the case with weak resins in the acid (RCOOH) or free-base (R_3N) forms, nor is it true for metal oxides/hydroxides because these media offer considerably more solid-phase diffusion resistance. Irrespective of fast or slow batch kinetics, all these media can be used effectively in column processes for contaminant removal from water because columns exhibit enormous contaminant-removal capacity and are exhausted over a period of many hours to many days. Leakage of contaminants, however, will be much more significant with media that exhibit relatively slow mass transfer rates.

Column Processes and Calculations

Binary IX. IX and adsorption column operations do not result in a fixed percentage of removal of contaminant with time, which would result, for example, in a steady state coagulation process (Lakshmanan et al., 2008). These column processes exhibit a variable degree of contaminant removal and gradual or sharp contaminant breakthroughs similar to (but generally much more complicated than) the breakthrough of turbidity through a granular filter. First, we consider the hypothetical case of pure binary IX before proceeding to the practical drinking water treatment case of multicomponent IX.

If pure calcium chloride solution is softened by continuously passing it through a bed of resin in the sodium form, IX (Eq. 12-2) occurs immediately in the uppermost differential segment of the bed (at its inlet). Here, all the resin is converted to the calcium form in the moving IX zone, where mass transfer between the liquid and solid phases occurs. These processes are depicted in Fig. 12-7.

The resin phase experiences a calcium wavefront that progresses through the column until it reaches the outlet. At this point, no more sodium-form resin exists to take up calcium, and

FIGURE 12-8 Effluent concentration histories (breakthrough curves) for softening reaction, that is, exchange of calcium for sodium.

calcium breaks through into the effluent, as shown in Fig. 12-8. In this pure binary IX case, the effluent calcium concentration never can exceed that of the influent; this is, however, generally not true for multicomponent IX, as we show later. The sharpness of the calcium breakthrough curve depends on both equilibrium (i.e., selectivity) and kinetic (i.e., mass transfer) considerations. Imperfect, that is, noninstantaneous interphase mass transfer of sodium and calcium, coupled with flow channeling and axial dispersion, always acts to reduce the sharpness of the breakthrough curve and result in a broadening of the IX zone.

This is equivalent to saying that nonequilibrium (non-instantaneous) mass transfer produces a diffuse calcium wave and a somewhat gradual calcium breakthrough.

A breakthrough curve can be gradual even if mass transfer is instantaneous and flow channeling and axial dispersion are absent because the first consideration in determination of the shape is the resin's affinity (an equilibrium consideration) for the exchanging ions. Mass transfer is the second consideration. If the exchange isotherm is favorable, as is the case here (i.e., the entering ion, calcium, is preferred to sodium), then a perfectly sharp (squarewave) theoretical breakthrough curve results. If the IX isotherm is unfavorable, as is the case for the reverse reaction of sodium chloride fed to a calcium-form resin, then a gradual breakthrough curve results even for instantaneous (equilibrium) mass transfer. These two basic types of breakthrough curves, sketched in Fig. 12-9, result from the solution of mass-balance equations assuming instantaneous equilibrium and constant adsorbent capacity.

FIGURE 12-9 Theoretical breakthrough curves for equilibrium IX with no mass transfer limitations. An unfavorable isotherm (Fig. 12-4b) results in a broadening wavefront (breakthrough), whereas a favorable isotherm (Fig. 12-4a) results in a self-sharpening wavefront.

Multicomponent IX. The breakthrough curves encountered in water supply applications are much more complicated than those in Figs. 12-8 and 12-9. The greater complexity is caused by the multicomponent nature of the exchange reactions when treating natural water.

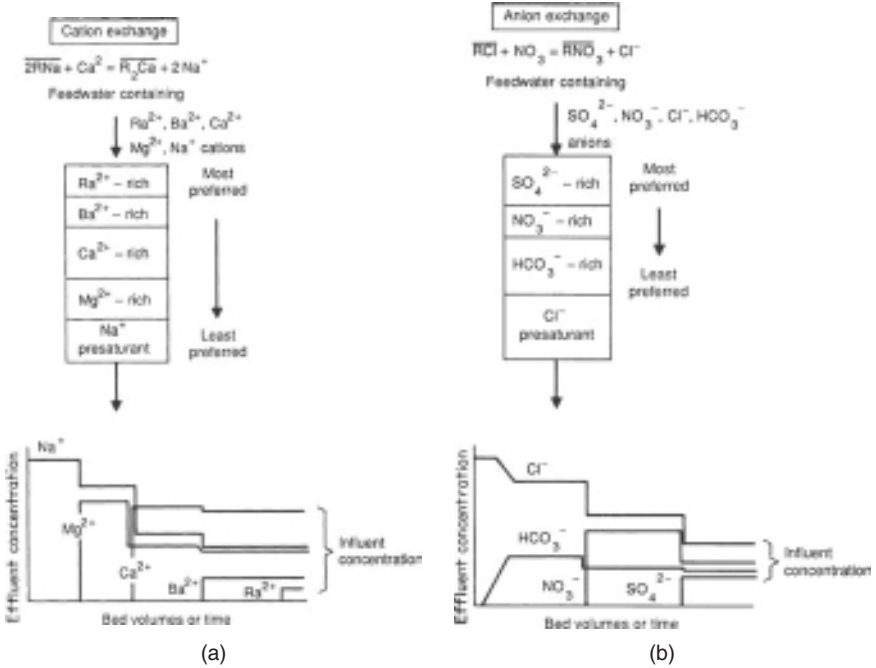

FIGURE 12-10 (a) Ideal resin concentration profile (above) and breakthrough curves (below) for typical softening and radium removal. Note that the column was run far beyond hardness (Mg^{2+}) breakthrough and slightly beyond radium breakthrough. The most preferred ion is Ra^{2+} , followed by $Ba^{2+} > Ca^{2+} > Mg^{2+} > Na^+$. After Ra^{2+} breakthrough, effluent concentration equals influent concentration for all ions. (b) Ideal resin concentration profile (above) and breakthrough curves (below) for nitrate removal by chloride-form anion exchange with strong-base resin. Note that the column was run far beyond nitrate breakthrough and somewhat beyond sulfate breakthrough. The most preferred ion is SO_4^{2-} , followed by $NO_3^- > Cl^- > HCO_3^-$.

Some ideal resin concentration profiles and breakthrough curves for hardness removal by IX softening and for nitrate removal by chloride-form anion exchange are sketched in Fig. 12-10. The important determinants of the shapes of these breakthrough curves are (1) the feed water composition, (2) the resin capacity, and (3) the resin's affinity for each of the ions as quantified by the separation factor α_{ij} or the selectivity coefficient K_{ij} . The order of elution of ions from the resin, however, is determined solely by the selectivity sequence, which is the ordering of the components i from 1 to n , where 1 is the most preferred and n is the least preferred ion. Finally, before continuing with our discussion of multicomponent IX column behavior, we must remind ourselves of Eq. 12-26, which shows that the α_{ij} values for divalent and higher-valent ions, and thus the order of elution of ions, also will be determined by the total ionic concentration C of the feed water.

In carrying out the cation or anion exchange reactions, ions in addition to the target ion, for example, calcium or nitrate, are removed by the resin. All the ions are concentrated, in order of preference, in bands or zones in the resin column, as shown in the resin concentration profiles of Fig. 12-10. As these resin boundaries (wavefronts) move through the column, the breakthrough curves shown in the figure result. These are based on theory (Helfferich and Klein, 1970) but have been verified in actual breakthrough curves published by Clifford (1982, 1985), Snoeyink and colleagues (1987), and (Guter, 1995).

The following rules can be applied to effluent histories in multicomponent IX (and adsorption) systems theory (Helfferich and Klein, 1970; Clifford, 1982, 1991):

1. Ions higher in the selectivity sequence than the presaturant ion tend to have long runs and sharp breakthroughs; those less preferred than the presaturant ion will always have early, gradual breakthroughs, as typified by HCO_3^- in Fig. 12-10b.
2. The most preferred species (radium in the case of softening and sulfate in the case of nitrate removal) are last to exit to column, and their effluent concentrations never exceed their influent concentrations.
3. The species exit the column in reverse preferential order, with the less preferred ions (smaller separation factors with respect to the most preferred species) leaving first.
4. The less preferred species will be concentrated in the column and will, at some time, exit the column in concentrations exceeding their influent concentrations (*chromatographic peaking*). This is a potentially dangerous situation depending on the toxicity of the ion in question. Good examples of chromatographic peaking, that is, effluent concentration greater than influent concentration, are visible in Fig. 12-10. A magnesium peak is shown in Fig. 12-10a and bicarbonate and nitrate peaks in Fig. 12-10b.
5. When all the breakthrough fronts have exited the column, the entire resin bed is in equilibrium with the feed water. When this happens, the column is exhausted, and the effluent and influent ion concentrations are equal.
6. The effluent concentration of the presaturant ion (Na^+ in Fig. 12-10a and Cl^- in Fig. 12-10) decreases in steps as each new ion breaks through because the total ionic concentration of the water C (meq/L) must remain constant during simple IX.

One way to eliminate the troublesome chromatographic peaking of toxic ions such as nitrate and arsenate is by inverting the selectivity sequence so that the toxic contaminant is the ion most preferred by the resin. This requires preparation of special-purpose resins. This has been done in the case of nitrate removal and is discussed later. Potential peaking problems still remain with other inorganic contaminants, notably arsenic [As(V)] (Ghurye et al., 1999) and selenium [Se(IV)] (Clifford, 1991). An alternative means of eliminating or minimizing peaking is to operate several columns in parallel, as will be discussed in the section "Multicolumn Processes" below.

Breakthrough Detection and Run Termination. Clearly, an IX column run must be stopped before a toxic contaminant is dumped during chromatographic peaking. Even without peaking, violation of the MCL will occur at breakthrough when the contaminant feed concentration exceeds the MCL. Detecting and preventing a high effluent concentration of contaminant depends on the sampling and analysis frequency. Generally, continuous on-line analysis of the contaminant, for example, nitrate or arsenate, is too sophisticated for small communities, where most of the inorganic contaminant problems exist. On-line conductivity detection, the standard means of effluent quality determination in IX demineralization processes, is not easily applied to the detection of contaminant breakthrough in single-contaminant removal processes such as radium, barium, nitrate, or arsenate removal. This is so because of the high and continuously varying conductivity of the effluents from cation or anion beds operated on typical water supplies. Conductivity should not be ruled out completely because even though the changes may be small, as the various ions exit the column, a precise measurement may be possible in selected applications.

On-line pH measurement is a proven, reliable technique that sometimes can be applied as a surrogate for contaminant breakthrough. For example, pH change can be used to signal the exhaustion of a weak-acid resin ($-\text{RCOOH}$) used for carbonate hardness removal. When exhausted, the WAC resin ceases to produce acidic carbon dioxide, and the pH

quickly rises to that of the feed water. This pH increase is, however, far ahead of the barium or radium breakthrough. Effluent pH change sometimes can be used as an indicator of nitrate breakthrough, as discussed in the section on nitrate removal.

The usual method of terminating an IX column run is to establish the relevant breakthrough curve by sampling and analysis and then to use these breakthrough data to terminate future runs based on the metered volume of throughput with an appropriate safety factor. If a breakthrough detector such as a pH or conductivity probe is applied, the sample line to the instrument can be located upstream (e.g., 15–30 cm, or 6–12 in) of the bed outlet to provide advance warning of breakthrough.

Typical Service Cycle for a Single Column. IX and adsorption columns are operated on similar service cycles consisting of six steps: exhaustion, backwash, regeneration, slow rinse, fast rinse, and return to service. A simple single-column process schematic is shown in Fig. 12-11 and includes an optional bypass for a portion of the feed water. Bypass blending will be a common procedure for drinking water treatment applications because IX resins usually can produce a contaminant-free effluent that is purer than that required by law. Therefore, to minimize treatment costs, part of the contaminated feed water, typically 10 to 50 percent, will be bypassed around the process and blended with the effluent to produce product water approaching some fraction (e.g., 70 percent) of the MCL acceptable to the regulatory agency. An alternative means of providing efficient column utilization when significant contaminant leakage is allowed is to operate several columns in parallel, as discussed in the section “Multicolumn Processes” below.

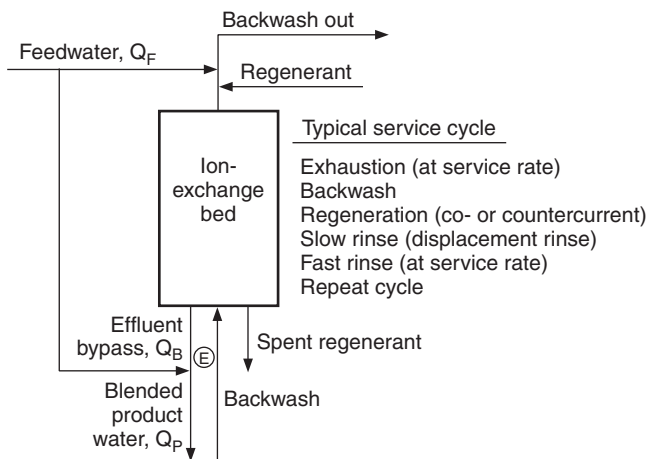

FIGURE 12-11 Schematic and service cycle of a single-column IX process.

Partial Regeneration and Regenerant Reuse. Yet another means of optimizing column utilization and minimizing process costs is to use the technique of partial regeneration. This involves the use of only a fraction, for example, 25 to 50 percent, of the regenerant required for complete, for example, 90 to 100 percent, removal of the contaminant from the exhausted resin. The result is often, but not always, a large leakage of contaminant on the next exhaustion run caused by the relatively high level of contaminant remaining on the resin. This high effluent contaminant concentration (leakage) prior to breakthrough often can be tolerated without exceeding the MCL. Partial regeneration is particularly useful in

nitrate removal, as discussed in detail later. Generally, either bypass blending or partial regeneration is used; use of both processes simultaneously is possible but creates significant process control problems.

Reuse of spent regenerant is another means of reducing costs and minimizing waste disposal requirements. In order for a spent regenerant to be reused, either the target contaminant ion must be removed from the regenerant before reusing it, or the resin must have a strong preference for the regenerant ion in favor of the contaminant ion, which accumulates in the recycle brine. The recent literature suggests that spent brine reuse is possible in more applications than previously thought possible. Removing nitrate from the recycle brine by means of biological denitrification was the approach used by me and my colleagues (Clifford and Liu, 1993; Liu and Clifford, 1996a, 1996b) for their nitrate IX process with brine reuse. In our pilot-scale experiments, a denitrified 0.5 M Cl^- brine was reused 38 times without disposal. Hiremath et. al. (2006) developed a similar process for reuse of perchlorate-contaminated brine. Clifford and colleagues (2003) determined that spent arsenic-contaminated brine could be reused more than 20 times simply by maintaining the Cl^- concentration at 1.0 M without removing the arsenic. Kim and Symons (1991) showed that DOC anions could be removed from drinking water by SBA exchange with regenerant reuse. No deterioration of DOC removal was noted during nine exhaustion-regeneration cycles with spent brine (a mixture of NaCl and NaOH) reuse when the Cl^- and OH^- levels were maintained at 2.0 and 0.5 M, respectively. Further information on these processes is provided in the "Applications" section below.

Reusing the entire spent-regenerant solution is not necessary. In cases where there is a long tail on the contaminant elution curve, the first few bed volumes of heavily contaminated regenerant are discarded, and only the least-contaminated portions are reused. In this case, a two-step roughing-polishing regeneration can be used. The roughing regeneration is completed with the partially contaminated spent regenerant, and the polishing step is carried out with fresh regenerant. The spent regenerant from the polishing step then is used for the next roughing regeneration.

The regenerant reuse techniques are relatively new to the IX field and are still being proven in full-scale long-term use for water supply applications. Although conserving regenerants and reducing waste discharge volumes, regenerant reuse can result in some significant disadvantages: (1) increased process complexity, (2) increased contaminant leakage, (3) progressive loss of capacity caused by incomplete regeneration and fouling, (4) the need to store and handle spent regenerants, and (5) the buildup (concentration) of trace contaminants as the number of regenerant reuse cycles increases.

FIGURE 12-12 Two-column roughing-polishing system with third column in standby or regeneration. After exhaustion of column 1, it is taken out of service; partially exhausted column 2 becomes the new roughing column, and freshly regenerated column 3 becomes the polishing column. The cycle is repeated in a merry-go-round pattern.

Multicolumn Processes. IX or adsorption columns can be connected either in series to improve product purity and regenerant usage or in parallel to increase throughput, minimize peaking, and smooth out product water quality variations. If designed properly, multicolumn systems can be operated in parallel, series, or parallel-series modes.

Columns in Series. A series roughing-polishing (lead-lag) sequence is shown in Fig. 12-12. In such a process, a completely exhausted roughing (lead) column is regenerated when the partially exhausted polishing column effluent exceeds the MCL. This

unregenerated polishing column becomes the new roughing column, and the old roughing column, now freshly regenerated, becomes the new polishing column. Often three columns are used. While two are in service, the third is being regenerated. A multicolumn system consisting of three or more columns operated in this manner is referred to as a *merry-go-round system*, which should not be confused with a continuously rotating carousel ISEP[®] system (Calgon Carbon Corp., 2009), which is typically operated as 20 columns in parallel at various stages of exhaustion, rinsing, and regeneration.

Columns in Parallel. In addition to bypass blending (see Fig. 12-11), an alternative means of allowing a predetermined amount of contaminant leakage in the product water is to employ multiple columns in parallel operated at different stages of exhaustion. For example, with three columns operated in parallel, the first one could be run beyond MCL breakthrough, whereas the second and third columns would not have achieved breakthrough. Thus, even after contaminant breakthrough in the first column, the average concentration of the three blended effluents would be below the MCL. Multiple parallel column operation gives a more consistent product water quality and also can prevent, or at least smooth out, chromatographic peaks from serious overruns. During normal operation of multiple parallel column systems, some columns are being exhausted, whereas others are being rinsed and regenerated or are in standby mode. The columns may be stationary (www.basinwater.com, 2009) or moving, as in the *ISEP* system described earlier.

Process Differences: Resins Versus Metal-Oxide Adsorbents. The design of a process for contaminant adsorption and regeneration using hydrous metal oxides (alumina, GFH, GFO, and titanium or zirconium oxides/hydroxides) is similar to that for IX resins but with some significant exceptions. First, contaminant leakage is inherently greater with the adsorptive media; adsorption zones are longer, and breakthrough curves are more gradual because metal oxide/hydroxide adsorption kinetics are much slower than IX. Second, effluent chromatographic peaking of the contaminant (e.g., fluoride, arsenic, or selenium) is rarely seen when using adsorptive media because these contaminants are usually the most preferred ions in the feed water. Finally, complex two-step base-acid regeneration is required to rinse out the excess base and return the metal oxide to a useful form.

Design Considerations

Resin Characteristics. Several hundred different resins are available from U.S. and European manufacturers. Of these, resins based on the polystyrene divinylbenzene matrix see widest use. Representative ranges of properties of these resins are shown in Table 12-5 for the two major categories of resins used in water treatment. IX capacity is expressed in milliequivalents per milliliter (wet-volume capacity) because resins are purchased and installed on a volumetric basis ($\text{meq/mL} \times 21.8 = \text{kgain CaCO}_3/\text{ft}^3$). A wet-volume capacity of 1.0 meq/mL means that the resin contains 6.023×10^{20} exchange sites per milliliter of wet resin, including voids. The dry-weight capacity in milliequivalents per gram of dry resin is more precise and is used often in scientific research.

The *operating capacity* is a measure of the actual performance of a resin under a defined set of conditions, including, for example, feed water composition, service rate, and degree of regeneration. The operating capacity is always less than the advertised exchange capacity because of incomplete regeneration and early contaminant leakage, which cause early run termination. Some example hardness operating capacities during softening are given in Table 12-6, where the operating capacity for softening is seen to be a function of the amount of regenerant used.

Bed Size and Flow Rates. A resin bed depth of 76 cm (30 in) is usually considered the minimum, and beds as deep as 3.7 m (12 ft) are not uncommon. The *empty-bed contact time* (EBCT) chosen determines the volume of resin required and is usually in the range of

TABLE 12-5 Properties of Styrene-Divinylbenzene Gel-Type Strong-Acid Cation and Strong-Base Anion Resins

Parameter	Strong-acid cation resin	Type 1 strong-base anion resin
Screen size, U.S. mesh	-16 + 50	-16 + 50
Shipping weight, kg/m ³ (lb/ft ³)	850 (53)	700 (44)
Moisture content, %	45-48	43-49
pH range	0-14	0-14
Maximum operating temp, °C (°F)	140 (280)	OH ⁻ form 60 (140)
Turbidity tolerance, ntu	5	5
Iron tolerance, mg/L as Fe	5	0.1
Chlorine tolerance, mg/L Cl ₂	1.0	0.1
Backwash rate, m/h (gpm/ft ²)	12-20 (5-8)	4.9-7.4 (2-3)
Backwash period, minutes	5-15	5-20
Expansion volume, %	50-100	50-75
Regenerant and concentration ^a	NaCl, 3%-12%	NaCl, 3%-12%
Regenerant dose, kg/m ³ (lb/ft ³)	80-320 (5-20)	80-320 (5-20)
Regenerant rate, min/BV (gpm/ft ³)	15 (0.5)	15 (0.5)
Rinse volume, BV (gal/ft ³)	2-8 (15-60)	2-10 (15-75)
Exchange capacity, meq/mL (kgr CaCO ₃ /ft ³) ^b	1.8-2.0 (39-41)	1-1.3 (22-28)
Operating capacity, meq/mL (kgr CaCO ₃ /ft ³) ^c	0.9-1.4 (20-30)	0.4-0.8 (12-16)
Service rate, BV/h (gpm/ft ³)	8-40 (1-5)	8-40 (1-5)

^aOther regenerants such as H₂SO₄, HCl, and CaCl₂ also can be used for SAC resins, whereas NaOH, KOH, and CaCl₂ can be used for SBA regeneration.

^bKilograins CaCO₃/ft³ are the units commonly reported in the resin manufacturer literature. To convert kgr CaCO₃/ft³ to meq/mL, multiply by 0.0458.

^cOperating capacity depends on method of regeneration, particularly on the amount of regenerant applied. See Table 9.6 for SAC resins.

TABLE 12-6 Softening Capacity^a as a Function of Regeneration Level

Regeneration level		Hardness capacity		Regeneration efficiency	
lb NaCl/ft ³ resin	kg NaCl/m ³ resin	kgr CaCO ₃ /ft ³ resin	eq CaCO ₃ /L resin	lb NaCl/kgr CaCO ₃	eq NaCl/eq CaCO ₃
4	64	17	0.78	0.24	1.40
6	96	20	0.92	0.30	1.78
8	128	22	1.00	0.36	2.19
10	160	25	1.15	0.40	2.38
15	240	27	1.24	0.56	3.30
20	320	29	1.33	0.69	4.11
Infinite	Infinite	45	2.06	Infinite	Infinite

^aOperating capacity values are based on the performance of a typical 8 percent cross-linked styrene divinylbenzene SAC resin. Values given are independent of EBCT and bed depth, provided that the minimum criteria [EBCT = 1.0 minute; bed depth = 0.76 m (2.5 ft)] are met. More efficient regeneration may be possible using "shallow-shell technology (SST) resins," which are not functionalized to the core (www.purolite.com/SST).

1.5 to 7.5 minutes. The reciprocal of EBCT is the *service flow rate* (SFR) or *exhaustion rate*, and its accepted range is 8 to 40 BV/h (1–5 gpm/ft³). These relationships are expressed as

$$\text{EBCT} = \frac{V_R}{Q_F} = \text{average water detention time in an empty bed} \quad (12-33)$$

$$\text{SFR} = \frac{1}{\text{EBCT}} = \frac{Q_F}{V_R} \quad (12-34)$$

where Q_F is the feed water volumetric flow rate, L/min (gal/min), and V_R is the resin bed volume including voids, m³ (ft³).

Fixed-Bed Columns. IX columns are usually steel pressure vessels constructed so as to provide (1) a good feed and regenerant distribution system, (2) an appropriate bed support, including provision for backwash water distribution, and (3) enough free space above the resin bed to allow for expected bed expansion during backwashing. Additionally, the vessel must be lined so as to avoid corrosion problems resulting from concentrated salt solutions and, in some cases, acids and bases used for regeneration or resin cleaning. There must be minimal dead space below the resin bed where regenerants and cleaning solutions might collect and subsequently bleed into the effluent during the service cycle.

Cocurrent versus Countercurrent Regeneration. Historically, downflow exhaustion followed by downflow (cocurrent) regeneration has been the usual mode of operation for IX columns. However, the recent trend, especially in Europe, is to use upflow (countercurrent) regeneration for the purpose of minimizing the leakage of contaminant ions on subsequent exhaustions of IX demineralizers. Theoretically, countercurrent regeneration is better because it exposes the bottom (exit) of the bed to a continuous flow of fresh regenerant and leaves the resin located near the outlet of the bed in a well-regenerated condition. Our research on nitrate (Clifford et al., 1987) and arsenate removal (Clifford et al., 1999), however, has called into question the conventional wisdom that countercurrent is always better than cocurrent regeneration. It has been found that cocurrent downflow regeneration is superior to countercurrent upflow regeneration for contaminants such as arsenate and nitrate, which are concentrated at the bed outlet at the end of a run. The proposed reason for the superiority of downflow regeneration in these situations is that the contaminant is not forced back through the entire resin bed during regeneration. The forcing of the contaminant back through the bed tends to leave relatively more contaminant in the resin. This is discussed in more detail in the sections on nitrate and arsenic removal.

Spent Brine Reuse. In order for a spent regenerant to be reused, either the target contaminant ion must be removed from the regenerant before reusing it, or the resin must have a strong preference for the regenerant ion in favor of the target ion, which accumulates in the recycle brine. The recent literature suggests that spent brine reuse is possible in more applications than previously thought possible. Brine reuse was discussed earlier in the section "Partial Regeneration and Regenerant Reuse."

APPLICATIONS OF IX AND ADSORPTION

Sodium IX Softening

As already mentioned, softening water by exchanging sodium for calcium and magnesium using SAC resin (see Eq. 12-2) is the major application of ion-exchange technology for drinking water treatment. Prior to the advent of synthetic resins, zeolites, i.e., inorganic

crystalline aluminosilicate ion exchangers in the sodium form were utilized as the exchangers. The story of one major application of ion-exchange softening at the Weymouth plant of the Metropolitan Water District of Southern California is well told by Bowers (1980) in *The Quest for Pure Water*. In that application, which included 1.5×10^6 m³/d (400 mgd) of softening capacity, softening by ion exchange eventually supplanted excess lime-soda ash softening because of better economics, fewer precipitation problems, and the requirement for a high alkalinity level in the product water to reduce corrosion. One advantage of the lime soda ash softening process is that it reduces the TDS level of the water by removing calcium and magnesium bicarbonates as CaCO₃(s) and Mg(OH)₂(s). The concomitant removal of alkalinity is, however, sometimes detrimental, thus favoring ion-exchange softening, which exchanges only cations leaving the anions intact. Lime-soda ash softening is covered in chapter 13.

As with most IX softening plants, the zeolite media at the Weymouth plant was exchanged for resin in the early 1950s, shortly after polystyrene sulfonate SAC resins were introduced. The SAC softening resins used today are basically the same as those early polystyrene resins. Their main features are high chemical and physical stability (even in the presence of chlorine), uniformity in size and composition, high exchange capacity, rapid exchange kinetics, a high degree of reversibility, and long life. A historical comparison between the life of the zeolites and that of the resins indicated that zeolites could process a maximum of 214,000 BV (1.6×10^6 gal H₂O/ft³ of zeolite) before replacement, whereas the resins could process up to 2,700,000 BV (20×10^6 gal H₂O/ft³ of resin) before they needed replacement. The softeners designed and installed for resins at this plant in 1966 were 8.5×17 m (28×56 ft) reinforced-concrete basins filled to a depth of 0.76 m (2.5 ft) and each containing 113 m³ (4000 ft³) of resin.

The Weymouth plant used IX softening for over 30 years. Softening ceased in 1975, when the source water hardness was reduced by blending. At that time, the 9-year-old resin in the newest softeners was still good enough to be resold. Other interesting design features of this plant included disposal of waste brine to a wastewater treatment plant through a 32 km long (20 mi) pipe flowing at 0.43 m³/s (15 ft³/s) with upflow exhaustion at 14.7 m/h (6.0 gal/min/ft²)—3.1 minute EBCT in a 0.76 m deep (2.5 ft) bed—followed by downflow regeneration.

Example 12-2 Softening Design Example

This typical design example illustrates how to establish the IX resin volume, column dimensions, and regeneration requirements for a typical water softener.

Design Problem

A groundwater is to be partially softened from 275 down to 150 mg/L of CaCO₃ hardness. IX has been selected instead of lime softening because of its simplicity and the ease of cycling on and off to meet the water demand. The well pumping capacity is 3.8×10^3 m³/d (1 mgd or 700 gpm), and the system must be sized to meet this maximum flow rate. The source water contains only traces of iron; therefore, potential clogging problems because of suspended solids are not significant. In applications where raw water suspended solids would foul the resins, coagulation-filtration or filtration pretreatment with dual- or multimedia filters would be required.

Outline of Solution

1. Select a resin and a regeneration level using the resin manufacturer's literature.
2. Calculate the allowable fraction f_B of bypass source water.
3. Choose the service flow rate (SFR, gpm/ft³, or EBCT, minutes).
4. Calculate the run length t_H and the bed volumes V_F that can be treated prior to hardness breakthrough.

5. Calculate the volume of resin V_R required.
6. Determine the minimum out-of-service time (in hours) during regeneration.
7. Choose the number of columns in the system.
8. Dimension the columns.
9. Calculate the volume and composition of wastewater.

Calculations

(1) *Selection of resin and resin capacity.* Once the resin and its regeneration level have been specified, the IX operating capacity is fixed based on experimental data of the type found in Table 12-6. The data are for a polystyrene SAC resin subjected to cocurrent regeneration using 10 percent (1.7 N) NaCl. If a regeneration level of 240 kg NaCl/m³ of resin (15 lb NaCl/ft³) is chosen, the resulting hardness capacity prior to breakthrough is 1.24 meq/mL of resin. *Note:* Much lower regeneration levels, for example, 80 kg NaCl/m³ of resin (5 lb NaCl/ft³ of resin) can be used to minimize salt usage at the cost of shorter runs.

(2) *Calculation of bypass water allowance.* Assume that the water passing through the resin has zero hardness. Actually, hardness leakage during exhaustion will be detectable but usually less than 5 mg/L as CaCO₃. The bypass flow is calculated by writing a hardness balance at blending point, point *E* in Fig. 12-11, where the column effluent is blended with the source water bypass.

Mass balance on hardness at point *E*:

$$Q_B C_B + Q_F C_E = Q_P C_P \quad (12-35)$$

Balance on flow at point *E*:

$$Q_B + Q_F = Q_P \quad (12-36)$$

where Q_B is the bypass flow rate, Q_F is the column feed and effluent flow rate, Q_P is the blended product flow rate (i.e., total flow rate), C_B is the concentration of hardness in the bypass raw water (275 mg/L as CaCO₃), C_E is the concentration of hardness in the column effluent (assumed to be 0), and C_P is the chosen concentration of hardness in blended product water (150 mg/L as CaCO₃).

The solution to these equations is obtained easily in terms of the fraction bypassed f_B :

$$f_B = \frac{Q_B}{Q_P} = \frac{C_P}{C_B} = 0.55 \quad (12-37)$$

The fraction f_F that must be treated by IX is

$$f_F = 1 - f_B = 0.45 \quad (12-38)$$

(3) *Choosing the exhaustion flow rate.* The generally acceptable range of SFR for IX is 8 to 40 BV/h (1–5 gpm/ft³). Choosing a value of 20 BV/h (2.5 gpm/ft³) results in an EBCT of 3.0 minutes and an approach velocity v_0 of 15.3 m/h (6.25 gpm/ft²) if the resin bed is 0.76 m (2.5 ft) deep.

$$\text{EBCT} = \frac{h}{20 \text{ BV}_s} \times \frac{60 \text{ minutes}}{h} = 3 \frac{\text{minutes}}{\text{BV}} \quad (12-39)$$

$$v_0 = \frac{\text{depth}}{\text{detention time}} = \frac{\text{depth}}{\text{EBCT}} = \frac{0.76 \text{ m}}{3 \text{ minutes}} \times \frac{60 \text{ minutes}}{h} = \frac{15.3 \text{ m}}{h} \quad (12-40)$$

$$v_0 = \text{SFR} \times \text{depth} = 2.5 \text{ (gpm/ft}^3) \times 2.5 \text{ (ft)} = 6.25 \text{ gpm/ft}^2 \quad (12-41)$$

(4) *Calculation of run length.* The exhaustion time to hardness breakthrough t_H and the bed volumes to hardness breakthrough BV_H are calculated from a mass balance on hardness, assuming again that the resin effluent contains zero hardness. Expressed in words and equation this mass balance is Equivalents of hardness removed from the water during the run = equivalents of hardness accumulated on the resin during the run

$$Q_F C_F t_H = V_F C_F = q_H V_R \quad (12-42)$$

where q_H is the hardness capacity of resin at the selected regeneration level (eq/L, kgr/ft³), V_R is the volume of the resin bed including voids (L), $Q_F t$ is volume of water fed to column V_F during time t .

Then

$$\frac{V_F}{V_R} = BV_H = \frac{q_H}{C_F} \quad (12-43)$$

Based on the hardness capacity in Table 12-6, the bed volumes to hardness breakthrough BV_H following a regeneration at 15 lb NaCl/ft³ is

$$BV_H = \frac{1.24 \text{ equiv CaCO}_3}{\text{L resin}} \times \frac{1 \text{ L H}_2\text{O}}{275 \text{ mg CaCO}_3} \times \frac{550000 \text{ mg CaCO}_3}{\text{equiv CaCO}_3} \quad (12-44)$$

$$BV_H = 225 \text{ volumes of H}_2\text{O treated/volume of resin}$$

The time to hardness breakthrough t_H is related to the bed volumes to breakthrough BV_H and the EBCT:

$$t_H = \text{EBCT} \times BV_H \quad (12-45)$$

$$t_H = 3.0 \frac{\text{minutes}}{\text{BV}} \times 225 \text{ BVs} \times \frac{1 \text{ h}}{60 \text{ minutes}} = 11.2 \text{ h} \quad (12-46)$$

If the EBCT is decreased by increasing the flow rate through the bed, that is, SFR, then the run time is proportionately shortened even though the total amount of water treated V_F remains constant.

(5) *Calculation of resin volume V_R .* The most important parameter chosen was the service flow rate (SFR) because it directly specified the necessary resin volume V_R according to the following relationships based on Eq. 12-34:

$$V_R = \frac{Q_F}{\text{SFR}} = Q_F (\text{EBCT}) \quad (12-47)$$

Numerically, for a column feed flow Q_F of 45 percent (the amount not bypassed) of $3.8 \times 10^3 \text{ m}^3/\text{d}$,

$$V_R = \frac{1700 \text{ m}^3}{\text{day}} \times 3 \text{ minutes} \frac{\text{day}}{1440 \text{ minutes}} = 3.5 \text{ m}^3 \text{ or } \frac{(3.28 \text{ ft})^3}{\text{m}^3} = 124 \text{ ft}^3 \quad (12-48)$$

(6 & 7) *Calculation of the number of columns and the minimum out-of-service time for regeneration.* For a reasonable system design, two columns are required—one in operation and one in regeneration or standby. A single-column design with product water storage is possible but provides no margin of safety in case the column has to be serviced. Even with two columns, the out-of-service time t_{OS} for the column being regenerated should not exceed the exhaustion run time to hardness breakthrough t_H .

$$t_{OS} \leq t_{BW} + t_R + t_{SR} + t_{FR} \quad (12-49)$$

where t_{BW} = time for backwashing, 5 to 15 minutes
 t_R = time for regeneration, 30 to 60 minutes
 t_{SR} = time for slow rinse, 10 to 30 minutes
 t_{FR} = time for fast rinse, 5 to 15 minutes

A conservative out-of-service time would be the sum of the maximum times for backwashing, regeneration, and rinsing (i.e., 2 hours). This causes no problem in regard to continuous operation because the exhaustion time is more than 11 hours.

(8) *Calculation of column dimensions.* The resin depth h was specified earlier as 0.76 m (2.5 ft); thus the column height, after we allow for 100 percent resin bed expansion during backwashing, is 1.5 m (5.0 ft). The bed diameter D then is

$$D = \sqrt{\frac{4V_R}{\pi h}} = 2.4 \text{ m (8 ft)} \quad (12-50)$$

The resulting ratio of resin bed depth to column diameter is 2.5:8 or 0.3:1. This is within the acceptable range of 0.2:1 to 2:1 if proper flow distribution is provided. Increasing the resin depth to 1.2 m (4 ft) increases the column height to 2.4 m (8 ft) and reduces its diameter to 1.9 m (6.3 ft). Clearly, a number of depths and diameters are possible. Before specifying these, the designer should check with equipment manufacturers because softening units in this capacity range are available as predesigned packages.

Important: Another alternative would be to use three or more columns with two or more in service and one or more on standby. This offers a more flexible design. For a three-column system with two in service and one on standby, the resin volume of the in-service units would be $3.5 \text{ m}^3/2 = 1.75 \text{ m}^3$ (62 ft³) each; that is, the flow would be split between two 1.75 m³ (62 ft³) resin beds operating in parallel. Regeneration would be staggered such that only one column would undergo regeneration at any time. *An important advantage of operating columns in parallel with staggered regeneration is that product water quality is less variable than with single-column operation.* This can be a major consideration when the contaminant leakage or peaking is relatively high during a portion of the run; when this happens, combining the high leakage from one column with the low leakage from another produces an average leakage—presumably less than the MCL—over the duration of the run. Also, operating multiple columns in parallel with staggered regeneration is appropriate when nontargeted contaminants are removed for a portion of the run and then are subject to peaking before the target-contaminant run is complete. A good example is the removal of the target contaminant arsenic (which exceeds its MCL in the feed) in the presence of the nontarget contaminant nitrate (which is present but does not exceed its MCL in the feed). Generally, the arsenic run length would be 400 to 1200 BV, whereas nitrate typically would break through before 400 BV and peak at up to three times its feed water concentration. If the nitrate peaking causes the nitrate to exceed its MCL, then averaging the product water from two or more columns in parallel will be necessary to keep nitrate below its MCL while still allowing a long run length for arsenic. Carousel systems generally operate up to 20 columns in parallel, which protects against peaking of all contaminants and provides a consistent (averaged) product water quality.

(9) *Calculation of volume and composition of wastewater.* The spent regenerant solution consists of the regenerant and the slow-rinse (displacement-rinse) volumes. These waste solutions must be accumulated for eventual disposal as detailed in Chap. 22. The actual wastewater volume per regeneration will depend on the size of the resin bed, that is, whether one, two, or three beds are chosen for the design. The following calculations are in terms of bed volumes and can be converted to fluid volume once the column design has been fixed. The chosen regeneration level, 240 kg/m³ (15 lb NaCl/ft³) of

resin, is easily converted to bed volumes of regenerant required. Given that a 10% NaCl solution has a specific gravity of 1.07, the regenerant volume applied is

$$\begin{aligned} & \frac{240 \text{ kg NaCl}}{\text{m}^3 \text{ resin}} \times \frac{1.0 \text{ kg solution}}{0.1 \text{ kg NaCl}} \times \frac{1.0 \text{ L solution}}{1.07 \text{ kg solution}} \times \frac{1.0 \text{ m}^3 \text{ resin}}{1000 \text{ L resin}} \\ & = 2.25 \frac{\text{L solution}}{\text{L resin}} = 2.25 \text{ BVs} \\ & 15 \frac{\text{lb NaCl}}{\text{ft}^3 \text{ resin}} \times \frac{1 \text{ lb soln}}{0.1 \text{ lb NaCl}} \times \frac{\text{ft}^3 \text{ soln}}{1.07 \times 6624 \text{ lb soln}} = 2.25 \text{ BV} \quad (12-51) \end{aligned}$$

Following the salt addition, a displacement (slow) rinse of 1 to 2 BV is applied. The total regenerant wastewater volume is made up of the spent regenerant (2.25 BV) and the displacement rinse (2.0 BV):

$$\text{Regenerant wastewater} = 2.25 + 2.0 = 4.25 \text{ BV}$$

In this example, the wastewater volume amounts to approximately 1.9 percent $[(4.25/225)100]$ of the treated water or 0.9 percent (1.9×0.45) of the blended product water. Choosing 1.0 L of resin as a convenient bed size (for calculation purposes), we set 1.0 BV = 1.0 L; thus the regenerant wastewater volume from a 1.0 L bed is 4.25 L. For our example bed containing 3.5 m^3 (124 ft^3) of resin, the wastewater volume is 14.9 m^3 [524 ft^3 (3930 gal)].

If the small quantity of ions in the water used to make up the regenerant solution is disregarded, the waste brine concentration (equiv/L) can be calculated as follows:

$$\begin{aligned} \text{Total ionic concentration of wastewater} &= \text{hardness concentration} \\ &+ \text{excess NaCl concentration} \quad (12-52) \end{aligned}$$

$$\text{Wastewater hardness concentration} = \frac{\text{equiv hardness removed}}{\text{regenerant wastewater volume}} \quad (12-53)$$

From Table 12-6, we see that 1.24 equivalents of hardness are removed from the feed water per liter of resin at a regeneration level of 15 lb NaCl/ft³ of resin. During steady state operation, this is the amount of hardness removed from the resin with each regeneration. Therefore,

$$\text{Waste hardness concentration} = \frac{1.24 \text{ eq}}{4.25 \text{ L}} = 0.29 \frac{\text{eq}}{\text{L}} \quad (12-54)$$

This amounts to 14,500 mg CaCO₃ hardness/L, which can be further broken down into the separate Ca and Mg concentrations using the known ratio of Ca to Mg in the raw water.

The excess NaCl concentration can be calculated from the following relationship where equiv NaCl applied = 3.3 × equiv hardness removed, as seen in Table 12-6:

$$\begin{aligned} \text{Excess NaCl concentration} &= \frac{\text{eq NaCl applied} - \text{eq hardness removed}}{\text{regenerant wastewater volume}} \\ \text{Excess NaCl concentration} &= \frac{(1.24)3.3 - 1.24}{4.24} = 0.67 \frac{\text{eq NaCl}}{\text{L}} \quad (12-55) \end{aligned}$$

This excess NaCl concentration corresponds to 39,300 mg NaCl/L. The total cation composition of the wastewater is 0.96 eq/L made up of 0.29 eq/L hardness and 0.67 eq/L

sodium. These, in addition to chloride, are the major constituents of the wastewater. Other minor contaminant cations removed from the source water will be present in the regenerant wastewater. These can include Ba^{2+} , Sr^{2+} , Ra^{2+} , Fe^{2+} , Mn^{2+} , and others. The minor anionic contaminants in the wastewater will be bicarbonate and sulfate from the source water used for regeneration and rinsing. ▲

Brine Disposal from Softening Plants. The usual method for disposing of spent regenerant brine is through metering into a sanitary sewer. In coastal locations, direct discharge into the ocean is a possibility. Other alternatives are properly lined evaporation ponds in arid regions or brine disposal wells in areas where such wells are permitted or already in existence. The uncontrolled discharge (batch dumping) of the spent regenerant brine into surface waters or sanitary sewers is never recommended because of the potential damage to biota from localized high salinity. For the interested reader, the subject of waste disposal is covered in detail in Chap. 22.

Hydrogen IX Softening

Softening water without the addition of sodium is sometimes desirable. In this case, hydrogen can be exchanged for hardness ions using either strong- or weak-base cation exchangers. Hydrogen-form strong-acid resins (Eq. 12-1) are seldom used in this application because of the acidity of the product water, the inefficiency of regeneration with acid, and the problems of handling corrosive acids and of excess acid disposal. Hydrogen-form weak-acid cation (WAC) exchangers are sometimes used for sodium-free softening. Only the removal of temporary hardness is possible, and this proceeds according to Eq. 12-4, resulting in partial softening, alkalinity removal, and TDS reduction. Regeneration is accomplished with strong acids such as HCl or H_2SO_4 and proceeds according to Eq. 12-5 backwards (from right to left).

The partially softened, alkalinity-free column effluent from WAC softening must be stripped of CO_2 and blended with raw water to yield a noncorrosive product water. Alternatively, the pH of the column effluent can be raised by adding NaOH or $\text{Ca}(\text{OH})_2$ following CO_2 stripping. This, however, costs more and results in the addition of either sodium or hardness to the product water.

Barium Removal by IX

During all types of IX softening, barium is removed in preference to calcium and magnesium. This is shown graphically in Fig. 12-10a, where, in theory, barium breaks through long after hardness (magnesium). This is true even though barium-contaminated groundwater always will contain much higher levels of calcium and magnesium. Snoeyink and colleagues (1987) summarized their considerable research on barium removal using hydrogen- and sodium-form SAC and WAC resins operated to barium breakthrough. They found that the main problem with using SAC resin for barium removal is the difficulty of removing barium from the exhausted resin. Barium accumulates on the resin and reduces the exchange capacity of subsequent runs if sufficient NaCl is not used for regeneration.

When using WAC resins in the hydrogen form for barium removal, the same considerations apply as with WAC softening. Divalent cations are preferentially removed, cation removal is equivalent to alkalinity, partial desalting occurs, CO_2 must be stripped from the column effluent, and bypass blending will be required. The advantage of WAC resins is that barium is removed easily during regeneration with a small excess, typically 20 percent, of HCl or H_2SO_4 . In summary, using a hydrogen-form WAC resin for barium or combined hardness and barium removal produces higher-quality product water with less wastewater

volume compared with a sodium IX. The WAC process, however, is more complex and more expensive because of chemical costs, the need for acid-resistant materials of construction, wastewater neutralization, and the need to strip CO₂ from the product water.

Radium Removal by IX

Radium-226 and radium-228 are natural groundwater contaminants occurring at ultratrace levels. Their combined MCL is limited to 5.0 pCi/L, which corresponds to 11.1 radium-226 disintegrations/minute/L or 0.185 Bq/L. For radium-226 alone, 5 pCi/L corresponds to 5×10^{-9} mg radium/L. An up-to-date list of radium violations has not been published by U.S. Environmental Protection Agency (USEPA); however, in 1998, approximately 200 community water systems exceeded the radium MCL (USEPA, 2000b), and in 2003, Illinois reported 99 systems in violation of the radium MCL (Illinois EPA, 2003). Cation exchange with either sodium- or hydrogen-form resins is an effective means of radium removal because radium is preferred over all the common cations found in water. As with hardness and barium removal, radium can be removed effectively using sodium-form SAC or hydrogen-form WAC resins.

Radium Removal During Softening. During the normal sodium IX softening process, radium is completely (>95 percent) removed; thus softening is an effective technique for meeting the radium MCL. Pilot studies on a groundwater containing 18 pCi/L total radium and 275 mg/L total hardness in Lemont, IL, resulted in the following conclusions regarding sodium IX softening for radium removal (Subramonian et al., 1990):

1. On the first exhaustion run to radium breakthrough, hardness breakthrough occurred at 300 BV, whereas radium did not break through until 1200 BV.
2. On the second and subsequent exhaustion runs following salt regeneration at 240 kg NaCl/m³ (15 lb NaCl/ft³) of resin, radium broke through simultaneously with hardness at 300 BV. This long first run to radium breakthrough followed by shorter subsequent runs was not an anomaly but was repeated with other SAC resins. *Note:* Similar performance of softening beds is expected at much lower regeneration levels, for example, 80 kg NaCl/m³ (5 lb NaCl/ft³) of resin.
3. When the resin bed was operated in the normal fashion, that is, exhausted downflow and never run beyond hardness breakthrough, no radium was removed during the first three cocurrent regenerations at 240 kg NaCl/m³ (15 lb NaCl/ft³) of resin. And five exhaustion/regeneration cycles were required to reach a steady state where radium sorption during exhaustion equaled radium desorption during regeneration.
4. WAC resins (containing relatively hydrophilic carboxylate functional groups) had a lower relative affinity for radium than SAC resins. Macroporous SAC resins had the highest affinity for radium but were more difficult to regenerate because of this high affinity.
5. Radium never broke through before hardness in any of the 80 experimental runs with five different SAC and WAC resins. Furthermore, the radium concentration of the effluent never exceeded that of the influent; that is, chromatographic peaking of radium never occurred.
6. Radium was difficult to remove from exhausted resins presumably because it is a large, poorly hydrated ion that seeks the relatively inaccessible hydrophobic regions of the resin phase. Increasing the regeneration time beyond the usual 15 to 30 minutes helped only slightly to remove the radium from the spent resin. In this regard, radium behaved differently from barium (Myers et al., 1985), which was much more efficiently eluted at 30 minutes compared with the 15 minute EBCT for the regenerant.

Dealing with Radium-Contaminated Brines. If one is consistent with existing practices regarding the disposal of radium-contaminated brines, disposal into the local sanitary sewer should be allowed. For example, in many Midwest communities where water is being softened on both a residential and a municipal scale, radium removal is also taking place, and the radium-contaminated brines are being disposed of in the usual fashion, that is, by metering into the local sanitary sewer. To determine the radium concentration in waste brines from softeners, a simple calculation can be made. In a hypothetical situation in which the raw water contains as much as 20 pCi/L of radium and the softening run length is 300 BV, the 5 BV of spent regenerant contain an average of 1200 pCi/L of radium. This is a concentration factor of 60 (i.e., 300/5) and is typical of softeners in general.

If necessary, a spent regenerant brine solution could be decontaminated prior to disposal by passing it through a radium-specific adsorbent such as the Dow complexer or BaSO₄-loaded activated alumina (Clifford, 1990). [Note: The Dow *radium-selective complexer* (RSC) is not really a complexer but a BaSO₄-impregnated SAC resin (Hatch, 1984) that adsorbs radium onto the BaSO₄ even in the presence of a high concentration of competing ions such as Ca²⁺, Mg²⁺, and Na⁺.] This brine decontamination process has been tested on a small municipal scale (Mangelson, 1988) and found to work well. The RSC was loaded to a level of 2700 pCi/cm³ and was still decontaminating spent brine after 1 year of operation. However, disposal of a radium-containing solid at a level of 2700 pCi/cm³ (2.7×10^6 pCi/L) is potentially a more serious problem than disposal of the original radium-contaminated brine.

Nitrate Removal by IX

IX of chloride for nitrate is currently the simplest and lowest-cost method for treating nitrate-contaminated drinking water supplies. The process is shown schematically in Fig. 12-11. The anion exchange process for nitrate removal is similar to cation exchange softening except that (1) anions rather than cations are being exchanged, (2) nitrate is a monovalent ion, whereas calcium is divalent, and (3) nitrate, unlike calcium, is not the most preferred common ion involved in the multicomponent IX process used to treat a typical nitrate-contaminated groundwater. The latter two exceptions lead to some significant differences between softening and nitrate removal.

Chloride-form SBA exchange resins are used for nitrate removal according to Eq. 12-7. Excess NaCl at a concentration of 1.5 to 12 percent (0.25–2.0 M) is used for regeneration to produce a reversal of that reaction. The apparently simple process is not without complications, however, as detailed below.

Effects of Water Quality on Nitrate Removal. The source water quality and, in particular, the sulfate content influence the bed volumes that can be treated prior to nitrate breakthrough, which is shown along with that for chloride and bicarbonate in Fig. 12-13. The effect of increasing sulfate concentration on nitrate breakthrough is shown in Fig. 12-14, constructed from data obtained by spiking Glendale, Ariz., water with sodium sulfate (Clifford et al., 1987). As sulfate increased from the natural value of 43 mg/L (0.9 meq/L) to 310 mg/L (6.5 meq/L), that is, an increase of 5.6 meq/L, the experimental run length to nitrate breakthrough decreased 55 percent from 400 to 180 BV. Similar response to increasing sulfate is expected for all conventional type 1 and type 2 strong-base resins, disregarding the special nitrate-selective resins, which are less sensitive to sulfate.

Because all commercially available SBA resins prefer sulfate to nitrate at the TDS and ionic strength levels of typical groundwater, chromatographic peaking of nitrate occurs following its breakthrough. This peaking, when it does occur, means that effluent nitrate concentrations will exceed the source water nitrate level. No easy way is available to

FIGURE 12-13 Breakthrough curves for nitrate, bicarbonate, and chloride following complete regeneration of type 2 gel SBA resin in chloride form. C_I = influent concentration.

FIGURE 12-14 Effect of sulfate concentration on nitrate breakthrough for source and sulfate-spiked Glendale, Ariz., groundwater.

calculate whether a peak will occur or what the magnitude of the expected nitrate peak will be. Peak magnitude depends primarily on the TDS level, the specific composition of the source water (including its sulfate, nitrate, and alkalinity concentrations), and the type of SBA resin used. Computer estimates of the magnitude of the nitrate peak can be made using the EMCT Windows (Tirupanangadu, 1996) and IX Windows computer programs (Guter, 1998).

As the TDS level of the source water increases, selectivity reversal can occur, with the result that nitrate is preferred to sulfate. In this case, which was reported by Guter in his McFarland, Calif., nitrate-removal pilot studies (Guter, 1982), sulfate broke through prior to nitrate, and no nitrate peaking occurred.

In laboratory and pilot studies (Clifford and Weber, 1978; Clifford et al., 1987), nitrate peaking clearly was observed with both simulated groundwater and actual groundwater. The theoretical nitrate breakthrough curves for the standard type 1 and type 2 SBA resins are depicted in Fig. 12-10*b*, where idealized nitrate peaking is shown. Figure 12-13 depicts the pH, nitrate, and bicarbonate breakthrough curves observed in the Glendale nitrate-removal pilot studies (Clifford et al., 1987). In this groundwater, which is considered typical of nitrate-contaminated groundwater, the effluent nitrate concentration peaked at 1.3 times the feed water value.

Detecting Nitrate Breakthrough. When the usual type 1 and type 2 SBA resins are used to remove nitrate from a typical groundwater containing sulfate and having an approximate ionic strength of 0.010 M or less, chromatographic peaking of nitrate can occur. Even if it does not occur, a single column run still must be terminated prior to the breakthrough of nitrate. If the source water concentration is reasonably constant, this termination can be initiated by a flowmeter signal when a predetermined volume of feed has passed through the column. Terminating a run at a predetermined volume of treated water cannot always be recommended because of the variable nature of nitrate contamination in some types of groundwater. For example, in a 6-month period in McFarland (Guter, 1982), the nitrate content of one well varied from 5 to 25 mg/L $\text{NO}_3\text{-N}$. Such extreme variations did not occur during the 15-month pilot study in Glendale (Clifford et al., 1987), where the nitrate content of the study well (which was pumped occasionally to fill a large tank for the pilot study) varied only from 18 to 25 mg/L $\text{NO}_3\text{-N}$.

In the Glendale pilot study, a pH change of about 1.0 pH unit accompanied the nitrate breakthrough. This pH wave is visible in Fig. 12-13, where we see that if the run had been terminated when the effluent pH equaled the feed pH, the nitrate peak would have been avoided. The observed pH increase resulted from the simultaneous elution of carbonate and nitrate. The carbonate elution was a fortunate coincidence, and it allowed pH or differential (feed versus effluent) pH to be used to anticipate nitrate breakthrough. Such pH waves are not unique to the Glendale water but are expected when significant (>1.0 meq/L) concentrations of sulfate and bicarbonate are present and when ionic strength is 0.01 M or less. In practice, the pH detector should be located slightly upstream of the column effluent to provide a safety factor. Another way to avoid nitrate peaking is to employ multiple parallel columns as described in the section "Multicolumn Operations."

Choice of Resin for Nitrate Removal. Both laboratory and field studies of nitrate removal by chloride-form anion exchange have shown that no significant performance differences exist among the standard commercially available SBA resins. Both type 1 and type 2 polystyrene divinylbenzene SBA resins have been used successfully. Guter (1982) reported on the performance of a type 1 resin in a full-scale application, and Clifford and colleagues (1987) made extensive use of a type 2 SBA resin during a 15-month pilot-scale study in Glendale. When chromatographic peaking of nitrate must be avoided, however, a special nitrate-selective resin is necessary. Liu and Clifford (1996) also reported that nitrate-selective

resins were required with their brine denitrification and reuse process when the feed water contained 200 mg/L sulfate.

Guter (1982) described several such special resins that were nitrate selective with respect to sulfate based on their increased functional group charge separation distance and hydrophobicity. The nitrate-sulfate selectivities of these resins were in accord with the predictions of Clifford and Weber (1978, 1983), who found that (1) the sulfate preference of a resin was reduced significantly by increasing the distance between charged IX sites and (2) the nitrate preference of a resin was improved by increasing matrix and functional group hydrophobicity.

Nitrate-over-sulfate-selective (NSS) resins are available from most resin suppliers. Basically, NSS resins are similar to the standard type 1 resins, which contain trimethyl amine functionality $[\text{RN}(\text{CH}_3)_3]$, but the NSS resins have ethyl, propyl, or butyl groups substituted for the methyl groups to increase the charge-separation distance and resin hydrophobicity. Although the tripropyl and tributyl NSS resins have higher relative nitrate preferences, the less expensive triethyl resins generally have proven to be adequate for applications that require a nitrate-selective resin.

Regeneration of Nitrate-Laden Resin. Regardless of the regeneration method used, all previous studies have demonstrated that sulfate is much easier to elute than nitrate.

Typical sulfate and nitrate elution curves are shown in Fig. 12-15. For a complete regeneration, divalent sulfate, the most preferred ion during exhaustion, is the first to be stripped from the resin during regeneration because of the selectivity reversal (nitrate is preferred by the resin in brine) that occurs in high-ionic-strength (0.25–3 M) salt solutions.

Regeneration of the nitrate-laden resin was studied extensively in Glendale by using the complete and partial regeneration techniques. For complete regeneration, that is, removal of more than 95 percent of the sorbed nitrate, the more dilute the regenerant, the more efficient it was. For example, 0.5 M NaCl required 4.0 equivalents of chloride per equivalent of resin, whereas 1.7 M NaCl (10% NaCl) required 170 percent of this value. An obvious disadvantage of dilute regenerants is that larger tanks are required when the spent regenerants are stored. In addition, they produce more wastewater and require longer regeneration times.

FIGURE 12-15 Elution of sulfate and nitrate during complete regeneration of type 2 gel SBA resin following the exhaustion run shown in Fig. 12-13. Cocurrent downflow regeneration using 12% NaCl (2 N) at an EBCT of 19 minutes—nearly 100 percent recovery of sulfate and nitrate observed.

Complete regeneration is not very efficient in terms of the amount of salt required, but it does result in minimal leakage of nitrate during the subsequent exhaustion run. Because significant nitrate leakage (typically up to 7 mg $\text{NO}_3\text{-N}$ per liter) is permissible based on the MCL of 10 mg $\text{NO}_3\text{-N}$ per liter, complete regeneration is not required. Thus nitrate removal is an ideal application for incomplete or partial regeneration, that is, removal of 50 to 60 percent of the sorbed contaminant.

Partial regeneration levels of 0.64 to 2.0 equivalents per equivalent of resin (3–10 lb NaCl per cubic foot of resin) were studied at Glendale with the result that 1.0 eq Cl^- per equivalent of resin was acceptable if 7.0 mg $\text{NO}_3\text{-N}$ per liter could be tolerated in the effluent prior to the nitrate breakthrough that occurred earlier (350 BV) than in the complete-regeneration case (410 BV). Guter (1982) found that regeneration levels as low as 0.64 eq Cl^- per equivalent of resin (3 lb NaCl per cubic foot of resin) were acceptable in his pilot studies in McFarland. The acceptable level must be determined for each application, and it depends primarily on the feed water quality and the allowable nitrate leakage. Regardless of the level of salt used for partial regeneration, complete mixing of the resin bed is mandatory following regeneration. If mixing is not accomplished, excessive nitrate leakage will occur during the first 80 to 100 BV of the exhaustion cycle. The required mixing can be achieved mechanically or by introducing air into the backwash, but conventional (uniform) backwashing, even for extended periods, will not provide adequate mixing.

In the Glendale pilot study, a comparison of the optimal complete- and partial-regeneration methods indicated that partial regeneration would use 37 percent less salt. Bypass blending could not be used with partial regeneration because the nitrate leakage was 7 mg $\text{NO}_3\text{-N}$ per liter.

Disposal of Nitrate-Contaminated Brine. Because of its eutrophication potential, nitrate-contaminated brine cannot be disposed of into rivers or lakes, even if it is slowly metered into the receiving water. Furthermore, the high sodium concentration prevents disposal of spent regenerant onto land where its nitrogen content could serve as a fertilizer. To eliminate the high-sodium problem, calcium chloride could be used in place of NaCl, but this would be much more expensive and could result in the precipitation of $\text{CaCO}_3(s)$ during regeneration. Potassium chloride (KCl) is also feasible as a regenerant but is currently (2010) at least triple the cost of NaCl.

In one municipal-scale application of nitrate removal by chloride IX (Guter, 1982), the spent regenerant simply was metered into the sanitary sewer for subsequent biological treatment. This is probably possible only in applications where nitrate removal is being carried out in a fraction (e.g., <25 percent) of the wells in the supply system. If all the wells were being treated, the waste salt and varying salinity surely would have a negative effect on the biological treatment process.

In the Glendale studies, direct reuse of the spent brine (without removing the nitrate) was attempted but without success. Electroselectivity reversal does not occur with monovalent ions such as nitrate, and the high affinity of the resin for the nitrate in the brine resulted in excessive nitrate remaining on the resin following regeneration. The nitrate remaining on the resin was driven off subsequently by sulfate in the feed water, causing early nitrate leakage during the next exhaustion.

Biological Denitrification and Reuse of Spent Brine. Removing the nitrate from the spent brine prior to its reuse is possible via biological denitrification. Bench- and pilot-scale studies of this process have been reported by Van der Hoek and colleagues (1988), who found that biological denitrification and reuse were feasible below about 15,000 mg NaCl per liter (1.5% NaCl). Clifford and Liu (1993a, 1993b) developed a *sequencing batch reactor* (SBR) denitrification process for biological denitrification of spent nitrate IX brine. Their bench-scale experiments examined the feasibility of using an SBR to denitrify 0.5 M (3%) NaCl brine containing up to 835 mg $\text{NO}_3\text{-N}$ per liter. After acclimation, the denitrification rate in 0.5 M NaCl was only 10 percent lower than in the no-salt control reactor. The effect of mass ratio of methanol to nitrate-nitrogen on denitrification rate and residual TOC in the denitrified SBR effluent was studied in the range of 2.2 to 3.2. At the optimal methanol-to-nitrate-nitrogen ratio of 2.7, the time for more than 95 percent denitrification was 8 hours. In one set of runs, actual spent regenerant was reused 15 times; each time it was

denitrified in the SBR, filtered, and compensated with NaCl before reuse. Denitrification and reuse of the brine resulted in a 50 percent reduction in NaCl consumption and a 90 percent reduction in spent brine discharge. Their bench-scale research indicated that a denitrifying batch reactor provided simple operation, reliable effluent quality, and compatibility with the inherent batch operation of the nitrate IX process. Later Liu and Clifford (1996) reported on pilot-scale tests of the SBR denitrification brine reuse process (Fig. 12-16) for

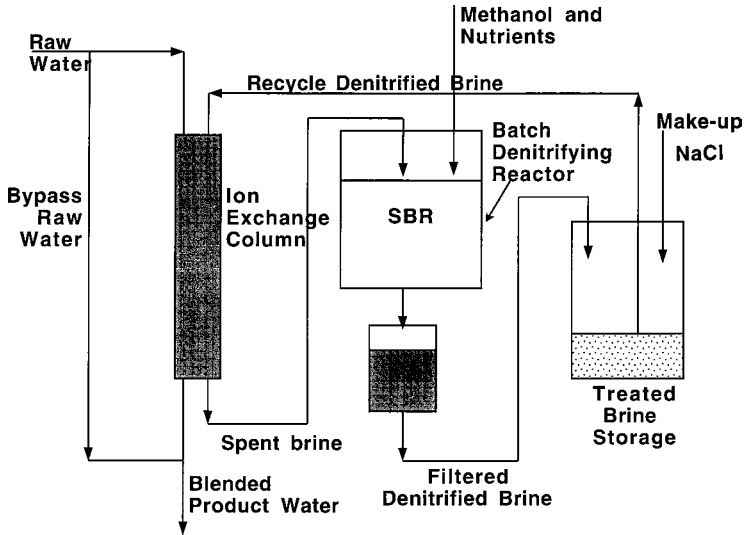

FIGURE 12-16 IX/biological denitrification process with sequencing batch reactor (SBR).

nitrate removal in McFarland, Calif., on a high-sulfate (140–220 mg/L) water. In those tests, which evaluated three different resins and partial and complete regeneration with and without brine reuse, the brine was denitrified and reused successfully up to 38 times. Because of sulfate buildup to 16,000 mg/L in the recycle brine, a nitrate-selective resin (with triethyl or tripropyl amine functional groups) was preferred to minimize nitrate leakage and maximize the number of brine reuse cycles. Even though the biologically denitrified brine was repeatedly in contact with microorganisms, methanol, and high TOC, the product water quality in terms of heterotrophic plate count, volatile organics, TOC, and methanol was not significantly different from product water from a conventional nitrate IX process. The pilot study of the SBR brine denitrification/reuse process verified that NaCl consumption could be reduced up to 75 percent compared with the optimal partial-regeneration process without brine reuse. Depending on the number of reuse cycles, the brine discharge volume could be reduced up to 95 percent compared with operation without brine reuse.

More recently, in a pilot study of nitrate and perchlorate destruction in IX brine using a fluidized-bed reactor (FBR) in California at the West Valley Water District, Lehman and colleagues (2008) demonstrated that IX brine (4.5% NaCl) containing up to 550 mg/L $\text{NO}_3\text{-N}$ could be completely denitrified in 3 days with a hydraulic retention time (HRT) of 13 hours. The FBR proved to be far more challenging to inoculate and operate than the SBR used in earlier research.

The brine denitrification/reuse process, although more complex than processes using direct disposal of waste regenerants, should be considered where wastewater disposal is a major consideration.

Fluoride Removal by Activated Alumina

Activated alumina, a semicrystalline porous inorganic adsorbent, is an excellent medium for fluoride removal. Alumina is far superior to synthetic organic anion exchange resins because fluoride is one of the ions most preferred by alumina, whereas, with resins, fluoride is the least preferred of the common anions. (Compare the position of fluoride in Eq. 12-27, the activated alumina anion selectivity sequence, with Table 12-3 containing the relative affinity of anions for resins.) The usefulness of alumina as a fluoride adsorbent has been known for more than 70 years, and municipal defluoridation of public water supplies using packed beds of activated alumina has been practiced since the 1930s and 1940s (Fink and Lindsay, 1936; Maier, 1953). More recently, POE and POU fluoride-removal systems using activated alumina have come into common use (Water Quality Research Council, 1987) or at least are being considered for individual-home treatment (Bellen et al., 1986).

The fundamentals of fluoride adsorption onto activated alumina were covered in the section "Granular Media Adsorption" above, where attention was drawn to Eqs. 12-11 through 12-17. The following discussion focuses on the important design considerations for municipal defluoridation. Although pH adjustment is not ordinarily performed prior to POE and POU defluoridation, the discussion also may prove useful to designers of these systems because the important factors, including pH, governing fluoride capacity are explained.

Alumina Defluoridation System Design. A typical fluoride-removal plant using activated alumina consists of two or more adsorption beds operated alternately or simultaneously in parallel or series. The source water pH is adjusted to 5.5 to 6.0 and passed downflow through a 0.9 to 1.5 m deep (3–5 ft) bed of fine, 0.3 to 0.6 mm diameter (28×48 mesh) medium that adsorbs the fluoride. The fluoride breakthrough curve (some typical examples are shown in Fig. 12-17) is not sharp compared with the usual IX resin breakthrough curves. The effluent fluoride concentration is continuously increasing, thereby making use of the bypass blending technique shown in Fig. 12-11 difficult to implement. Instead, a product water storage tank sometimes is provided to equalize the column effluent fluoride concentration and to maximize the column run length.

FIGURE 12-17 Typical fluoride breakthrough curves for activated alumina operated at a feed pH of 5.5 and an EBCT of 5 minutes.

A target level of fluoride, usually in the range of 1 to 3 mg/L, must be chosen for the process effluent before the operating procedures and economics can be established. The MCL for fluoride is 4 mg/L, and the secondary maximum contaminant level (SMCL) is 2 mg/L (USEPA, 2009a; see also Chap. 1). However, a recent study by the National Academy of Sciences (2006) concluded that a 4 mg/L fluoride MCL is not sufficiently protective of public health, and the USEPA is under pressure to lower the MCL. When the source water contains 3 to 6 mg/L fluoride and a maximum fluoride effluent (breakthrough) concentration of 1.4 mg/L is chosen, a run length of approximately 1000 to 1300 BV can be expected with a typical alumina. Some typical data from pilot-scale defluoridation processes are presented in Table 12-7 for source water fluoride concentrations of 2 to 5 mg/L, and some detailed design recommendations are given in Table 12-8.

TABLE 12-7 Fluoride Capacity of F-1 Activated Alumina Columns at pH 5.5 to 6.0: Field Results

Feedwater F ⁻ conc., mg/L	Feedwater TDS, mg/L	Alumina particle size ^a (mesh size)	Run length, BV to 1.4 mg F ⁻ /L	Fluoride capacity, g/m ³
2.0 ^b	810	0.3–0.6 mm (28 × 48)	2300	3700
3.0 ^c	1350	0.6–1.2 mm (14 × 28)	1200	2700
5.0 ^d	1210	0.3–0.6 mm (28 × 48)	1150	4600

^a28 × 48 mesh is “fine” alumina with faster kinetics than 14 × 28 “coarse” alumina, which also can be used but yields lower fluoride capacity.

^bSan Ysidro, New Mexico; average of 3 pilot-scale runs (Clifford and Lin, 1991).

^cTaylor, TX; average of 3 pilot-scale runs.

^dGila Bend, Ariz; typical pilot-scale run (Rubel and Woosley, 1979).

Following exhaustion, the medium is backwashed and then subjected to a two-step regeneration with base followed by acid. Because many types of high-fluoride groundwater are located in hot, arid climates, the spent regenerant brines are neutralized and sent to a lined evaporation pond for interim disposal. The ultimate disposal of high-fluoride salt residues is a problem still unsolved.

Factors Influencing the Fluoride Capacity of Alumina. The fluoride capacity of alumina is sensitive to pH, as shown in Fig. 12-18a based on laboratory equilibrium data obtained by using minicolumns of granular alumina exposed for up to 30 days to pH-adjusted fluoride solutions in deionized water. The fluoride capacities in Fig. 12-18a can be considered the maximum attainable (equilibrium) capacities for similar aluminas because potentially competing anions such as silicate, arsenate, phosphate, selenite, and sulfate were minimized or entirely absent in the test solutions (Singh and Clifford, 1981). Pilot-scale field studies on typical fluoride-contaminated water have resulted in the observation that single columns of fine (28 × 48 mesh) alumina operated to 1.4 mg fluoride per liter breakthrough and a 5 to 10 minute EBCT can attain 25 to 50 percent of the equilibrium capacities in deionized water (Rubel and Woosley, 1979; Clifford and Lin, 1991). See also Fig. 12-18b based on previously unpublished field studies in Taylor, Texas. Using coarse-mesh (14 × 28 mesh) alumina under the same conditions yields lower fluoride capacities.

The inability of a pilot- or full-scale continuously operated alumina column to rapidly and closely approach fluoride equilibrium is related primarily to solid-phase mass transfer limitations. These limitations cause the fluoride breakthrough curve to be gradual and the run to be terminated long before the alumina is saturated. This is a classic case in which the process economics can be improved by operating two columns in series in a roughing-polishing

TABLE 12-8 Process Design Criteria for Fluoride Removal by Activated Alumina

Parameter	Typical value or range
Fluoride concentration	3–6 mg/L
Media ^a	Alcoa F-1 activated alumina
Surface area	250 m ² /g
Bulk density	0.85 g/cm ³ (55 lb/ft ³)
Media size ^b	0.29–0.59 mm diameter (28 × 48 mesh)
Media depth	1–2 m (3–6 ft)
Fluoride capacity	3000–5000 g/m ³ (1300–2200 gr/ft ³)
Bed volumes to MCL, 1.4 mg F ⁻ /L ³	1000–1500 (pH 5.5–6.0)
Exhaustion flow rate	EBCT = 5 minutes (1.5 gpm/ft ³)
Exhaustion flow velocity	10–20 m/h (4–8 gpm/ft ²)
Backwash flow rate	20–22 m/h (8–9 gpm/ft ²)
Backwash time	5–10 minutes using raw water
NaOH Regeneration	
Volume of regenerant	5 BV
Regenerant flow rate ^d	EBCT = 15 minutes (0.5 gpm/ft ³)
Regenerant concentration ^e	0.25 N NaOH (1% NaOH)
Total regenerant contact time	75 minutes
Displacement rinse volume	2 BV
Displacement rinse rate	EBCT = 15 minutes (0.5 gpm/ft ³)
H ₂ SO ₄ Neutralization	
Regenerant flow rate ^d	EBCT = 15 minutes (0.5 gpm/ft ³)
Acid concentration ^f	0.4 N H ₂ SO ₄ (2.0% H ₂ SO ₄)
Acid volume ^g	Sufficient to neutralize the bed to pH 5.5, typically 1.5 BV
Displacement rinse volume	2 BV
Displacement rinse rate	EBCT = 15 minutes (0.5 gpm/ft ³)

^aAluminum hydroxide activated at 400°C–600°C in a mixture of hot air and combustion gases, 92% Al₂O₃ (Misra, 1986). Mention of trade names does not imply endorsement. Similar activated alumina adsorbents are available from other sources.

^bCoarse (14 × 28) mesh alumina also has been used successfully.

^cCapacity and BV to fluoride breakthrough depend on adsorbent particle size, surface area and surface chemistry, EBCT, and feed water quality, including pH and fluoride and sulfate concentrations.

^dConcurrent (same direction as exhaustion flow) or countercurrent (opposite direction to exhaustion flow) regeneration may be used.

^eHigher regenerant NaOH concentrations (e.g., 2%–4%) also have been used successfully at shorter contact times. Media losses (dissolution of alumina) increase with increasing NaOH concentration and contact time.

^fLower and higher H₂SO₄ concentrations have been used successfully. HCl also can be used, and it may be preferred to H₂SO₄ because chloride does not compete with fluoride for adsorption sites. Media losses (dissolution of alumina) increase with increasing H₂SO₄ concentration and contact time.

^gAlternatively, the neutralization and acidification steps can be combined. This is accomplished by lowering the initial feed water pH to approximately 2.5 to produce a bed effluent pH slowly dropping from a high initial value (>13) down to a continuous effluent pH in the range of 5.5–6.0.

(lead-lag) sequence, as depicted in Fig. 12-12. The two-column sequence allows the roughing (lead) column to attain a near-saturation fluoride loading prior to regeneration. The obvious disadvantages of such systems are greater complexity and higher capital costs.

In POE and POU alumina systems, a closer approach to equilibrium may be expected because of the intermittent operation of the alumina bed. In these installations, the solid-phase fluoride concentration gradient has a chance to *relax* completely (approaching equilibrium) during the many prolonged off periods experienced by columns in residential applications. This results in a high concentration gradient between the liquid and the surface of the solid and much improved fluoride removal when the column is restarted.

FIGURE 12-18 (a) Effects of pH and fluoride concentration on capacity of F-1 activated alumina in equilibrium minicolumn studies using DI water solutions of NaF, pH adjusted with Na_2CO_3 and H_2SO_4 . (b) Effect of pH on fluoride capacity of 28×48 mesh pilot-scale F-1 activated alumina columns operated to 1.4 mg F^- per liter breakthrough. Taylor, Texas, feedwater $\text{F}^- = 3.0 \text{ mg/L}$, $\text{SO}_4^{2-} = 380$ to 540 mg/L , TDS = 1300 to 1450 mg/L , EBCT = 5 to 10 minutes, pH adjusted with H_2SO_4 .

Another reason for the less-than-equilibrium fluoride capacities of actual columns is the effect of competing anions such as silicate and sulfate present in the source water. During a laboratory study (Singh and Clifford, 1981) of the effect of competing ions on fluoride capacity at optimal pH, bicarbonate and chloride ions did not compete measurably with fluoride for adsorption sites. Sulfate, however, did cause a significant reduction in fluoride adsorption. For example, 50 mg of sulfate per liter lowered the fluoride capacity by about 16 percent. The maximum reduction in fluoride capacity because of sulfate was about 33 percent, and

it occurred at approximately 500 mg of sulfate per liter. Beyond this, no further fluoride capacity reduction occurred, probably because the alumina contains a high proportion of fluoride-specific sites that are not influenced by sulfate. Fluoride-removal pilot studies in Taylor, Texas, corroborated the sulfate effect because pH adjustment with HCl gave 16 percent higher fluoride capacity than H_2SO_4 at the same adjusted pH (5.7).

Results of fluoride-removal pilot studies in Taylor, Texas, indicated that measurable silicate $[\text{Si}(\text{OH})_3\text{O}^-]$ adsorption onto alumina occurs at about pH 7 and above and can cause a serious reduction in the fluoride capacity of a column operated in the pH range of 7 to 9. This reduction is particularly detrimental during cyclic operation because silicate is only partially removed during a normal (base-acid) regeneration to remove fluoride. The presence of silica in the water had no observable effect on fluoride capacity for columns operated in the optimal (5.5–6.0) pH range, provided that the columns were never operated in the 7 to 9 pH range prior to optimal pH operation. Activated alumina columns that had been operated at pH in the 7 to 8 range adsorbed so much silica, which was not completely removed during regeneration, that subsequent runs at the optimal pH of 5.5 to 6.0 had 30 to 40 percent shorter run lengths, presumably owing to silica retained on the alumina.

Regeneration of Fluoride Spent Alumina Columns. Prior to regeneration to elute fluoride, the exhausted column must be backwashed to remove entrained particles, break up clumps of alumina, and reclassify the medium to eliminate packing and channeling. Following a 5 to 10 minute backwash, regeneration is accomplished in two steps—the first using NaOH and the second using H_2SO_4 . Because fluoride leakage is such a serious problem, the most efficient regeneration is accomplished by using countercurrent flow. Nevertheless, cocurrent regeneration is used more commonly because of its simplicity. Rubel and Wossley (1979) recommend a two-stage upflow-then-downflow application of base followed by downflow acid neutralization. A slow rinse follows both the base addition and acid addition steps to displace the regenerant and conserve chemicals. The rinsing process is completed by using a fast rinse applied at the usual exhaustion flow rate. The total amount of wastewater produced amounts to about 4 percent of the blended product water and is made up of 8 BV of backwash, 5 BV of NaOH, 2 BV of NaOH displacement rinse, 1.5 BV of acid, 2 BV of acid displacement rinse, and 30 to 50 BV of fast rinse water. Further details regarding regeneration can be found in Table 12-8.

Essentially complete (>95 percent) removal of fluoride from the alumina is possible by using the regeneration techniques described; however, in addition to the complexity of regeneration, its efficiency is poor. For example, an alumina bed employed to remove fluoride from a typical 800 to 1200 mg TDS/L groundwater containing 4 to 6 mg fluoride per liter would contain an average fluoride loading of 4600 g F^- per cubic meter. Removing this fluoride typically would require 5 BV of 1% NaOH (30 gallons of 1% NaOH per cubic foot). This equates to 19 percent base regeneration efficiency, or 5.2 hydroxide ions required for each fluoride ion removed from the alumina. When the amount of acid required (1.5 BV of 0.4 N H_2SO_4) is added into the efficiency calculation, an additional 2.5 hydrogen ions are required for each fluoride ion removed, and the overall efficiency drops to 13 percent, or a total of 7.7 regenerant ions required for each fluoride ion removed from the water. Despite the complexity of the process and the inefficiency of regeneration on an ion-for-ion basis, fluoride removal by activated alumina is probably the lowest-cost alternative compared with other acceptable methods, such as reverse osmosis and electro dialysis (USEPA, 1985). To our knowledge, no study has reported on (1) the influence of NOM adsorption on the alumina capacity for fluoride or (2) the influence of activated alumina dissolution on the aluminum content of the treated water. Because the affinity of alumina for NOM anions (fulvates and humates) is significant, one would expect a decrease in fluoride capacity with increasing NOM concentration. Because aluminum is used widely as the primary coagulant for surface water, there has not been much concern about the effluent aluminum from

activated alumina, which is basically low-temperature dehydrated aluminum hydroxide. Nevertheless, aluminum in treated water from activated alumina systems should be studied, especially in low-pH (5.5–6.0) systems. Also, direct reuse of the spent NaOH regenerant should be studied to improve regeneration efficiency.

Arsenic Removal by Adsorptive Media and IX

As with other toxic inorganic contaminants, arsenic is almost exclusively a groundwater problem. Although it can exist in both organic and inorganic forms, only inorganic arsenic in the +III or +V oxidation state has been found to be significant where potable water supplies are concerned (Andea, 1978).

The MCL for arsenic is 0.010 mg/L or 10 µg/L (USEPA, 2003; see also Chap. 1). To assist small communities in meeting the revised MCL, the USEPA initiated a full-scale demonstration program of commercial-ready arsenic treatment technologies in 2002 (Zeilig, 2005). Over a 5-year period, 50 demonstration projects in 28 states were funded, with the goal to determine the cost and performance of these treatment systems operating under a variety of conditions. The results from the USEPA demonstration projects are summarized in the following sections, along with results from other laboratory and field studies.

The primary arsenate species (As(V)) found in groundwater in the pH range of 6 to 9 are monovalent H_2AsO_4^- and divalent HAsO_4^{2-} . These anions result from the dissociation of arsenic acid (H_3AsO_4), which exhibits $\text{p}K_a$ values of 2.2, 7.0, and 11.5. Uncharged arsenious acid (H_3AsO_3) is the predominant species of As(III) found in natural water. Only at pH values above its $\text{p}K_a$ of 9.2 does the monovalent arsenite anion (H_2AsO_3^-) predominate.

Both anion exchange resins and adsorptive media require anionic forms of arsenic to be effective; thus redox potential and pH are important raw water characteristics. As(V) is removed effectively by both processes, whereas uncharged As(III) is not removed by IX, and is poorly removed by most the adsorptive media products. Consequently, if As(III) is the predominant arsenic form, the preoxidation of As(III) to As(V) is generally required. The choice of oxidants among treatment processes depends on many factors, including water quality, wastewater quality and quantity, waste disposal options available at the site, and capital and operating costs.

Oxidation of As(III) to As(V). IX processes require arsenite to be oxidized to arsenate to achieve any removal. For the adsorptive media process to be cost-effective, arsenite also should be oxidized to arsenate. Little if any As(III) is removed by activated alumina (Frank and Clifford, 1984), and a laboratory study of As(III)/As(V) removal by 11 different adsorptive media showed that most of them achieve a significantly higher percent removal of As(V) than of As(III) (Amy et al., 2005).

The importance of oxidizing As(III) to As(V) was clearly demonstrated during a 3500 m³/d (640 gpm) full-scale test of an iron-based adsorptive media system at Brown City, MI, treating raw water with 15 µg/L As(III) (Chen et al., 2009). It appeared that 10 µg/L arsenic breakthrough would occur at about 30,000 BV; however, the run length was increased to more than 70,000 BV by switching from post- to prechlorination to oxidize As(III) to As(V) ahead of the adsorptive media (Fig. 12-19).

Ghurye and Clifford (2004) conducted a laboratory study of seven oxidants to convert As(III) to As(V): chlorine, permanganate, ozone, monochloramine, chlorine dioxide, a manganese dioxide solid oxidizing media, and 254 nm ultraviolet UV light. The study evaluated the effects of pH (6.3–8.3), temperature (5–25°C), and the interfering reductants Mn^{2+} , Fe^{2+} , S^{2-} , and TOC. Of the seven oxidants investigated, only chlorine and permanganate provided complete oxidation in less than 1 minute under all conditions. Ozone was fast and effective but was significantly affected by TOC. The solid manganese dioxide medium provided complete oxidation except on the test water having low dissolved oxygen

FIGURE 12-19 Effect of moving the point of chlorination on As(III) granular ferric oxide media—Brown City, Mich., demonstration plant.

(0.1 mg/L). Dissolved oxygen (DO) was not studied as an oxidant in this study because DO was known to be unreliable as an oxidant for As(III). For example, Frank and Clifford (1986) showed that pure oxygen sparging could not oxidize As(III) to As(V) in 1 hour, but complete oxidation of As(III) to As(V) occurred during 2 months of ambient temperature storage of synthetic groundwater. Field studies of possible air oxidation of As(III) by Lowry and Lowry (2001) at three test sites with varying water quality found that spray, bubble, and packed-tower aeration were ineffective in oxidizing As(III) to As(V).

Inadvertent, unpredictable microbial-assisted oxidation of As(III) to As(V) has been observed in several University of Houston studies with As(III) (Rosenblum and Clifford, 1984; Frank and Clifford, 1986; Clifford and Lin, 1986, 1991). Lytle and colleagues (2007) also reported the oxidation of As(III) in laboratory-, pilot-, and full-scale adsorption system studies. Analysis of the microbial community from the studies identified the isolates having strong As(III) oxidizing ability. Reduction of As(V) also has been reported by numerous researchers (Tamaki and Frankenberger, 1992; Ahmann et al., 1994; Laverman et al., 1995; Jones et al., 2002; Lloyd et al., 2003; Tadanier et al., 2005; Oremland, 2006). Therefore, As(III) and As(V) should be considered as interconvertible under appropriate conditions.

Adsorptive Media Processes for Arsenic Removal. Until the late 1990s, activated alumina was the dominant adsorptive medium used for arsenic removal, and the process was similar to that already described for fluoride removal. To achieve maximum arsenic removal capacity, the activated alumina process usually was designed with the pH of the raw water being reduced to 5.5 similar to the activated alumina fluoride removal process (Rubel and Hathaway, 1985). Regeneration of the activated alumina also was practiced and usually occurred after 30 to 90 days. Because of the difficulty in removing arsenic from the activated alumina, the regenerant NaOH concentration was 4 percent (1.0 N) compared with the 1 percent NaOH used for fluoride removal. The successful performance of several small activated alumina plants without regeneration was reported by Wang and colleagues (2002).

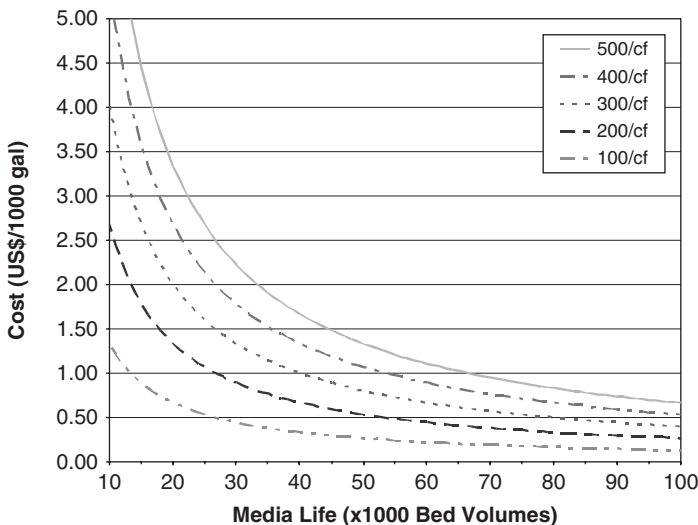

In the late 1990s, new adsorptive media products tailored for arsenic removal began to be developed and marketed. Most of these new products were iron oxide/hydroxide-based,

TABLE 12-9 List of Adsorptive Media Products in the USEPA Arsenic Demonstration Program

Medium	Composition	Supplier
Bayoxide E33 G	Granular ferric oxide (granular form)	Bayer/Severn Trent
Bayoxide E33 P	Granular ferric oxide (pelletized form)	Bayer/Severn Trent
GFH	Granular ferric hydroxide	GEH Wasserchemie
ARM 200	Iron oxide/hydroxide	Engelhard Corp.
CFH-0818	Iron oxide/hydroxide	Kemira Water Solutions
G2	Iron oxide/hydroxide-coated diatomite	ADI International
AAFS 50	Alumina modified with iron oxide/hydroxide	Alcan Chemical
A/I Complex 2000	Alumina modified with iron oxide/hydroxide	Aquatic Treatment Systems
ArsenXnp	Anion resin modified with iron oxide/hydroxide	Purolite
Isolux	Zirconium oxide/hydroxide	MEI
Adsorbia GTO	Titanium oxide/hydroxide	Dow Chemical

although several titanium oxide/hydroxide and zirconium oxide/hydroxide products also were produced. Other products include iron-modified activated alumina, iron-modified IX resins, and iron-coated diatomite. Table 12-9 lists 11 media products evaluated in the USEPA arsenic demonstration program. Most of these media were developed for one-time exhaustion without regeneration, the exceptions being the iron-modified resin (Cumbal and Sengupta, 2005) and the iron-coated diatomite (ADI G2 Medium), which can be regenerated. Research and full-scale demonstrations have started on the regeneration of other iron-based media, and it is anticipated that routine regeneration of these products will soon occur (Chen and Wang, 2010).

The two most significant factors in media selection are arsenic capacity, which determines the bed volumes to medium exhaustion, and cost. Currently, the cost range of adsorptive media is roughly \$80 to \$500/ft³. Figure 12-20 shows the water treatment cost (\$/1000 gallons of treated water) as a function of medium cost (\$/ft³) and arsenic capacity measured as bed volumes of water treated before medium exhaustion. The cost curves shown are for

**FIGURE 12-20** Effect of adsorptive media life and media cost on treatment cost for arsenic removal.

media only and do not include the costs associated with media replacement and disposal. The relationship is

$$\$/1000 \text{ gal water treated} = 134 [\text{medium cost } (\$/\text{ft}^3)/\text{BV}]$$

A typical adsorptive media system is a pressurized downflow fixed-bed process. A system can consist of one or more tanks configured in parallel or series. Multibed series systems, although more complex to build and operate than single-bed systems, yield higher arsenic loading on the exhausted medium because of the way in which they are operated. For example, in a two-bed (lead-lag or roughing-polishing) series system, the lead column (the first column to encounter the raw water) typically is exhausted completely when it is regenerated or replaced at the time of MCL breakthrough from the second (lag) column. The partly exhausted lag column then becomes the lead column, and fresh or regenerated medium is used as the lag column. The USEPA arsenic demonstration included both parallel- and series-design systems (Tables 12-10 and 12-11), and performance of the systems listed ranged from treatment runs as low as 3700 BV to greater than 65,000 BV of treated water before arsenic breakthrough at 10 $\mu\text{g/L}$. Vendor estimates also have been reported above 100,000 BV of treated water. For single parallel columns, as shown in Table 12-10, operating in the pH range of 7.2 to 7.8, longer run lengths are, as expected, associated with lower arsenic, silica, and phosphate concentrations. The data listed in Table 12-11, for the two-columns-in-series configurations, indicate that adding a second column typically increases the run length of the series about 20 to 30 percent compared with a single column. Additional data need to be collected to determine if this trend continues as the lag column is used to replace the lead column on subsequent runs.

Factors Influencing the Arsenic Capacity of Adsorptive Media. Contaminant adsorption onto metal oxide/hydroxide-based media is a ligand exchange process that depends on a number of factors including the type of medium, source water quality, and the fluid-medium contact time [measured as empty-bed contact time (EBCT)]. For metal oxide/hydroxide media and coagulants, arsenic speciation and concentration, pH, and the competing anions phosphate, silicate, and vanadate are considered the most significant source water quality parameters affecting removal capacity (Meng et al., 2000, 2002; Amy et al., 2005; Zeng et al., 2008; Lakshmanan et al., 2008). For all metal oxide/hydroxide media, adsorption capacity decreases significantly as pH increases from 5 to 9. Experimental As(V) capacity determinations on GFH, the first of the iron-based adsorptive media, indicated a sharp decrease in As(V) capacity with increasing pH, as shown in Fig. 12-21 (Driehaus et al., 1998). Laboratory studies by Amy and colleagues (2005) with five iron- and aluminum-based media showed arsenic adsorption capacity increasing as pH dropped from 8 to 7 to 6, even with the test waters containing phosphate, silica, and vanadium. The extent of the pH effect varied with each medium, and their alumina results confirmed the work of Rosenblum and Clifford (1984).

The impact of pH was demonstrated during a full-scale (200 m^3/d , or 37 gpm) test of an iron-modified alumina (AAFS50) at Valley Vista, Ariz., with a pH 7.8 source water containing 40 $\mu\text{g/L}$ As(V) (Valigore et al., 2007). With the two-tanks-in-series treatment system running continuously at a total EBCT of 7.0 minutes, the effluent reached the arsenic MCL of 10 $\mu\text{g/L}$ at 8800 BV at pH 7.8 and at 23,000 BV when the pH was lowered to 6.9.

Because lowering the pH generally increases arsenic capacity, pH adjustment may be cost-effective; thus in the USEPA demonstration program, pH adjustment was initiated at most sites having a pH above 8. Source water pH normally was adjusted into the 7 to 7.6 range using carbon dioxide. The advantage of using CO_2 over sulfuric or hydrochloric acid is that the excess CO_2 can be stripped easily from the process effluent, thereby reducing the potential for any lead or copper problems in the distribution system. Using H_2SO_4 or HCl to adjust the pH would require on-site storage and dilution of these corrosive acids

FIGURE 12-21 Arsenate capacity of GFH as a function of pH at arsenic equilibrium concentration of $10 \mu\text{g As(V)}$ per liter in deionized water. (Source: Based on the data of Driehaus et al., 1998.)

and post-pH adjustment using caustic or lime addition. Managers of systems applying pH adjustment must be cognizant of the need to maintain pH control at all times because the loss of pH adjustment can result in the release of arsenic and other anions removed by the adsorptive medium (Min et al., 2007). The degree of desorption (size of the released contaminant spike) depends on the medium and its arsenic loading.

Phosphate, silica, vanadium, chloride, nitrate, fluoride, and TOC have been suggested as possible competing anions that reduce the arsenic capacity of metal oxide/hydroxide media (Amy et al., 2005). More recently, several adsorptive media products have been found to remove uranium and antimony, indicating that these two anions also can compete with arsenic for adsorptive sites (Cumming et al., 2009; Westerhoff et al., 2008). Phosphate, silica, and vanadium are considered to be the most significant competing ions for solid media (Meng et al., 2002; Amy et al., 2005; Xie et al., 2007) and oxide/hydroxide coagulants (Lakshmanan et al., 2008), whereas sulfate, chloride, nitrate, and fluoride do not have any major detrimental effects on arsenic adsorption on iron oxide/hydroxide media and coagulants (Meng et al., 2000; Youngran et al., 2007; Lakshmanan et al., 2008). Sulfate, however, was found to lower As(V) adsorption by 20 percent or more on GFH (Driehaus et al., 1998) and on alumina at pH 6.0 (Rosenblum and Clifford, 1984). Phosphate has been found to be strongly competitive with arsenic on iron oxide/hydroxide media probably because the chemistry of phosphoric acid (H_3PO_4 , with $\text{p}K_a$ values of 2.1, 7.2, and 12.2) is similar to that of arsenic acid (H_3AsO_4 , with $\text{p}K_a$ values of 2.2, 7.1, and 12.3); phosphate anions (H_2PO_4^- , HPO_4^{2-}) occur naturally in groundwater in microgram per liter ($\mu\text{g/L}$) concentrations similar to arsenic.

The chemistry of silica is complex, and depending on pH and concentration, silica can occur as soluble silicic acid [$\text{Si}(\text{OH})_4$, $\text{p}K_1 = 9.6$] or anionic silicate [$\text{Si}(\text{OH})_3\text{O}^-$] or as insoluble colloidal silica. Colloidal silica can coat the medium, thereby limiting access to the available sites for arsenic adsorption. Silicate anions compete strongly with arsenate on iron-based media (Xie et al., 2007; Moller and Sylvester, 2007) and coagulants (Lakshmanan et al., 2008). Despite the small fraction of silicate anions present in the neutral pH range, their concentration relative to arsenate is significant because silica generally is present in groundwater at concentrations 1000 times higher than the concentration of arsenic. From laboratory test results, Moller and Sylvester (2007) concluded that at pH 7, the effect of silica as high as 70 mg/L was relatively minor on the arsenic-removal capacity

of iron oxide/hydroxide-based (ArsenX[®]) media because the silica was predominately present as uncharged silicic acid [$\text{Si}(\text{OH})_4$]. At pH 7.5 and 30 mg/L of silica, the arsenic-removal capacity was affected significantly presumably because of the higher concentration of silicate. A similar pH dependence of silica interference (i.e., the higher the pH, the greater is the silicate interference) was noted for arsenate sorption onto iron oxide/hydroxide-based coagulants (Lakshmanan et al., 2008).

At a USEPA full-scale demonstration project in the Reno, NV, area with a pH 7.5 raw water containing 67 $\mu\text{g/L}$ arsenic, 75 mg/L SiO_2 , and 115 $\mu\text{g/L}$ $\text{PO}_4\text{-P}$, the 1900 m^3/d (350 gpm) treatment plant achieved 10 $\mu\text{g/L}$ As breakthrough at only 7000 BV with an iron hydroxide medium (GFH) (Cummings et al., 2008). The source water had 15 $\mu\text{g/L}$ antimony that was removed to less than the Sb MCL (6 $\mu\text{g/L}$) for approximately 3000 BV. Because of the short treatment runs for both arsenic and antimony, laboratory and field studies using rapid small-scale column tests (RSSCTs) were conducted with eight different media (Westerhoff et al., 2008) in order to identify higher-capacity media. The results of the laboratory and field RSSCT studies are shown in Table 12-12. Based on the test results,

TABLE 12-12 Summary of Test Results of Rapid Small-Scale Column Tests on Washoe County, NV, Groundwater

Medium	Medium type	Manufacturer	RSSCT results, BV
GFH	Iron-based	GEH	(L) 11,000

Adsorbisia GTO	Titanium-based	Dow Chemical	(L) 4500

(L) = lab RSSCT; (F) = field RSSCT.

GFH and Kemira CFH media were chosen for additional full-scale tests. The second GFH run was shorter than the first, with antimony and arsenic breakthroughs at 1200 and 3700 BV, respectively, because of higher 90 $\mu\text{g/L}$ arsenic concentration in the second run. The differences in results between the full-scale system and laboratory RSSCT test results were attributed to the differences in the influent water quality. The laboratory-test water had a consistent arsenic level of 51 $\mu\text{g/L}$, whereas the full-scale treatment system influent arsenic concentration varied from a low of 35 $\mu\text{g/L}$ to a high of 110 $\mu\text{g/L}$. The poor performance of the full-scale system and the RSSCT tests for all the media tests was attributed mainly to the high silica in the source water, although the phosphate and high arsenic levels also were believed to have some impact.

Laboratory studies conducted by Amy and colleagues (2005) on the impact of phosphate (125 and 250 $\mu\text{g/L}$ as PO_4^{3-}) showed reductions in arsenic removal capacities with all media products tested. With 125 $\mu\text{g/L}$ of phosphate, the arsenic-reduction capacity for two iron-based media products ranged from 4 to 40 percent depending on the pH. Because phosphate occurs in micrograms per liter ($\mu\text{g/L}$) rather than milligrams per liter (mg/L), the magnitude of its impact on arsenic is difficult to quantify. Phosphate was removed to some degree at all the USEPA arsenic demonstration program sites, with one site having the phosphate reduced up to 50,000 BV.

The impact of vanadium has not been studied extensively, and therefore, the magnitude of its interference is not fully known. Of the 50 USEPA demonstration projects across the

country, 35 sites were found to have vanadium above the detection limit of 0.1 $\mu\text{g/L}$. The concentrations ranged from 1 to 120 $\mu\text{g/L}$, with the median value being 5 $\mu\text{g/L}$. At the demonstration site with the highest level (120 $\mu\text{g/L}$), vanadium was found to be totally removed for 6000 BV and reached total breakthrough around 15,000 BV. Arsenic (40 $\mu\text{g/L}$), on the other hand, continued to be reduced to below 10 $\mu\text{g/L}$ at 25,000 BV when the project ended, indicating that arsenic was more preferred than vanadium (Wang et al., 2008). Lakshmanan and colleagues (2008), studying iron oxide/hydroxide coagulants, found that vanadate (50 $\mu\text{g/L}$ as V) did interfere with arsenate removal in the absence of silica and phosphate, but in their presence (SiO_2 at 20 mg/L and $\text{PO}_4\text{-P}$ at 40 $\mu\text{g/L}$), the vanadate effect on arsenate removal was not significant.

EBCT can significantly influence arsenic removal, and manufacturers usually recommend an EBCT range for their specific product. EBCT values as low as 1.5 minutes to as high as 10 to 12 minutes have been specified. With 14×28 mesh Alcan A-400G alumina at pH 7.5, Simms and Azizian (1997) found that arsenic run length was linearly proportional to EBCT in the range of 3 to 12 minutes and that doubling the EBCT from 6 to 12 minutes increased the run length by 30 percent from 10,700 to 14,000 BV. In arsenic-removal studies at Albuquerque, N.M., Clifford and colleagues (1998) found a similar relationship between EBCT and run length when using a finer 28×48 mesh alumina and operating at pH 6.0. At a 5 minute EBCT, the run length was 6400 BV, whereas at a 10 minute EBCT, the run length increased about 37 percent to 8800 BV. At several USEPA arsenic demonstration sites where two or three tanks of media were used in series, arsenic-removal run lengths were found to increase around 30 percent when the EBCT was doubled (see Table 12-11). For example, at the Rimrock, Ariz., site using E33 G medium, the run length to arsenic MCL breakthrough was 391,000 BV from the first tank (5.4 minute EBCT) and 52,100 BV from the second tank (10.8 minute EBCT), an increase of 33 percent (Valigore et al., 2008). A similar increase was found at the Goffstown, N.H., site also using E33 G medium, where at a 2.9 minute EBCT (first tank), the run length was 19,800 BV, and at a 5.8 minute EBCT (two tanks in series), the run length increased 30 percent to 257,000 BV (McCall et al., 2009).

Disposal of Residuals of Arsenic Adsorptive Media. Potential residuals from an adsorptive media process consist of (1) media backwash water, (2) regeneration wastewater, and (3) exhausted (used) media. Some, but not all, adsorptive media require an occasional backwash to fluff the medium and remove particulate material that has accumulated at the top of the medium bed. Backwash water normally includes some suspended solids, with the amount depending on the quality of the source water and the physical properties of the adsorptive medium. The backwash process can produce media fines, which will be removed along with any source water turbidity removed by the filtering action of the medium bed. Source waters having high iron and/or manganese normally will require pretreatment to protect the medium from being fouled, particularly when preoxidation is needed for As(III). When oxidized, untreated source waters with low levels of iron and/or manganese will have some iron and possibly manganese particulates formed that could be removed in the medium bed. The iron particulates actually can be advantageous because they will absorb some arsenic, which will extend the life of the medium. The potential disadvantage of the iron/arsenic particulates is that they may break through into the product water or end up in the backwash water, creating a disposal problem.

The USEPA arsenic demonstration program collected extensive data on the characteristics of the backwash water where media backwashing was required. The results show that, in most cases, the soluble arsenic (8–56 $\mu\text{g/L}$, median 16 $\mu\text{g/L}$) in the backwash water was less than in the raw water used for backwashing (median 20 $\mu\text{g/L}$), indicating that some arsenic was removed by the medium during the backwashing process. If treated water having low levels of arsenic is used for backwashing, some arsenic desorption from the

medium can be expected. Total arsenic levels ranged from 8 to 257 $\mu\text{g/L}$ (median 75 $\mu\text{g/L}$) in the backwash waste water, with most arsenic the particulate form, likely attached to the iron solids. The total iron in the backwash waste ranged from 0.1 to 18.9 mg/L (median 7.4 mg/L) and was essentially all particulate iron from media fines or precipitated $\text{Fe}(\text{OH})_3(\text{s})$ from the raw water or a combination of both. The soluble iron in the backwash waste was less than 0.2 mg/L (median 0.12 mg/L) at all sites and frequently less than the detectable limit of 0.025 mg/L . At sites where the only option for backwash water disposal is recycle, these iron solids can be removed by a combination of settling in a backwash storage tank and poststorage bag filtration. If the arsenic level in the backwash water is low, some states have rules that will allow surface discharge of the wastewater.

The current practice is for exhausted adsorptive media to be removed and replaced with virgin media. Studies have shown that these exhausted media pass the standard federal toxicity characteristic leaching procedure (TCLP) (USEPA, 1992) and thus are classified as nonhazardous waste. The reason is that the arsenic loading is low, and the TCLP test is performed at pH 5, which is near the optimal pH for arsenic adsorption onto most of the adsorptive media products. All the exhausted media from the USEPA arsenic demonstration program projects have passed the TCLP for arsenic, even with an exhausted media loading of 8.3 mg/g . Of the seven other metals included in the TCLP rule, the only detectable measurement was for barium, which ranged from 0.39 to 1.63 mg/L , well below the limit of 100 mg/L . Because these spent media are classified as nonhazardous, they can be disposed of in common sanitary landfills.

Activated alumina, the newly developed iron-modified resins, and the iron-coated diatomite products can be regenerated. The regeneration of other exhausted adsorptive media products, particularly the iron-based products, has not been investigated extensively. However, Chen and colleagues (2008) have shown in laboratory testing that NaOH regeneration of exhausted iron-based media is feasible, and it is anticipated that eventually regeneration will be common. Until regeneration is demonstrated to be practical and cost-effective, adsorptive media simply will be thrown away when exhausted.

Arsenic Removal by IX

If the source water contains less than 500 mg/L TDS, less than 150 mg/L sulfate, and/or multiple contaminants (e.g., nitrate and arsenate), IX may be the arsenic-removal process of choice (Clifford and Lin, 1986; Clifford et al., 1997, 1999). Preoxidation to convert As(III) to As(V) is necessary, but raw water pH adjustment generally is not required. The oxidized and filtered raw water is passed downflow through a 0.8 to 1.6 m deep (2.5–5 ft) bed of chloride-form strong-base anion exchange resin, and the chloride-arsenate IX reaction (Eq. 12-56) takes place in the near-neutral pH range. Regeneration, according to Eq. 12-57, is not difficult because a divalent ion (arsenate) is being replaced by a monovalent ion (chloride) in high-ionic-strength solution, where electroselectivity favors monovalent ion uptake by the resin. Regeneration returns the resin to the chloride form, ready for another exhaustion cycle:

Although chloride-arsenic IX is simple in concept, several issues must be addressed when implementing the process for drinking water treatment. Among the important factors are the following: choice of SBA resin, effect of multiple contaminants such as arsenic and nitrate, arsenic leakage, effect of sulfate concentration, optimal EBCT, regenerant strength (% NaCl), regenerant level (kg NaCl/m^3 resin or lb/ft^3), spent brine reuse, and spent brine

treatment. These factors have been examined in field studies in Hanford, Calif. (Clifford and Lin, 1986), McFarland, Calif. (Ghurye et al., 1998), Albuquerque, N.M. (Clifford et al., 1999), and Vale, Ore. (Chen et al., 2008).

Breakthrough Curves in As(V) IX. Prechlorination followed by IX proved to be an effective means of As(V) removal in Hanford. A typical set of breakthrough curves for pH, arsenic, and sulfate is shown in Fig. 12-22. Here, a commercially available type 1 STY-DVB SBA resin (Dowex 11) could effectively treat 4200 BV (16.6 day run length at a 6.6 minute EBCT) of water before the arsenic level reached 0.05 mg/L. However, despite its low concentration, sulfate still was the most preferred anion, and it eventually drove arsenate off the column and caused arsenic to peak at 0.136 mg As(V) per liter (i.e., 160 percent of its feed concentration). (As mentioned earlier, in normal operation, the run would have been stopped at a predetermined volume of throughput, before the peak occurred.)

In contrast with nitrate-chloride IX, a significant pH change did not occur simultaneously with As(V) breakthrough in Fig. 12-22. The effluent pH began at a relatively low value (5.6) and rose to the influent value of 8.7 at about 1300 BV (5 days), whereas As(V) did not reach 0.01 mg/L (the current MCL) until about 3000 BV. In this or a similar situation, a column run simply could be terminated at a predetermined length of, say, 2700 BV, which is far short of the point at which the effluent As(V) concentration reaches its influent value of 0.085 mg/L (5200 BV).

Effect of Process Variables on As(V) Removal BY IX

Choice of Resins for Arsenic Removal. Five different commercially available SBA exchange resins, including polystyrene type 1, were tested for As(V) removal performance in Hanford, Calif. (Clifford and Lin, 1986). After the exchange capacity was taken into account,

FIGURE 12-22 Typical IX exhaustion run showing pH and arsenic and sulfate breakthrough curves from chloride-form anion exchange column. Effluent arsenic peaks above influent concentration. C_I = influent concentration.

the resins differed very little in their ability to remove As(V). Dowex 11, an improved-porosity polystyrene type 1 resin, and Ionac ASB-2, a polystyrene type 2 resin, seemed to have a slight edge over the others in terms of bed volumes to arsenic breakthrough, so they were studied extensively. In contrast with subsequent field studies in McFarland (Ghurye et al., 1998) and Albuquerque (Clifford et al., 1999), where the run length remained stable after many regenerations, run length deteriorated 3 to 5 percent following each regeneration in the Hanford study. The reason for the decrease was not established, but it was thought to have been caused by the mica fouling observed on the exhausted resin. Most, but not all, of the black coating was removed on NaCl regeneration. Presumably this sort of fouling could be eliminated by multimedia filtration ahead of the anion resin because it is never a good idea to use a resin bed as a particulate filter.

More recently, a STY-DVB macroporous type 2 SBA resin has been used successfully to treat shallow wells near the Republican River in McCook, NB, for the combined removal of arsenic (15 µg/L), nitrate-N (15 mg/L), and uranium (50 µg/L) from a high-sulfate (265 mg/L) water containing TOC (4.0 mg/L). The resin bed also contained 15 percent of an acrylic resin for TOC removal and easier regeneration with NaCl without NaOH. Although the process was successful, the run lengths were quite short at 130 to 150 BV (Boodoo et al., 2008). Resin fouling from TOC was not a problem in McCook. However, the presence of 2.0 mg/L TOC in the Vale, Ore., groundwater seemed to seriously foul the type 1 SBA resin that was used to treat a water containing arsenic (20 µg/L), sulfate (64 mg/L), phosphate-P (300 µg/L), vanadium (50 µg/L), and silica (58 mg/L). Initial run lengths were more than 600 BV but fell to 300 to 400 BV after less than 1 year of operation, apparently owing to TOC fouling of the resin. NaOH was used to clean the resin, which partially restored the capacity, but fouling occurred again during several months of continued operation. Attempts to solve the problem by adding 15 percent acrylic resin to the bed were not successful because run lengths of less than 400 BV were typical.

In addition to TOC, silica can foul anion resins used to treat groundwater to remove arsenic. This apparently occurred in Alamosa, Colo., pilot studies on a pH 8.2 raw water containing 50 µg/L arsenic and more than 100 mg/L silica, most of which was soluble (Brandhuber et al., 2008). Although the water was low in sulfate (<5 mg/L) and projected run lengths were more than 2000 BV, effluent arsenic was erratic, often exceeding the MCL (10 µg/L), and early arsenic breakthrough was apparent. During exhaustion, the pressure drop in the beds exceeded 152 kPa (22 psi), which was attributed to particulate/colloidal silica fouling, which was not removed on backwashing. Installing a particulate filter ahead of the IX unit and regenerating the resin with NaOH and then NaCl appeared to solve the problem of early arsenic leakage. The pilot study was discontinued when a decision was made to install iron coagulation microfiltration for arsenic removal despite the high silica (100 mg/L) concentration.

Combined Arsenic and Nitrate Removal. Combined nitrate and arsenic removal was studied in McFarland, where the chlorinated water contained 13 µg/L arsenic, 10 mg/L NO³-N, and 40 mg/L sulfate. Here, the triethyl (IRA 996) and tributyl (Ionac SR-6) nitrate-over-sulfate-selective (NSS) SBA resins were compared with two conventional sulfate-selective (CSS) resins. The results of a typical exhaustion cycle are summarized in Fig. 12-23, which presents the arsenic breakthrough curves for all four resins. It is clear from the figure that the conventional SBA resins (IRA 404 and IRA 458) are far superior to the nitrate-selective resins (Ionac SR6, IRA 996) on the basis of run length to arsenic breakthrough. Also evident is the arsenic peaking, which occurs with all the resins, because arsenate is not the most preferred ion by any of the resins. Table 12-13, which gives more details of the runs depicted in Fig. 12-23, shows that because it is the most preferred ion, nitrate does not peak with the nitrate-selective resins but does peak with the conventional sulfate-selective resins.

To summarize, arsenic is removed from water as divalent HAsO₄²⁻, which has poor affinity for monovalent (nitrate) selective resins. Therefore, when removing both nitrate

FIGURE 12-23 Comparison of As(V) breakthrough curves for conventional (sulfate-selective) SBA resins compared with nitrate-selective SBA resins.

and arsenic, nitrate-selective resins should be avoided, and the runs should be stopped before nitrate breakthrough to avoid peaking of nitrate and, possibly, arsenate. It is counterproductive to lower the feed pH to produce the monovalent H_2AsO_4^- because H_2AsO_4^- is much lower in the selectivity sequence than is divalent HAsO_4^{2-} .

Effect of Arsenic Concentration on Run Length. Because arsenic is a trace species and not the most preferred ion, its concentration does not significantly influence its major breakthrough, according to multicomponent chromatography theory (Helfferich and Klien, 1970). Nevertheless, higher concentration produces higher leakage and shorter run length. To test these predictions, the As(V) concentration was deliberately increased 14-fold from 0.085 to 1.2 mg/L by spiking the feed water during one run at Hanford (Clifford and Lin, 1986). The general trend predicted from theory did occur: The run length to arsenic breakthrough decreased only 46 percent, which was not linearly proportional to the 14-fold

TABLE 12-13 Performance of Nitrate-over-Sulfate-Selective (NSS) and Conventional Sulfate-Selective (CSS) Resins for Combined Arsenic and Nitrate Removal

Parameter	Ionac SR-6	IRA 996	IRA 404	IRA 458
Selective for	Nitrate, NSS	Nitrate, NSS	Sulfate, CSS	Sulfate, CSS
Matrix	STY-DVB	STY-DVB	STY-DVB	Acrylic

As breakthrough, BV ^a	220	330	850	950
Nitrate breakthrough, BV	680	750	560	610
As peaking factor ^b	1.4	3.7	2.7	4.0
Nitrate peaking factor ^b	1.0	0.9	2.5	2.2

^aArsenic breakthrough to 10 µg/L.

^bPeaking factor is the ratio of peak concentration to influent concentration.

increase in concentration. The shorter run was primarily a result of greater arsenic leakage at the 14-fold higher influent arsenic concentration.

Arsenic Leakage During Exhaustion. The IX field tests in McFarland, Hanford, and Albuquerque proved that IX could easily meet a 0.010 mg/L arsenic MCL when treating a up to 50 µg/L arsenic-contaminated groundwater containing up to 220 mg/L sulfate. Average arsenic leakages during runs with EBCTs in the range of 1.5 to 3 minutes were 0.2 to 0.8 µg/L for the three SBA resins tested, ASB-2 (polystyrene type 2), IRA 458 (polyacrylic type 1), and IRA 404 (polystyrene type 1). Runs with a 3 minute EBCT produced essentially the same arsenic leakage as runs with a 1.5 minute EBCT. In all cases, cocurrent downflow regenerations with 1 M (6%) NaCl at 320 kg NaCl/m³ of resin (20 lb/ft³) were employed. Subsequent experiments with regeneration levels as low as 80 kg NaCl/m³ of resin (5 lb/ft³) resulted in similar leakage values.

Arsenic leakage from SBA resin columns increased dramatically in the presence of particulate iron(III), which strongly adsorbed As(V) and was not well filtered by the resin. This fact was discovered during some tests in McFarland using water that was visibly contaminated with particulate Fe(III). Serious arsenic leakage (up to 6 µg/L) tracked the iron contamination in the IX column effluent. The problem was solved by adding a multimedia prefilter ahead of the IX column; the prefilter eliminated the particulate iron in the arsenic-contaminated feed to the SBA column, and arsenic leakage returned to normal.

Effect of Sulfate on Arsenic Run Length. As was observed during nitrate removal, increasing sulfate concentration leads to shorter IX runs because sulfate is preferred to nitrate and arsenate when using the recommended CSS resins. Table 12-14 compares arsenic run lengths for ASB-2 resin using various waters with different TDS values and sulfate concentrations. Even with 100 mg/L sulfate in the feed water, a run length of 540 BV was observed with the spiked McFarland water. The 275 BV run length at 220 mg/L sulfate was considered relatively short for economical full-scale operation, which is why less than 150 mg/L sulfate is suggested as one criterion for selecting IX for arsenic removal.

TABLE 12-14 Arsenic Run Length as a Function of Influent Sulfate Concentration^a

Location	As, µg/L	TDS, mg/L	Sulfate, mg/L	Run length, BV ^b

Regeneration of Arsenic Spent Resins. During the original Hanford studies in 1984, arsenic recoveries on downflow (cocurrent) regeneration were essentially complete. Regeneration with 3 BV of 1.0 N NaCl (11 lb NaCl/ft³ of resin) was more than adequate to elute all the adsorbed arsenic, which was even easier to elute than bicarbonate—a non preferred ion. One reason why arsenic elutes so readily is that it is a divalent ion (HAsO₄²⁻) and thus is subject to a selectivity reversal in the high-ionic-strength (>1 M) environment of the regenerant solution. This ease of regeneration is a strong point in favor of IX over adsorptive media for arsenic removal in low-TDS, low-sulfate waters.

In confirmation of similar findings from the nitrate studies in Glendale, Ariz. (Clifford et al., 1987), the Hanford experiments (Clifford and Lin, 1986) showed that dilute regenerants (0.25–0.5 N) were more efficient (use fewer kg NaCl/m³ of resin) than concentrated ones for eluting arsenic. The greater efficiency of dilute regenerants was further verified in the Albuquerque field study (Clifford et al., 2003), where 0.5 N NaCl outperformed 1.0 and 2.0 N regenerants in downflow regeneration experiments on similar aliquots of exhausted resin. When analyzing the data, however, it appeared that the regenerant flow velocity was an important factor that had not been considered previously. At the low superficial flow velocities (<1.2 m/h) associated with the higher regenerant concentrations, regenerant channeling occurred, which resulted in poor arsenic recoveries. The resulting rule of thumb was that the regenerant *superficial linear velocity* (SLV) should exceed 1.2 m/h with typical U.S. 16 × 50 mesh resins. With SLV's greater than 1.2 m/h, there was not much difference between the performance of 0.5 and 1.0 N regenerants at regeneration levels of 1 to 2 eq Cl⁻ per equivalent of resin (5–10 lb NaCl/ft³).

Downflow Versus Upflow Regeneration. It is conventional wisdom that countercurrent upflow regeneration is better than cocurrent downflow to minimize contaminant leakage in cyclic IX operations. Normally this is true, especially in demineralizer operation, where minimal leakage is critical. However, with arsenic IX, it is not necessary to use counterflow (upflow) regeneration to minimize leakage. When upflow was compared with downflow regeneration in the Albuquerque field study (Clifford et al., 1999), conventional downflow regeneration performed somewhat better; that is, it gave lower arsenic leakage during subsequent exhaustions. The reason for the superiority of cocurrent downflow regeneration is that, at exhaustion, most of the arsenic on the resin is concentrated in a thin zone near the column outlet. Based on experimental results, it is preferable to elute the arsenic by the shortest route, that is, cocurrent regeneration, as opposed to flushing it back through the entire resin bed, where some of it apparently remains during countercurrent regeneration.

Reuse of Spent Regenerant. The major finding of the Albuquerque arsenic study was that spent regenerant could be reused without treatment to remove arsenic. In the series of exhaustion/regeneration cycles shown in Fig. 12-24, the ASB-2 column was exhausted

FIGURE 12-24 Arsenic breakthrough curves for 18 exhaustion/regeneration cycles reusing the same brine with chloride concentration maintained at 1 M.

and regenerated 18 times using recycled regenerant that had been compensated each cycle with NaCl to maintain the chloride concentration at 1.0 N. Despite the fact that the arsenic concentration in the reuse brine rose to 19,000 µg/L, sulfate reached 151 g/L (3.1 N), and bicarbonate reached 24.4 g/L (0.39 N), the arsenic leakage during exhaustion was typically less than 0.4 µg/L, and run lengths were consistently in the 400 to 450 BV range. After 18 cycles of reuse, attempts were made to continue reusing the brine without chloride compensation in the hope that the high bicarbonate level in the brine would be sufficient to elute the arsenic. These attempts failed because the arsenic leakage rose to 10 µg/L after only four runs without chloride addition. When chloride addition was resumed with the same recycle brine, the arsenic leakage dropped back to 0.4 µg/L, but the run lengths were a little shorter (380–400 BV). Based on the Albuquerque field-study results, it appears that spent brine can be reused at least 20 times and possibly more. Eventually, the spent brine will have to be wasted, but it should be treated to remove arsenic before disposal. This can be accomplished by iron(III) or aluminum(III) precipitation, as discussed below.

Treatment of Spent IX Regenerant. Arsenic(V) can be precipitated from the waste brine by using iron(III) or aluminum salts such as ferric chloride or alum or lime [Ca(OH)₂]. The stoichiometric reactions are

Al₂(SO₄)₃·14H₂O may be substituted for FeCl₃ in Eq. 12-58 to produce Al(H₂AsO₄)₃(s).

Iron or aluminum is required in greater-than-stoichiometric amounts in practice. A wastewater of pH 9.9 resulting from a 1.0 N NaCl regeneration was treated to remove As(V) in Hanford, Calif. For the wastewater, which contained 90 mg As(V) per liter and 50,000 mg TDS per liter, about 12 times the stoichiometric amount of iron (adjusted final pH 8.5) or aluminum (adjusted final pH 6.5) was required to reduce the As(V) level from 90 mg/L to less than 5 mg/L. To reduce As(V) to less than 1.5 mg/L required a 20-fold stoichiometric dose of either metal salt. The iron floc was heavier and settled better than the alum floc. When subjected to the Extraction Procedure EP test to determine As(V) leachability from the air-dried sludges, both sludges passed the test with about 1.5 mg As(V) per liter in the leachate when the EP MCL was 5 mg As/L (Clifford and Lin, 1986).

Similar Fe(III) precipitation of arsenic experiments were carried out in the Albuquerque field study (Clifford et al., 2003). In these tests, however, the spent brine contained only 3.5 mg/L arsenic initially. The arsenic removals achieved were found to be strongly dependent on pH. When using a molar Fe:As ratio of 20:1, the arsenic removals observed were 98.7 and 99.5 percent at final pH values of 6.4 and 5.5, respectively. TCLP tests will have to be run on precipitated arsenic sludges to verify their suitability for land disposal.

Natural Color and Organics Removal by Resins

Naturally occurring *dissolved organic carbon* (DOC) or NOM consisting primarily of humate and fulvate anions has been recognized for more than 40 years as a common foulant of the anion exchangers used in demineralization processes (McGarvey and Reents, 1954; Frisch and Kuin, 1957; Wilson, 1959). The symptoms of organic fouling are product water quality deterioration, resin darkening, brown-colored regenerant, exchange capacity loss, and increased frequency of regeneration. Early on it was found that occasionally regenerating the fouled SBA resin with a mixture of NaCl and NaOH would reverse most

of the fouling and lead to acceptable run lengths and resin life (Wilson, 1959). Despite an early history of problems with DOC in surface waters treated by SBA resins, it was found that DOC could be removed from groundwater and surface water by using resins, especially macroporous anion exchangers in the chloride form. Published research on the IX process for DOC removal is scarce, and much remains to be done to optimize the process. However, the few reported studies to date have suggested that IX is a viable process for DOC and disinfection-by-product (DBP) control in drinking water supplies.

History of DOC Removal by IX. One of the earliest reports on the use of resins to treat drinking water to remove DOC was a 2-year successful pilot study of color removal on the Merrimack River in Massachusetts during the period 1962–1964 (Coogan, 1968). Duolite A-7—a hydrophilic matrix granular weak-base phenol formaldehyde anion resin regenerated with NaOH—was tested extensively. Although A-7 is an anion exchanger at low pH, it had almost no IX capacity at the pH of the influent water (6.4–6.9). Thus the removal of color appeared to be due to adsorption of anion-cation pairs rather than by IX, but this was not proven. The main findings of the study were as follows: (1) With color values of 50 to 100 on the raw water, diatomaceous earth (DE) prefiltration to remove about 10 percent of the presumably larger color bodies was required ahead of the resin bed, (2) EBCTs in the 3.75 to 7.5 minute range were acceptable, with the 3.75 minute time giving only a small decrease in run length, which was 2000 to 2500 BV for 7.5 minutes, (3) typically, 80 to 100 percent color removal was attained at the start of a run, decreasing to 50 to 75 percent the end, (4) NaOH at a level of 64 kg/m³ (4 lb/ft³) was adequate to regenerate the resin during more than 200 exhaustion/regeneration cycles in which the resin capacity for DOC remained relatively constant, and (5) iron removals were about 25 percent across the DE filter and 95 percent through the resin bed, which led to the suggestion that soluble iron was being removed by complexation with the adsorbed color bodies. This study and others reported by Abrams (1982) led researchers to try A-7 and similar weak-base resins for adsorption rather than IX of DOC. Later, it was found that SBA resins regenerated with NaOH or a mixture of NaCl and NaOH also could be used in cyclic operation to control organics in surface and groundwaters.

Baker and colleagues (1977) reported that the substitution of the acrylic-matrix gel SBA resin IRA 458 for a conventional polystyrene type 2 resin in a demineralizer system solved the organic fouling problems that had plagued the system for years. The acrylic-matrix resin performed better because it was more efficiently regenerated than the original polystyrene resin. The authors explained that there is minimal van der Waals attraction between the hydrophobic organic molecules and the hydrophilic acrylic resin matrix, which makes regeneration easier and more complete. In 1977, when Baker's paper was published, the acrylic resin had been placed into service at 125 sites worldwide because of its superior regenerability and resistance to organic fouling.

Kolle (1984) described a DOC-removal process using anion exchange for treatment of a highly colored Hannover, West Germany, groundwater. The 2500 m³/d (15.8 mgd) full-scale process used a macroporous type 1 polystyrene SBA resin (Lewatit MP 500 A) in four single beds operated in parallel with an EBCT of 1.2 minutes. Regeneration was accomplished with 2 BV of a mixture of 1.7 N (10%) NaCl, and 0.5 N (2%) NaOH. A striking feature of the process was the reuse of regenerant seven times with the NaCl and NaOH concentrations replenished after each use. The DOC was not removed from the recycled regenerant, and it built up to 25,000 mg/L prior to disposal, which was triggered when the sulfate concentration increased to the chloride level. This reuse method allowed for a 20,000:1 ratio of product water to spent regenerant.

Typical breakthrough curves for DOC, chloride, and sulfate from the early portion of the run in the Hannover process are shown in Fig. 12-25. After sulfate breakthrough at 250 BV, the DOC removal remained at about 50 percent until 5000 BV—the point of run termination.

FIGURE 12-25 Typical breakthrough curves for DOC, sulfate, and chloride from a macroporous SBA exchanger removing fulvate and humate anions from Hannover, West Germany, groundwater. Column was operated to 5000 BV before regeneration. Between 400 and 5000 BV, the DOC removal was approximately 50%, with influent sulfate at 130 mg/L. (Source: Kolle, 1984.)

Although far from complete, the 50 percent DOC removal was sufficient to increase the bacterial doubling time in the product water from 5 to 12 hours and to drastically reduce the chlorine consumption with its attendant organic halide formation problems. The overall treatment efficiency was reduced only 10 percent because of fouling and resin losses over a period of 2 years of full-scale operation.

Brattebo and colleagues (1987) described a similar DOC-removal process designed to treat a highly colored Norwegian surface water containing 3 to 6 mg/L DOC, primarily in the greater than 10,000-Da molecular weight (MW) range. During their pilot studies, they verified the superiority of macroporous MP 500 A type 1 SBA resin compared with a limited number of other polystyrene resins of macroporous and gel porosity. They also effectively reused the 1.7 N NaCl/0.5 N NaOH regenerant as many as eight times by wasting a fraction of the first eluate containing most of the DOC and making up the remainder with fresh NaCl and NaOH. For water containing up to 4 mg DOC per liter, they recommended the IX method implemented by using a four-column merry-go-round IX system (similar to Fig. 12-12, a three-column merry-go-round system) in which the resting, freshly regenerated fourth column automatically became the final polisher when the effluent DOC from the three columns in series reached a predetermined level. At this time, the lead column was taken out of service and regenerated. They also determined that the EBCT for the series of columns was the most important design parameter, and they suggested a range of 5 to 10 minutes for this surface water, which is considerably longer than the 1.2 minutes used in the full-scale Hannover groundwater system. The difference in optimal EBCT likely was due to differences in the nature (e.g., size, aromaticity, and hydrophobicity) of the various surface and groundwater organics involved.

The same Norwegian research group tested the multibed anion exchange process on a small water supply using a full-scale 3 m³/h (13 gpm) plant and reported the following conclusions: (1) NaOH was a necessary constituent of the regenerant because with NaCl alone, the DOC recovery was less than 80 percent. (2) reusing up to 75 percent of the spent regenerant did not reduce the DOC adsorption capacity on subsequent runs, (3) mass transfer of DOC was particle diffusion limited such that a reduction in temperature from 15°C to 5°C required a 20 percent increase in EBCT, and (4) for small water supplies with relatively low (<4 mg/L) DOC, the anion exchange process was estimated to be less costly to build and operate than a conventional coagulation process (Brattebo et al., 1987).

Fundamentals of DOC IX. Fu and Symons (1990) conducted research on the fundamentals of DOC IX. Their IX isotherm experiments indicated that within the limits of experimental error, each milliequivalent of DOC in the 1000 to 5000 Da fractions sorbed was balanced by an equal amount of chloride ion released (Fig. 12-26). Overall, their results

FIGURE 12-26 Proof of 1000 to 5000 Da MW fraction TOC removal by IX (as opposed to adsorption) using chloride-form SBA resin. (Source: Fu and Symons, 1990.)

showed that the sorption mechanism for DOC removal was IX, with only a small percentage of the DOC in the less than 1000 Da and greater than 10,000 Da fractions being removed by adsorption. Also using equilibrium isotherm tests, they found that the resin matrix and porosity exhibited significant influences on DOC removal. Generally, for DOC MW of 1000 Da or more, the hydrophilic polyacrylic resins were preferred for DOC removal compared with the relatively hydrophobic polystyrene resins. And, for all MW fractions greater than 1000 Da, macroporous resins performed better than gel types; that is, the greater the resin porosity, the better was the DOC removal. At less than 1000 Da MW, the resin porosity did not influence the DOC removal, which was, however, influenced by the resin matrix. In this low-MW range, hydrophobic polystyrene resins performed somewhat better than the hydrophilic polyacrylic resins. Thus the resin of choice for removing NOM depends on the actual water supply being treated. They also found that the resin's ability to sorb DOC of 1000 Da or greater MW was positively correlated with its tendency to swell in water, that is, its hydrophilicity, which is another way of explaining why acrylic resins were preferred by Baker and colleagues (1977) over polystyrene resins for DOC removal.

Fu and Symons (1990) found that coagulation performed in a similar manner to IX for removing DOC and that neither process was particularly good for the less than 1000 Da fraction. Their column study results suggested that the DOC could be divided into three categories: (1) not removed, (2) less preferred than sulfate, and (3) more preferred than sulfate. Figure 12-27 shows the TOC effluent history and the sulfate breakthrough point during a test with the less than 10,000 Da TOC fraction. With only 6 mg/L sulfate and 18 mg/L chloride in the dialyzed feed water, the 3000-BV run length to sulfate breakthrough was exceptionally long compared with typical drinking waters. Prior to sulfate breakthrough, TOC removal was about 75 percent. At sulfate breakthrough, a TOC peak appeared that was the TOC less preferred than sulfate being driven off the column by the advancing sulfate wavefront. After sulfate breakthrough, the TOC more preferred than sulfate was being removed for a total TOC removal of about 50 to 60 percent until 9000 BV. Then TOC removal dropped gradually to zero at about 12,000 BV. These column results were similar

FIGURE 12-27 TOC effluent history for a bench-scale test with IRA 958 (acrylic SBA) resin fed with less than 1000-Da MW TOC fraction in low TDS water. (Source: Fu and Symons, 1990.)

to those of Coogan and colleagues (1968) and Kolle and colleagues (1984) in that TOC removal started out at 70 to 80 percent and dropped to a long period of about 50 percent removal following sulfate breakthrough.

Kim and Symons (1991) focused their research on the field performance of the macroporous polyacrylic SBA resin (IRA 958) when treating an alum-coagulated, filtered surface water at a City of Houston water plant. Following conventional treatment, the water fed to their minicolumns was 0.45- μm -cartridge filtered, dechlorinated (Na_2SO_3), and adjusted to pH 6.8. Figure 12-28 illustrates the virgin resin breakthrough curves for the sulfate and TOC (which was DOC for these filtered waters). As with the previously described nitrate- and arsenate-removal processes and all the column experiments with DOC removal, the background sulfate concentration determined the performance of the system. When sulfate broke through at about 500 BV, it caused the TOC that was less preferred than sulfate to peak at about 120 percent of the influent TOC concentration (4.0 mg/L). When the effluent histories of the various TOC fractions were studied, it was found that with the exception of the less than 500-Da fraction, all peaked at essentially the same time, indicating that all fractions, except the less than 500-Da fraction, contained some TOC less preferred than sulfate. The less than 500-Da fraction was only about 25 percent removed throughout the run and was not influenced by sulfate. The TOC effluent histories also indicate that, generally, the higher the MW, the better is the TOC

FIGURE 12-28 TOC and sulfate breakthrough curves from virgin macroporous polyacrylic SBA resin (IRA 958) during pilot tests with treated Houston water. pH = 6.8; EBCT = 10 minutes. (Source: Kim and Symons, 1991.)

removal before and after the sulfate breakthrough. Running beyond sulfate breakthrough was not very effective with this coagulated water because only about 25 percent overall TOC removal was achieved from 1300 to 2700 BV.

The Kim and Symons (1991) TOC regeneration study determined that the most effective TOC regenerant was a mixture of 2 N NaCl with 0.5 N NaOH, which is in agreement with the 1.7 N NaCl–0.5 N NaOH mixture used by Kolle (1984) and Brattebo and colleagues (1987) in their larger-scale studies. This 2 N NaCl–0.5 N NaOH mixture was used in the regenerant reuse study, which showed that a polyacrylic macroporous resin (IRA 958) could be exhausted and regenerated nine times with the same regenerant that had been compensated with salt and caustic after each regeneration to maintain the original chloride and hydroxide concentrations. Although the TOC removed from the resin during regeneration following the eighth reuse cycle was only 13 percent, the overall performance of the resin for TOC removal up to sulfate breakthrough was essentially unchanged. Kim and Symons suggested that the TOC not removed during regeneration was building up in the deeper pores of the resin, where it did not interfere with the reversible IX, which appeared to be taking place closer to the resin surface.

When Kim and Symons (1991) tested the sequence of IX (IRA 958) followed by GAC (Calgon F-400) for trihalomethane formation potential (THMFP) control, they found that it was much superior to GAC alone. When regenerating the resin at sulfate breakthrough, the IX/GAC process consistently achieved 95 percent THMFP removal to 5000 BV, whereas IX alone achieved only 50 percent removal after 200 BV and GAC alone achieved only 75 percent removal after about 2000 BV.

In summary, experimental evidence shows that NOM in groundwater and surface water can be removed by adsorption onto weak-base resins and is also amenable to removal by using macro- and microporous chloride-form SBA resins with both polystyrene and polyacrylic matrices. With SBA resins, the sulfate concentration of the raw water determines run length to the first DOC breakthrough, which peaks above the influent DOC concentration. After this, DOC removal may be continued if 50 percent and lower removals can be tolerated. Filtration always should be employed ahead of IX to protect against resin fouling. When coagulation precedes IX, the DOC remaining is difficult to remove because the two processes are similar in their DOC-removal profiles.

Magnetic Ion Exchange (MIEX) Treatment Process for DOC Removal. To this point, only packed bed (column-based) IX processes have been described because IX polymers (beads and particles) are almost always used in columns. Equilibrium-stage mixer/settlers and fluidized-bed ion exchangers are not often employed because (1) contaminant loading on the resin is low because resins are in equilibrium with the effluent contaminant concentration as opposed to the influent contaminant concentration for packed beds, and (2) very small resin particles are required in equilibrium-stage contactors for kinetic reasons, and these particles don't settle well because their densities are near that of water. An innovative class of exchangers that has attracted attention in the past decade is MIEX resins, which, although 1/10 the size of resin beads, aggregate and settle quickly in the resin separators (clarifiers or settlers) that must follow the resin contactors (fluidized beds or equilibrium-stage contactors). Although such MIEX resins can be used in both cation and anion exchange applications, magnetic anion resins have attracted the most attention because they have been used successfully at bench-, pilot-, and full-scale applications for DOC removal from water to prevent DBP formation and membrane fouling. One such process using magnetic anion exchangers is the MIEX process developed by Orica, Ltd. (2010), the Australian Water Quality Centre, and the Commonwealth Scientific Industrial Research Organization.

In the dual-stage MIEX process, raw water is contacted with small (20 to 50 μm diameter) magnetic resin particles in a stirred-tank contactor, with a typical resin dose being in the range of 0.5 to 2.5 percent (v/v). Anionic contaminants typically are exchanged for chloride on the resin, and the contents of mixed tank are sent to a settler (typically upflow), where

magnetic resin particles aggregate and settle quickly at overflow rates of up to 14.6 m/h (6 gpm/ft²). Although resin recoveries can exceed 99 percent; there is usually a small carryover of resin, and downstream filtration is necessary. The underflow from the settler is recycled back to the mixer/contactor, with a draw off of 1 to 20 percent of the recycled resin diverted for regeneration. Regeneration typically is performed using a 2 M (12%) NaCl solution, and the regenerated resin is sent to a resin feed tank, where a small amount of fresh resin is added to compensate for the resin lost owing to carryover from the settler. Given the higher solubility of TOC at an alkaline pH, caustic may be added to the NaCl brine solution to efficiently desorb TOC.

Using a MIEX-type process, Boyer and Singer (2006) determined that DOC removal was accompanied by a stoichiometric release of the exchanging chloride ion, verifying the work of Fu and Symons (1990), which showed that DOC removal occurs by anion exchange rather than sorption. Allpike and colleagues (2005) showed that the MIEX process outperformed the more traditional enhanced-coagulation process. MIEX removed more organic carbon than enhanced coagulation, and in contrast to enhanced coagulation, MIEX removed organic carbon across all MW fractions studied and with no preference for aromatic versus aliphatic character. Regarding inorganic contaminants, Seidel (2004) reported that MIEX effectively removed arsenic, hexavalent chromium, and perchlorate from water. Similar to traditional IX, sulfate provided the greatest competition for exchange sites for both TOC- and inorganic contaminant-removal applications. Also, Orica (2010) is promoting the application of MIEX for removing sulfide, nitrate, and arsenate in addition to DOC and color (Pyles, 2009).

Uranium Removal by Anion Exchange

On December 7, 2000, the USEPA set an MCL of 30 µg/L and an MCL goal (MCLG) of 0 pCi/L for uranium owing to health concerns; it is a known kidney chemotoxin and a suspected human carcinogen (Cothorn and Lappenbusch, 1983). When the radionuclides rule was published (USEPA, 2000), the USEPA estimated that 500 community water supplies affecting 620,000 persons in the United States would be out of compliance and would have to reduce uranium concentrations to less than the 30 µg/L MCL (see Chaps. 1 and 2 for more information about the regulations and health effects).

Uranium Chemistry and Speciation. Uranium has four oxidation states: III, IV, V, and VI. However, only the IV and VI states are stable. The high affinity of uranium for oxygen results in the formation of uranium's most common oxygen-containing compound, uranyl ion (UO₂²⁺), which is the most stable state of uranium in aerated aqueous solution under acidic conditions (pH < 5.0). The uranyl ion (UO₂²⁺) in water readily combines with anionic ligands, including CO₃²⁻, F⁻, Cl⁻, NO₃⁻, SO₄²⁻, and HPO₄²⁻, to form stable complexes. When F⁻, H₂PO₄⁻, or HPO₄²⁻ is present in oxidizing waters, these ligands preferentially complex the UO₂²⁺ at pH below about 8 (Langmuir, 1978).

Carbonate is the most significant uranium ligand in natural water. In the near-neutral pH range, UO₂²⁺ combines with bicarbonate and carbonate anions in aqueous solution to form stable, charged and uncharged uranyl carbonates. Langmuir (1978) has calculated the distribution of typical uranium complexes as a function of pH in aerobic groundwater at a CO₂ partial pressure of 10⁻² atm. Under mildly acidic conditions of pH 5.0 to 6.5, the principal species is UO₂CO₃⁰. In the pH range of 6.5 to 7.5, the principal species is UO₂(CO₃)₂²⁻. Above pH 8.0, the predominant species is UO₂(CO₃)₃⁴⁻. Uranyl hydroxy complexes such as UO₂OH⁺ and (UO₂)₃(OH)₅⁵⁺ are also formed, but generally in small percentages unless at high temperature or for waters with low inorganic carbon (Mo, 1980).

History of IX for Uranium Removal. Both cation and anion exchange resins have been used for uranium removal, but because of their requirements for low feed water pH and

their relatively unsatisfactory uranium removal efficiency, cation resins probably are not practical for drinking water treatment (Lee and Bondietti, 1983).

Anion exchange exhibited much better performance than cation exchange for removing uranium from contaminated water. Sorg (1988) summarized the results of USEPA-funded studies for uranium removal by anion exchange, which he suggested would be the cost-effective method for treating small community water supplies. In these bench-, pilot-, and full-scale uranium IX studies, it was apparent that SBA resins exhibited an enormous capacity for the uranyl carbonate complexes— $\text{UO}_2(\text{CO}_3)_2^{2-}$ and $\text{UO}_2(\text{CO}_3)_3^{4-}$. For example, during field studies in Colorado and New Mexico, columns receiving 22 to 104 $\mu\text{g/L}$ uranium treated 8000 to 60,000 BV of groundwater with less than 1.0 $\mu\text{g/L}$ uranium in the effluent. In associated studies, two columns containing type 1 polystyrene SBA resins (gel Dowex 21K and macroporous Ionac 641) were operated to 17,400 and 31,300 BV and still removed 95 and 90 percent, respectively, of the total uranium in the feed water (Hathaway, 1983). Uranium-removal field studies by Zhang and Clifford (1994, 1995) have confirmed this earlier work and shown that chloride-form IX is an excellent process for removing uranium from groundwater. In their Chimney Hill, Texas, field study, they reported that a type 1 macroporous polystyrene SBA resin (Ionac A-642) exhibited enormous capacity for uranium removal because of its exceptionally high affinity for $\text{UO}_2(\text{CO}_3)_3^{4-}$. (Similar resins are available from other suppliers and should perform in a similar manner.) A pilot-scale SBA column was operated continuously for 478 days for a total throughput of 302,000 BV at pH 7.6 to 8.2. The feed water contained 120 $\mu\text{g/L}$ of uranium and 25 pCi/L of radium in a background water quality of 310 mg/L TDS, 150 mg/L alkalinity, 47 mg/L chloride, and less than 1 mg/L sulfate. Even after 300,000 BV, the effluent uranium concentration was less than 6 $\mu\text{g/L}$, which corresponds to a removal efficiency of 95 percent (Fig. 12-29). Before 260,000 BV, the uranium leakage was less than 1 $\mu\text{g/L}$, that is, more than 99 percent removal. Compared with typical granular activated carbon (GAC) columns, which showed

FIGURE 12-29 Effluent uranium levels from pilot-scale IX column during virgin exhaustion of macroporous polystyrene SBA resin (Ionac A-642) at pH 8.0. Chimney Hill Field Study. EBCT = 3 min until 10^5 BV, 2 min thereafter. Feed U = 67-125 $\mu\text{g/L}$. (Source: Based on the work of Clifford and Zhang, 1995.)

a capacity of a few thousand BV of throughput before more than 20 $\mu\text{g/L}$ uranium leakage, the capacity of anion resin for uranium was enormous in this low-sulfate water. After 300,000 BV, the uranium concentration averaged over the whole bed was 30 g/L of resin, which corresponds to 35.4 kg $\text{U}_3\text{O}_8/\text{m}^3$ of anion resin (2.2 lb $\text{U}_3\text{O}_8/\text{ft}^3$), or 63 percent of resin sites in uranium form based on a resin capacity of 1.0 meq/mL. Although this ultimate uranium capacity is truly impressive, drinking water treatment columns are not generally operated for 200 to 500 days to uranium breakthrough because of problems with resin fouling and excessive pressure drop. Cyclic run lengths in the range of 30,000 to 50,000 BV are considered to be more appropriate for uranium removal from drinking water.

Effect of pH and Competing Ions on Uranium Removal. Even though SBA resins exhibit enormous capacity for removing uranium from contaminated groundwaters, the removal efficiency and resin capacity are somewhat influenced by the usual parameters, including feed pH and the feed concentrations of uranium, sulfate, chloride, and possibly bicarbonate. The simple IX reactions expected between uranium compounds and SBA resins in the 6.5 to 9.5 pH range, where $\text{UO}_2(\text{CO}_3)_3^{2-}$ and $\text{UO}_2(\text{CO}_3)_3^{4-}$ are the predominant forms, can be expressed as follows:

where R_4N^+ represents a quaternary nitrogen anion exchange site on the resin. Because the resin highly prefers the tetravalent $\text{UO}_2(\text{CO}_3)_3^{4-}$ complex, there is a tendency for this complex to actually be formed within the resin from neutral and divalent uranyl carbonate complexes. This is similar to the in-resin formation of carbonate from bicarbonate, as described by Horng and Clifford (1997). The in-resin formation of $\text{UO}_2(\text{CO}_3)_3^{4-}$, as further explained next under the effect of pH, helps to explain why the performance of SBA resin is so good at a feed water pH of 5.8, where the predominant form of uranium in water is the neutral species UO_2CO_3^0 .

Effect of pH. Based on pH effects on uranium speciation (Langmuir, 1978), pH variations in the 5.8 to 8 range are expected to have a significant impact on resin performance when removing uranium. A substantial decrease in the resin's capacity for uranium is expected at a pH below 7 because the charge on the uranyl carbonate complex decreases with decreasing pH, as does the carbonate concentration in the feed water. However, when pH was decreased by HCl addition from 7.8 to 5.8, uranium removal efficiency was unchanged for 270,000 BV during the Chimney Hill field study (Zhang and Clifford, 1994, 1995). When the pH was decreased further to 4.3, however, serious uranium leakage (about 50 percent of the feed uranium concentration) occurred from the very beginning of a run with virgin chloride-form resin. This unexpectedly excellent performance at pH 5.8 probably resulted from the formation of uranyl tricarbonate complexes within the resin, whereas these complexes were virtually absent from the aqueous phase. At pH 5.8, the dominant uranium species in the aqueous system in the absence of anion resin is the zero-charged complex UO_2CO_3^0 . It is theorized that the direct formation of charged $\text{UO}_2(\text{CO}_3)_3^{4-}$ from uncharged UO_2CO_3^0 occurs within the ion exchanger because of the resin's high affinity for polyvalent anions and the high stability constant of the tricarbonate uranium complex. The suggested exchange reactions are

Reaction 12-62 is the conversion of four resin sites to the bicarbonate form by simple IX with chloride. In Reaction 12-63, the bicarbonate-form ($\text{R}_4\text{N}^+\text{HCO}_3^-$) resin sites are converted to the highly preferred uranyl tricarbonate ($(\text{R}_4\text{N}^+)_4\text{UO}_2(\text{CO}_3)_3^{4-}$) form with the production of carbonic acid [$\text{H}_2\text{CO}_3(aq)$]. In the Chimney Hill studies, the resulting lowering of pH by the $\text{H}_2\text{CO}_3(aq)$ produced was insignificant because of the very low concentration (0.0005 mM) of

UO_2CO_3^0 in the feed water compared with the total inorganic carbon (C_{T,CO_3}) of the carbonate buffer system—3.00 mM in the groundwater.

Adding Reactions 12-62 and 12-63 yields the net IX reaction:

Reaction 12-64 is effectively the uptake of the neutral UO_2CO_3^0 molecule from an acidic (pH 5.8) solution by a chloride-form SBA resin.

Effects of Uranium, Sulfate, and Chloride on Run Length. Uranium, sulfate, and chloride concentrations in the feed water have significant effects on uranium breakthrough. Increasing the concentrations of these components results in decreasing run length; however, they affect the runs to different degrees.

Uranium feed concentration was expected to have a big influence on column capacity. However, because of the extremely long runs and the potential regulatory problems associated with uranium spiking of raw water during the Chimney Hill field tests, it was not practical to vary the uranium concentration in the test water to determine its influence on BV to uranium breakthrough. Thus computer predictions of uranium breakthrough were made using the Equilibrium Multicomponent Chromatography Program with Constant Separation Factors (EMCT/CSF) (Hornig, 1983; Clifford, 1993; Tirupanangadu, 1996). This program is a user-friendly implementation of the equilibrium multicomponent chromatography theory (EMCT) of Helfferich and Klein (1970), which has been used by Clifford (1982) since the early 1980s for prediction of column effluent concentrations during selected-ion separations.

Using this program, the BV throughputs to uranium breakthrough were calculated at various uranium concentrations in the Chimney Hill water. The results from the computer prediction

FIGURE 12-30 Calculated (EMCT software) BV throughput from a macroporous polystyrene SBA resin column before uranium breakthrough vs. uranium feed concentration at different background concentrations of chloride, and sulfate. Bicarbonate-chloride water = 183 mg/L HCO_3^- , 49 mg/L Cl^- , 0 mg/L SO_4^{2-} . Bicarbonate-sulfate water = 183 mg/L HCO_3^- , 64 mg/L SO_4^{2-} , 0 mg/L Cl^- . (Source: Based on the data of Clifford and Zhang, 1995.)

are presented in the Fig. 12-30 curve labeled "Bicarbonate-Chloride water." This curve predicts that for a sulfate-free water such as the Bicarbonate-Chloride Chimney Hill feed water, an increase in the uranium concentration to 240 $\mu\text{g/L}$ would result in a decreased run length of 203,000 BV. Decreasing the feed water uranium concentration to 20 $\mu\text{g/L}$ would increase the run length to 815,000 BV. This high sensitivity of run length to uranium concentration was due to the fact that (1) uranium was a trace species with an exceptionally high affinity for the resin, (2) uranyl carbonate complexes occupied a significant fraction of the resin sites at exhaustion, and (3) there was no sulfate in the feed water. The Fig 12-30 water labeled "Bicarbonate-Sulfate" is the "Bicarbonate-Chloride" water with sulfate substituted for chloride to illustrate the strong negative influence of sulfate on uranium run length.

Among the common anions in groundwater, sulfate will exhibit the biggest impact on run length. The EMCT/CSF program also was used to predict the influence of sulfate on uranium run length at variable uranium concentration. In this simulation, sulfate replaced chloride in the Chimney Hill water, which was initially free of sulfate. The line labeled "Bicarbonate-sulfate water" in Fig. 12-30 demonstrates that replacing chloride with sulfate greatly affects the SBA resin's capacity for uranium removal. At the natural uranium concentration of 120 $\mu\text{g/L}$, when the sulfate concentration increases from 0 to 1.32 meq/L (64 mg/L), run length drops 60 percent from the experimental 340,000 BV down to a predicted 135,000 BV. This decrease at higher sulfate concentration is attributed to the fact that compared with chloride, sulfate ion has a high affinity for the SBA resin sites (see Table 12-3). Therefore, water containing significant concentrations of sulfate will produce significantly shorter runs than low-sulfate waters.

Regenerability of Uranium Spent SBA Resins. The Chimney Hill field experiments demonstrated that despite the high affinity of SBA resins for uranyl carbonate complexes, the uranium spent resins are not difficult to regenerate because of the electroselectivity reversal that takes place in the presence of 1 to 6 M chloride regenerant solutions. Furthermore, it is not necessary to completely remove the uranium from the resin during regeneration because the residual uranium does not leak into the effluent on subsequent runs (Zhang and Clifford, 1994). What is necessary for a practical cyclic exhaustion/regeneration process is that a steady state be reached in which the mass of uranium eluted during regeneration is equal to the mass sorbed during exhaustion. Such a steady state can be attained in uranium removal by chloride-form SBA exchange.

Effect of NaCl Concentration and Regeneration Level. Uranium recovery efficiency strongly depends on the regenerant NaCl concentration (Zhang and Clifford, 1994). Increasing NaCl concentration results in increased uranium recovery at a fixed regeneration level. This was established in the Chimney Hill field test, where NaCl concentrations ranging from 0.8 to 4.0 N were applied to columns partially exhausted to 30,000 or 41,000 BV. Although the NaCl concentration varied, the total amount of NaCl applied was maintained constant at 4.0, or 6.0 eq NaCl per equivalent of resin during two sets of experiments. At a regeneration level of 6.0 eq NaCl per equivalent of resin (346 kg NaCl/m³, or 21.6 lb NaCl/ft³), the recovery efficiencies for 4.0, 3.0, 2.0, 1.33, 1.0, and 0.8 N NaCl were 91, 86, 75, 67, 54, and 47 percent, respectively, as shown in Fig. 12-31. The uranium recovery did not appear to level off at 4.0 N, which suggests that even higher NaCl concentrations, for example, saturated NaCl (6.15 N at 20°C), might be tried. Increasing the regeneration level from 4 to 6 eq Cl⁻ per equivalent of resin did improve recovery, but not by very much at any NaCl concentration (see Fig. 12-31). Thus regeneration levels lower than 4 eq Cl⁻ per equivalent of resin should be considered because this would conserve salt, and as pointed out previously, it is not necessary to remove all or even most of the uranium from the exhausted resin because it does not seriously leak on subsequent exhaustions.

Other observations made during the regeneration experiments in Chimney Hill follow. Uranium was mostly desorbed in the first 1 or 2 BV of regenerant when 2 to 4 N NaCl was used. Addition of NaOH to the NaCl solution greatly reduced the recovery of uranium. When NaOH represented one-third of the regenerant equivalents at 4.0 N regenerant

FIGURE 12-31 Effect of equivalents and normality of NaCl on percent uranium recovery during cocurrent regeneration of SBA resin exhausted to 41,000 BV. Regenerant EBCT = 10 min, 5 BV slow rinse. (Source: Based on the data of Clifford and Zang, 1995.)

concentration, uranium recovery efficiency dropped from 91 to 15 percent. Reductions in regeneration efficiency also were observed when Na_2CO_3 and NaHCO_3 were added to NaCl. Uranium recovery efficiency was not affected by the degree of exhaustion when the anion resin was far away from complete exhaustion. Columns that were exhausted to 500 BV exhibited the same uranium-recovery percentages (75%–78%) during regeneration as did columns exhausted to 30,000 and 40,000 BV, whereas complete exhaustion was approximately 300,000 BV.

Combined Radium and Uranium Removal. In the Chimney Hill field study conducted by Clifford and Zhang (1994), a common NaCl-regenerated SAC resin water softener modified by the addition of approximately 10 percent SBA resin was used for the simultaneous removal of radium (25 pCi/L) and uranium ($120 \mu\text{g/L}$) from groundwater. Although a high regeneration level (590 kg NaCl/m^3 of resin (37 lb/ft^3)) was used in the field tests, typical softener regeneration levels in the range of 160 to 320 kg NaCl/m^3 of resin (10 – 20 lb/ft^3) are expected to be adequate for a cyclic radium- and uranium-removal process. However, to remove uranium effectively, it is important to keep the regenerant NaCl concentration as high as possible.

Thorough mixing of the SAC and SBA resins was preferred to stratifying the lighter anion resin over the cation resin in the modified softener. Stratified SBA/SAC beds, especially those containing 25 percent or more anion resin, produced greater radium and uranium leakages after cocurrent regeneration than mixed beds. In actual practice, backwashing the softener will tend to stratify the anion resin over the cation resin. This less desirable stratified condition, however, may be adequate for combined radium and uranium removal when the stratified bed contains 10 percent or less anion resin.

As a rule of thumb, an anion bed EBCT of 0.2 minute or more and an anion resin bed depth of greater than 2.5 cm (1 in) are recommended for the stratified SBA resin layer to produce less than $10 \mu\text{g/L}$ uranium leakage with $120 \mu\text{g/L}$ uranium in the feed water. Extensive tests

with the stratified and mixed beds showed that radium (and possibly uranium) leakage in stratified-bed softeners was attributed to precipitation of $\text{CaCO}_3(s)$ during regeneration of the cation resin from carbonate ions taken up and eluted from the anion resin. Minimizing the amount of anion resin and mixing it with the cation resin minimized $\text{CaCO}_3(s)$ precipitation and subsequent radium and uranium leakage. Countercurrent regeneration is also expected to eliminate excessive radium and uranium leakage.

Although 10 percent anion resin appeared to be a near-optimal amount, as little as 2.5 percent anion resin removed 50 percent of uranium from the Chimney Hill groundwater at conventional flow rates (EBCT of 3 minutes based on combined cation and anion resin volume). Potassium chloride proved to be superior to NaCl for radium elution from the softener in cyclic operation (Clifford and Zhang, 1994). The use of KCl, although typically triple the price of NaCl, should be considered for the additional health reason that potassium is preferable to sodium as an exchanging ion.

Perchlorate Removal by Anion Exchange

Perchlorate residual from ammonium perchlorate used in rocket fuel and explosives has contaminated U.S. water supplies serving more than 20 million people in 22 states. Perchlorate interferes with the proper operation of the thyroid gland, and a number of health-effect studies have been undertaken to establish the basis of an MCL for perchlorate. Currently, the USEPA has established a health reference level of 15 $\mu\text{g/L}$, and Massachusetts and California have perchlorate MCLs of 2 and 6 $\mu\text{g/L}$, respectively. Nitrate, oxidized from ammonium ion, typically is found as a cocontaminant with perchlorate; thus effective treatment technologies often will have to deal with perchlorate and nitrate. Although perchlorate can be removed from drinking water supplies by biological treatment (Kim and Logan, 2001), IX is usually the process of choice because most anion resins have a high to extremely high preference for the hydrophobic perchlorate oxyanion (Tripp and Clifford, 2006). See Chaps. 1 and 2 for additional information on regulations and health effects.

Factors Affecting Perchlorate Resin Selection. Tripp and Clifford (2006) conducted a laboratory study of 15 different SBA resins to relate resin properties to perchlorate/chloride selectivity ($\alpha_{\text{ClO}_4/\text{Cl}}$) and then input the selectivity data into computer programs to aid in process design and selection. They found that the $\alpha_{\text{ClO}_4/\text{Cl}}$ values varied from 5 to more than 1300, and they sorted the resins into three groups. Group 1 included polyacrylic resins with low perchlorate selectivity ($\alpha_{\text{ClO}_4/\text{Cl}} = 5\text{--}10$) and a preference order of sulfate > perchlorate > nitrate; group 2 included typical polystyrene resins with high perchlorate selectivity ($\alpha_{\text{ClO}_4/\text{Cl}} = 80\text{--}170$) and a preference order of perchlorate > sulfate > nitrate; group 3 included nitrate-selective resins and other resins with extremely high perchlorate selectivity ($\alpha_{\text{ClO}_4/\text{Cl}} = 600\text{--}1300$) and a preference order of perchlorate \gg nitrate > sulfate. Group 2 and 3 resins were sensitive to temperature, with $\alpha_{\text{ClO}_4/\text{Cl}}$ values decreasing about 30 percent for each 20°C increase in temperature. Thus these resins could be regenerated more easily at elevated temperatures in the range of 40 to 60°C (Tripp and Clifford, 2006). As with all contaminants, the background ions, particularly sulfate and nitrate, can reduce the perchlorate run lengths significantly. Thus the concentrations of these background ions must be carefully considered during process selection.

Perchlorate IX Process Considerations. Given these large variations in selectivity among resins, several possible options are available for perchlorate removal depending on the background concentrations of sulfate and nitrate in the water and the availability disposal options for regenerant brine. For water with less than 250 mg/L sulfate and a convenient source for brine disposal, the recommended treatment process would use a polyacrylic gel resin (group 1) with low perchlorate selectivity operated with countercurrent 6% NaCl regeneration at a level of 320 kg NaCl/m³ or more (≥ 20 lb NaCl/ft³) at ambient temperature. The run would be terminated at or before nitrate breakthrough. If

spent regenerant disposal is not available, the brine could be treated biologically to remove perchlorate and reused, as demonstrated in the bench- and pilot-scale sequencing batch reactor studies of Liu and colleagues (2007) and Lehman and colleagues (2007). Fluidized-bed reactors for perchlorate destruction in brine were successful, too, but proved to be more challenging to operate (Patel et al., 2008; Lehman et al., 2008). By destroying the perchlorate and nitrate in the spent brine, this available chloride salt can be recycled and used for many more regeneration cycles, which can decrease the amount of salt required for regeneration and the perchlorate-laden brine for disposal significantly.

For perchlorate-contaminated water containing sulfate less than 500 mg/L, $\text{NO}_3\text{-N}$ less than 5 mg/L, and readily available brine disposal, a polystyrene resin (group 2 with $\alpha_{\text{ClO}_4/\text{Cl}} = 80\text{--}120$) operated with 6 percent NaCl countercurrent regeneration at a level of 320 kg NaCl/m³ or more (≥ 20 lb NaCl/ft³) at 50 to 60°C might be selected. The process would be operated to sulfate breakthrough, which is often well beyond nitrate breakthrough.

For a similar water (sulfate < 500 mg/L, $\text{NO}_3\text{-N}$ < 5 mg/L) and no good option for brine disposal, the single use of highly perchlorate-selective resins (group 3, $\alpha_{\text{ClO}_4/\text{Cl}} > 600$) could be considered. This would require a careful evaluation of the cost of brine disposal versus the cost of highly perchlorate-selective resin. As raw water sulfate concentrations increase, however, the effective run length of the highly perchlorate-selective resin is decreased, diminishing the economic benefits of using this resin type. The highly perchlorate-selective resin typically would be operated as roughing-polishing columns in series with the roughing (lead) column run to nearly complete perchlorate exhaustion. The exhausted resin would be removed for regeneration at a central facility or disposed of and replaced with fresh resin. The one-time use of highly perchlorate-selective resins in waters that also require treatment for nitrate removal is not recommended because such resins cannot be run past nitrate breakthrough. Even though nitrate breakthrough for highly perchlorate-selective resins occurs later than for conventional sulfate-selective resins, the nitrate run length will be only a small fraction of that to perchlorate breakthrough.

Despite potential problems with shortened run length owing to nitrate and sulfate concentrations, the most common solutions to perchlorate contamination problems in California have been single-use IX systems. Aldridge and colleagues (2004b) estimated that for typical California waters contaminated with perchlorate ($\text{ClO}_4^- < 20$ µg/L, $\text{SO}_4^{2-} < 40$ mg/L, $\text{NO}_3\text{-N} < 9$ mg/L, $\text{Cl}^- < 30$ mg/L, and $\text{HCO}_3^- < 250$ mg/L), single-use systems would be more economical than chloride IX with regeneration. At that time, there were 17 full-scale systems in California with a total capacity of more than 60 mgd. Since then, additional perchlorate-selective resins have come onto the market with even greater effectiveness and economy.

IX MODELING USING EMCT

IX modeling can be a useful tool for researchers and practitioners because it allows for the rapid desktop screening of a number of IX resins and water qualities for a given application. The following discussion shows how IX modeling can help users during resin selection understand the influence (or sometimes noninfluence) of anion resin separation factors (α_{ij} values) and the influence of water quality constituents on contaminant run length.

Exhaustion or Breakthrough Curves and Resin Profile

With respect to the exchange of bicarbonate, nitrate, and sulfate on an SBA exchange resin, as shown in Fig. 12-10b, the following chromatographic characteristics that govern IX may be enumerated.

Resin Profile Characteristics

1. For n components, there will be n zones in the resin phase.
2. Each zone begins and ends with a wavefront and acts as an "affinity cut," with one species disappearing across the wavefront. For example, the sulfate-rich zone shown in Fig. 12-10*b* contains all n components. Sulfate, the most preferred anion or the anion with the greatest affinity for the resin, disappears across the wavefront that divides the sulfate- and nitrate-rich zones. Thus there is no sulfate in the nitrate-rich zone. Similarly, there is no sulfate or nitrate in the bicarbonate-rich zone. The chloride zone contains only chloride, the presaturant ion.

Effluent History Characteristics

1. The total effluent concentration of ions (meq/L) remains constant and is equal to the total feed concentration of ions.
2. A decrease in concentration of one ion is always accompanied by an increase in the concentration of another ion in the effluent. For example, in Fig. 12-10*b*, it can be seen that as chloride concentration decreases at the beginning of an exhaustion cycle, the bicarbonate concentration in the effluent increases.
3. The ion with the lowest affinity (bicarbonate in Fig. 12-10*b*) is the first to appear in the effluent (not including chloride, the presaturant ion), followed by the more preferred anions. That is, the order of appearance of ions in solution is the reverse of the selectivity sequence (described again below). The presaturant anion, chloride, is always present in the effluent.
4. For a system with n ions, $n - 1$ ions will undergo chromatographic peaking. That is, the effluent concentration will exceed its influent concentration. In Fig. 12-10*b*, bicarbonate peaks first, followed by nitrate. The most preferred anion, sulfate, does not peak, but its effluent concentration rises to equal its feed concentration.

The model used in the IX simulations described in this section is based on the equilibrium multicomponent chromatography theory (EMCT) developed by Helfferich and Klein (1970). Horng (1983) and Tirupanangadu (1996) used EMCT to develop a PC-based simulator, hereafter referred to simply as the *EMCT model*, to simulate IX processes. *Note:* This model is available by writing to D. Clifford at the University of Houston CEE Department (daclifford@uh.edu). Assumptions inherent in the EMCT model are listed below.

1. The resin column is assumed to be of uniform cross section, uniformly packed, and exhibits plug-flow behavior.
2. Instantaneous equilibrium is assumed between the exchanging species; that is, there are no mass transfer limitations. Of course, instantaneous equilibrium is not achieved, but simple mass transfer correction factors may be applied, as will be explained later.
3. Constant binary separation factors α_{ij} are assumed.
4. The resin is uniformly presaturated; that is, the entire resin bed has the same single- or multicomponent anionic composition.
5. The feed water composition and resin capacity are constant.

The mathematic basis for multicomponent equilibrium modeling is described in detail in Helfferich and Klein (1970) and summarized by Clifford (1982).

Selectivity Sequence. The order of preference that an anion has over the resin phase was explained earlier and depends on the ionic strength of the aqueous phase and the

chemical structure of the resin. For SBA exchangers in dilute solution (ionic strength range of 0.005–0.015 M), the following order of preference may be obtained from Table 12-3:

For specialty resins, this sequence changes. For example, the conventional order of preference of divalent over monovalent ions is reversed, and anions such as nitrate and perchlorate are more preferred over divalent ions such as sulfate. For such nitrate-over-sulfate-selective (NSS) resins, the following order of preference may be used:

Modeling Arsenic Removal on SBA Resins

Ghurye (2003) undertook an experimental and modeling study to determine the influence of various resin parameters (capacity and anion separation factors) on arsenic run length. Based on EMCT modeling, that study concluded that anion separation factors (including that of arsenic) had little to no influence on arsenic run length. This finding was nonintuitive, but an examination of the resin profile generated by the EMCT model showed that the arsenic-rich zone was extremely small, comprising less than 0.1 percent of total resin sites. Therefore, although an increase in arsenic separation factor increased the fraction of arsenic in the arsenic-rich zone, it did not change the run length to arsenic breakthrough significantly. The conclusion was that the best resin for trace species arsenic removal is the resin with the highest exchange capacity (eq/L). Use of the EMCT model for modeling exhaustion and the resin profiles obtained from EMCT thus provided an insight into a nonintuitive finding and helped to develop a simple rule for resin selection for trace species arsenic removal: Choose a conventional polystyrene, sulfate-selective SBA exchange resin with the highest exchange capacity.

In addition to understanding the relative influence of anion separation factors on the removal of trace species such as arsenic, EMCT modeling also can help to determine the influence of background ions on contaminant run length. For example, while using the NSF International–recommended challenge water quality for arsenic as a baseline, the relative influence of the concentration of commonly co-occurring anions such as bicarbonate, chloride, nitrate, arsenic, and sulfate was modeled using the EMCT model (Fig. 12-32). The

FIGURE 12-32 Influence of water quality on arsenic run lengths using the NSF International challenge water quality as a baseline.

relative impact of increasing anion concentration is greatest for sulfate because sulfate is the common anion most preferred by conventional SBA resins.

Modeling Nitrate Removal: Comparing Conventional Resins with Nitrate-Selective Resins

Based on the work of Clifford and Weber (1978), which showed that sulfate was preferred by resins with closely spaced exchange sites and that nitrate was preferred by hydrophobic resins, NSS resins were developed by Guter (1982), who introduced triethyl, tripropyl, and tributyl functional groups in place of the usual trimethyl group in type 1 resins. These bulkier and more hydrophobic functional groups exhibit much greater affinity for hydrophobic monovalent anions such as nitrate and perchlorate. However, the introduction of bulkier functional groups also reduces resin exchange capacity. For example, type 1 resin capacities range from 0.8 to 1.2 eq/L, and type 2 resins can have exchange capacities as high as 1.4 eq/L, whereas typical tributyl resin capacities are in the 0.8 to 0.85 eq/L range. The following discussion shows how IX modeling can be used to rapidly perform a desktop comparison of these resins for a nitrate-removal application. Note that for comparison, an acrylic resin with high sulfate selectivity but low nitrate selectivity is included in the modeling effort.

For the resins listed in Table 12-15 and using the Glendale water quality (Table 12-16) as a baseline, nitrate run lengths (for three different resins) were modeled as a function of sulfate concentration (Fig. 12-33). Note that caution is required when attempting to determine the influence of concentration simply by increasing the concentration of an anion. For example, Guter (1982) noted that the sulfate selectivity sequence for conventional resins was reversed at an ionic strength of 0.02 M. Clifford and colleagues (1987) experimentally determined selectivity reversal to occur at 0.03 M for nitrate removal on SBA resins in their Glendale study. In the modeling effort shown in Fig. 12-33, the maximum ionic strength modeled was 0.0163 M. Since this was less than the ionic strength reported to cause selectivity reversal by Guter (1982) and Clifford (1987), no attempt was made to keep the total ionic strength of the solution constant by proportionately reducing the concentration of the other anions (such as bicarbonate and chloride). The reason for choosing sulfate concentration as a variable was that the Glendale study (Clifford et al., 1987) found a significant reduction in nitrate run length with increasing sulfate concentration for conventional sulfate-selective (type 1 and type 2 SBA) resins.

TABLE 12-15 Input Parameters for EMCT IX Modeling

	Resin 1 (type 1) nitrate-selective NSS	Resin 2 (type 2) sulfate-selective CSS	Resin 3 (polyacrylic) sulfate-selective CSS
Matrix	STY-DVB	STY-DVB	Polyacrylic
Selectivity	Nitrate/Perchlorate	Sulfate	Sulfate
Functional group	Tributylamine	Dimethylethanol-amine	Trimethylamine
Capacity, meq/mL	0.85	1.40	1.20
Separation factors ^a

TABLE 12-16 Water Qualities for Model Simulations

Anion	Arsenic removal, NSF Intl. challenge water	Nitrate removal, glendale study ^a	Perchlorate removal, big dalton ^b
Bicarbonate, mg/L	183	124	122
Chloride, mg/L	71	122	30
Nitrate-N, mg/L	2	19.2	6
Arsenic, mg/L	0.05	NA	NA
Sulfate, mg/L	50	42.5	50
Perchlorate, mg/L	NA	NA	0.05

^aClifford et al., 1987.^bTripp et al., 2003.**FIGURE 12-33** Influence of sulfate concentration on nitrate run length for three resins (Glendale water).

The polyacrylic resin, by virtue of its hydrophilic nature and low nitrate-chloride separation factor (1.79 versus 11 for a nitrate-selective resin; see Table 12-15) underperforms both the type 2 CSS resin and the NSS resin. The type 2 resin, although possessing a lower nitrate-chloride separation factor (3.09 versus 11 for the nitrate-selective resin), performs nearly the same as the nitrate-selective resin because of the type 2 resin's much higher capacity (1.4 versus 0.85 meq/mL for the nitrate-selective resins).

It has been observed that CSS resins are much more easily regenerated than NSS resins owing to the fact that nitrate is a monovalent ion and is not subject to selectivity reversal at high ionic strength during regeneration. To illustrate how EMCT modeling can be used to model regeneration, an NSS (resin 1) and a CSS (resin 2) resin were used for modeling as follows: At nitrate breakthrough, the NSS resin comprises a single nitrate-rich zone. The fraction of resin sites in this zone was obtained from the resin profile provided by the EMCT model for the NS resin exhausted with Glendale water. However, for a CSS resin at nitrate breakthrough, the resin comprises a sulfate-rich zone and a nitrate-rich zone. As noted earlier, the EMCT model assumes uniform presaturation and cannot accept such multiple zones as an initial condition prior to regeneration. To simplify this problem, a mass balance on all four anions (Glendale water; Table 12-16) was used to determine the size of the sulfate- and nitrate-rich zones. Using this information and the resin profile provided by

FIGURE 12-34 Nitrate elution (regeneration) from an SS and NS resin with 1.0 M NaCl.

the EMCT model, a uniform presaturation assumption was made by compositing the anion concentration across the entire resin bed. The regeneration results are shown in Fig. 12-34, which shows that about twice as much chloride is required for complete elution of nitrate from the NSS resin than is required for the CSS resin. Note that an earlier modeling study by us (Ghurye and Clifford, 2008) using an IX model that does not require uniform presaturation prior to regeneration showed similar results in terms of salt usage. Thus, with the aid of EMCT modeling, it can be seen that under certain conditions of groundwater quality, it actually may be more advantageous to use a CSS resin despite its lower selectivity for nitrate.

Modeling Perchlorate Removal: Comparing Conventional Resins with Nitrate-Selective Resins

Previous research has shown that hydrophobic resins have much greater capacity for perchlorate removal, but owing to the lack of selectivity reversal during regeneration, hydrophobic resins are extremely difficult to regenerate because of their very high perchlorate selectivity (Tripp et al., 2003). Therefore, perchlorate IX in a single-use application is increasingly the treatment technique of choice (Siedel et al., 2006). Single-use application is favored by the fact that perchlorate separation factors can be very high on hydrophobic resins. For example, Tripp (2003) reported a perchlorate/chloride separation factor of 1300 for a tripropylamine resin. In comparison, the separation factors for bicarbonate, sulfate, and nitrate over chloride were 0.2, 4, and 11, respectively.

Perchlorate is the most preferred anion on hydrophobic resins. Therefore, at breakthrough, the perchlorate zone comprises the entire resin bed, and even small increases in the fraction of resin sites occupied by perchlorate as a result of increasing perchlorate selectivity lead to large increases in perchlorate run length. To illustrate the importance of perchlorate selectivity for single-use applications, the results of an EMCT modeling exercise based on Big Dalton groundwater composition, shown in Table 12-16, are shown in Fig. 12-35. In this exercise, the perchlorate separation factor was varied from 100 (polystyrene type 1 resin) to 3600 (highly perchlorate-selective resin) for varying feed perchlorate concentrations from 10 to 500 $\mu\text{g/L}$. Unlike the case of arsenic, perchlorate run lengths can be seen to increase substantially with increasing perchlorate separation factor, with run lengths approaching 300,000 BV for a feed perchlorate concentration of 10 $\mu\text{g/L}$.

FIGURE 12-35 Influence of perchlorate separation factor on run length for feed perchlorate concentrations in the range of 10 to 500 µg/L (Big Dalton water).

As noted earlier, IX modeling is also a useful tool to determine the impact of various water qualities on contaminant run length. Using Big Dalton groundwater quality as the baseline, hydrophobic perchlorate-selective resin was modeled by varying the concentration of bicarbonate, chloride, or sulfate while holding the perchlorate concentration constant at 0.05 mg/L. The results are shown in Fig. 12-36, where it can be seen that increasing concentrations of all the background ions shortens perchlorate run length, but nitrate has the most significant impact, and bicarbonate has almost no effect.

FIGURE 12-36 Modeling the influence of common groundwater anions on perchlorate run length on a hydrophobic resin with perchlorate-chloride separation factor of 1000 (Big Dalton water quality as baseline).

EMCT Correction Factor. It should be noted that contaminant breakthroughs using EMCT model simulations are ideal and appear as square, “self-sharpening” wavefronts for ions that have higher preference for the resin than the presaturant ion (typically chloride). EMCT modeling provides the run length to complete breakthrough without taking into effect mass transfer limitations. Real mass transfer–limited breakthrough curves are

S-shaped, and for anions such as perchlorate, the breakthroughs can last tens of thousands of bed volumes. Further, actual run lengths are decided by the MCL or chosen maximum allowable effluent concentration for a given contaminant, which is generally much lower than the influent concentration.

For example, the breakthrough of nitrate on a type 2 resin is shown in Fig. 12-37. The influent $\text{NO}_3\text{-N}$ concentration is 24 mg/L, whereas the MCL is 10 mg/L $\text{NO}_3\text{-N}$. The EMCT model-predicted run length for nitrate is a sharp wavefront at 356 BV. However, actual breakthrough

FIGURE 12-37 Use of correction factor for nitrate breakthrough.

is mass transfer-limited and follows an S-shaped curve. Because nitrate is not the most preferred anion, it chromatographically peaks over its influent concentration and then decreases to eventually equal its influent concentration. Major breakthrough for the actual S-shaped curve is estimated as the inflection point of the ascending exhaustion curve (shown by a solid line) and projecting that midpoint on the x axis. The point of major breakthrough thus is estimated as 335 BV, an error of 6 percent. This error may be caused by a number of factors, including errors in estimating separation factors for any of the major ions such as nitrate and sulfate and errors in reported or measured resin capacity, channeling, resin fouling, and fluctuations in both flow rate and anion composition during the course of an exhaustion run. The actual run length termination is user-defined. For the nitrate example shown in Fig. 12-37, the run length may be defined as that point in the exhaustion curve where the effluent concentration first exceeds the nitrate MCL of 10 mg/L as $\text{NO}_3\text{-N}$ or some fraction (typically 70%–90%) of the MCL. Therefore, the actual run length to 10 mg/L $\text{NO}_3\text{-N}$ is 300 BV, an error of 16 percent. Thus the EMCT prediction has to be corrected for the user-chosen effluent concentration set point (the MCL or some fraction thereof) that signals run termination. Generally, the greater the difference between the influent concentration of a contaminant and the set-point concentration that terminates a run, the greater is the correction factor that needs to be used to estimate run length from EMCT predictions.

Figure 12-38 shows a similar example but for perchlorate, which generally exhibits prolonged breakthrough on perchlorate-selective resins owing to resin-phase mass transfer limitations for perchlorate in these very hydrophobic resins (Tripp, 2001; Tripp et al., 2004). Note that perchlorate is the most preferred anion on a hydrophobic resin and does not peak chromatographically over its influent but approaches its influent concentration as the resin approaches exhaustion. The EMCT model-predicted run length for an influent perchlorate concentration of 500 $\mu\text{g/L}$ is 69,000 BV, whereas the midpoint of the ascending exhaustion curve is 54,000 BV (22% error), and the run length to 15 ppb ($\mu\text{g/L}$) effluent perchlorate concentration is 32,500 BV (error of 53%). As noted earlier, the greater the

FIGURE 12-38 Use of correction factor for perchlorate breakthrough.

difference between the feed concentration and the run length set point, greater is the correction factor that needs to be used for the EMCT prediction. In practice, the resin bed in the preceding example can be run to complete perchlorate exhaustion by using a two-bed roughing-polishing sequence.

Generally, for arsenic concentrations in the range of 0 to 100 $\mu\text{g/L}$, nitrate concentrations in the range of 0 to 40 mg/L as $\text{NO}_3\text{-N}$ and perchlorate concentrations in the range of 0 to 100 $\mu\text{g/L}$, recommended correction factors are 20, 10, and 35 percent, respectively.

WASTE DISPOSAL

To the extent possible, waste disposal considerations have been covered in the discussions of each contaminant-removal process. The focus has been on the design of processes that minimize regenerant use and on the reuse of spent regenerant to maximize the ratio of product water to spent regenerant for final disposal. Further explanations of how to deal with process residues are given in Chap. 22.

SUMMARY

In the first part of the chapter, the fundamentals of IX and ion adsorption processes were explained with the goal of demonstrating how these principles influence process design for inorganic contaminant removal. In the second part, IX and ion adsorption processes for the removal of hardness, barium, radium, nitrate, fluoride, arsenic, DOC, uranium, and perchlorate were described in detail. In the third part of the chapter, IX modeling using equilibrium multi-component chromatography theory with constant separation factors (EMCT/CSF) was covered. Because the selection of a process for removal of a given contaminant can be confusing owing to the many variables to be considered, summary Tables 12-17 and 12-18 have been added to aid the reader in process selection. However, the reader should refer back to the discussion of fundamentals and process alternatives to answer questions arising from the tables.

TABLE 12-17 Summary of Processes for Removing Inorganic Cations

Contaminant and its MCL	Usual form at pH 7–8	Removal options	Typical BV to MCL ^a	Pretreatment required	Typical regenerants and % recovery of sorbed contaminant	Effect of TDS on BV	Effect of hardness on BV	Notes
Hardness (no MCL)	Ca ²⁺	Na IX softening with SAC resin	200–700	Iron/Mn removal	6%–12% NaCl 90–100% recovery	Very signif. reduction		1–3
	Mg ²⁺	H ⁺ IX softening with WAC resin	200–500	None	1–2 N HCl or H ₂ SO ₄	Very signif. reduction		4–6
Barium, 1.0 mg/L	Ba ²⁺	Na IX softening with SAC resin	200–700	Iron/Mn removal	1%–12% NaCl 70%–100%	Very signif. reduction	Very signif. reduction	1–3 7, 8
Radium, 5 pCi/L	Ra ²⁺	Na IX softening with SAC resin	200–700	Iron/Mn removal	6%–12% NaCl 0%–100% recovery	Very signif. reduction	Very. signif. reduction	1–3, 9–12, 20
		Ca IX with SAC resin	300–1500	Iron/Mn removal	10%–15% CaCl ₂ 50%–100% recovery	Slight reduction	Slight reduction	12–16, 20
		Dow radium-selective complexer	20,000–50,000	Iron/Mn removal	Not regenerable	Slight reduction	Slight reduction	12, 17–19
		BaSO ₄ -impregnated alumina	20,000–50,000	Iron/Mn removal	Not regenerable	Slight reduction	Slight reduction	12, 17–19
		Activated alumina	1000–3000	Iron/Mn removal	2% HCl followed by 1% NaOH 70%–100% recovery	None	Slight reduction	12, 20

^aGenerally, run length depends on raw water contaminant concentration, allowable effluent concentration, competing ions, leakage, and the actual resin or adsorbent used.

1. Hardness capacity depends on regeneration level (lb NaCl/ft³ of resin).
2. Typically, spent regenerant is disposed of to sanitary sewer.
3. Iron and/or Mn removal by oxidation and filtration should be considered if total Fe_{tot} > 0.3 mg/L, Mn > 0.05 mg/L.
4. Only carbonate (temporary) hardness can be removed using WAC resins.
5. Carbon dioxide produced in the IX reaction must be removed from product water, and pH adjustment may be necessary.
6. TDS reduction occurs as a result of removing both the hardness and alkalinity.
7. Barium tends to build up on the resin and break through with hardness when insufficient regenerant is used.

(Continued)

TABLE 12-17 Summary of Processes for Removing Inorganic Cations (*Continued*)

-
8. If necessary, BaSO_4 can be precipitated from the spent regenerant by adding sulfate.
 9. With a virgin resin, radium breaks through long after hardness, but in cyclic operation, they eventually elute simultaneously.
 10. Even though radium accumulates on the resin, no leakage of radium occurs before hardness breakthrough.
 11. Current disposal practices allow the discharge of radium-contaminated spent regenerant to the sanitary sewer.
 12. Radon-222 is continuously generated from the radium-226 on the resin. Radon elution peaks can occur after idle periods.
 13. With Ca IX, immediate serious radium leakage occurs if extensive countercurrent regeneration is not used.
 14. CaCl_2 is much more expensive than NaCl as a regenerant.
 15. A process advantage is that sodium is not added to the product water.
 16. No softening is achieved in the calcium exchange process, and magnesium is exchanged for calcium.
 17. Radon generation is more serious with RSC and BaSO_4 -alumina because of the large amount of radium on the medium.
 18. Disposal of the spent medium is a serious problem because it is considered a low-level radioactive waste.
 19. RSC and BaSO_4 -alumina may have limited application owing to availability and rad-waste disposal problems.
 20. Spent regenerant disposal may be a problem if sanitary sewer disposal is not allowed.

TABLE 12-18 Summary of Processes for Removing Inorganic Anions

Contaminant and its MCL	Usual Form at pH 7–8	Removal Options	Typical BV to MCL ^a	Pretreatment Required	Typical Regenerants and % Recovery of Sorbed Contaminant	Effect of TDS on Run BV	Effect of SO ₄ ²⁻ on Run BV	Notes
Fluoride, 4.0 mg/L	F ⁻	Activated alumina	1000–2500	pH = 5.5–6.0	1% NaOH followed by 2% H ₂ SO ₄ 90%–100% recovery	None	Slight reduction	
Nitrate-N, 10 mg/L	NO ₃ ⁻	Anion exchange (complete regeneration)	300–600	Usually none	0.25–2.0 N NaCl (1.5%–12% NaCl) 90–100% recovery	Very signif. reduction	Very signif. reduction	1, 2
		Anion exchange (partial regeneration)	200–500	Usually none	1.0–2.0 N NaCl (6.0%–12% NaCl) 50% recovery	Very signif. reduction	Very signif. reduction	1, 3, 4
Arsenic, 0.010 mg/L	HAsO ₄ ²⁻ As(V)	GFO or GFH Adsorption	3000–70,000	pH = 5.5–6.5 Oxidize As(III) to As(V)	GFO and GFH usually not regenerated	None	None	5–8
		Anion exchange	1000–5000	Oxidize and prefilter to remove iron	1.0 N NaCl >95% recovery	Very signif. reduction	Very signif. reduction	1, 5, 9–11
Chromium, 0.10 mg/L	CrO ₄ ²⁻	Anion exchange	10,000–50,000	None	1.0 N NaCl 60%–90% recovery	Slight reduction	Slight reduction	12–14
DOC	Fulvates	Anion exchange	400–5000	Prefiltration for turbidity	Mixture of 2.0 N NaCl and 0.5 N NaOH	Very signif.	Very signif.	15–17
Uranium, 20 µg/L	UO ₂ (CO ₃) ₃ ⁴⁻	Anion exchange	30,000–300,000	Prefiltration for turbidity	2–4 N NaCl 60%–90% recovery	Slight reduction	Signif.	18
Perchlorate	ClO ₄ ⁻	Anion exchange	400–50,000	Prefiltration for turbidity	0.5–3 N NaCl 0%–90% recovery	Slight reduction	Very. signif. reduction	19, 20

^aGenerally, run length depends on raw water contaminant concentration, allowable effluent concentration, competing ions, leakage, and the actual resin or adsorbent used.

1. Chromatographic peaking of contaminant is possible after breakthrough.
2. No significant leakage of nitrate occurs prior to breakthrough.

(Continued)

TABLE 12-18 Summary of Processes for Removing Inorganic Anions (*Continued*)

3. Continuous significant (>5 mg/L) leakage of nitrate occurs following partial regeneration during all runs
4. Resin must be mixed mechanically following partial regeneration to avoid excessive early nitrate leakage.
5. As(III) should be oxidized to As(V) prior to adsorption and must be oxidized prior to anion exchange.
6. If pH is not lowered into 5.5–6.5 range, adsorption run lengths to arsenic breakthrough will be shorter.
7. Regeneration of GFO or GFH using NaOH and H₂SO₄ is possible and is under further study.
8. Silicate, phosphate, and vanadate anions compete with As(V) for adsorption.
9. IX capacity may decrease following each exhaustion/regeneration cycle owing to organic or particle fouling of resin.
10. Chloride-form anion exchange can be the process of choice for low-sulfate (<50 mg/L) and low-TDS (<500 mg/L) water.
11. As(V) can be coprecipitated from spent regenerant using ferric sulfate or alum.
12. Cr(III) can be precipitated from the spent regenerant after reduction with ferrous sulfate or acidic sodium sulfite.
13. Macroporous resins and polystyrene resins have a higher preference for chromate than gel and acrylic resins.
14. Resins with higher chromate affinity are relatively more difficult to regenerate.
15. DOC has no MCL. Major DOC breakthrough and peaking occur just ahead of sulfate breakthrough. Typical DOC removals are 60%–80% before and 40%–60% after sulfate breakthrough. Highly colored waters should be prefiltered.
16. Direct reuse of spent regenerants for DOC removal by IX is possible if chloride and hydroxide concentrations are maintained. It is not necessary to remove DOC from spent regenerants before reuse.
17. Polyacrylic resins swell more than polystyrene resins in water and consequently are more suited to removal of large organic anions. Furthermore, polyacrylic resins are less subject to organic fouling than polystyrene resins.
18. All SBA resins have an extremely high affinity for uranyl tricarbonate anions. For cyclic operations, shortened run lengths in the range of 30,000–50,000 BV are suggested. Higher regenerant concentrations are more efficient.
19. Polystyrene resins have a much higher perchlorate affinity than polyacrylic resins, which are used in cyclic exhaustion/regeneration processes for perchlorate removal, typically achieving 400–600 BV runs. High salt (NaCl) consumption and perchlorate-contaminated brine disposal are major problems.
20. Single-use, high-perchlorate-selectivity SBA resins, for example, STY-DVB resins with tributyl functionality, may achieve run lengths exceeding 50,000 BV and are reportedly more cost-effective than regenerable polyacrylic resins.
21. STY-DVB weak-base anion resins also may be used for perchlorate removal if pH is lowered to less than 4.5. Posttreatment to strip CO₂ and raise pH using NaOH is necessary. The process is reportedly less costly than NaCl regeneration of SBA resin.

ABBREVIATIONS

A-7	phenol formaldehyde polyamine WBA resin, Dow-Rohm and Haas
AA	activated alumina
AAFS 50	iron(III)-modified activated alumina available from Alcan Corp.
ADI G2	iron(III)-modified diatomaceous earth available from AGI, Inc.
ALOOH	aluminum oxyhydroxide adsorbent solid
Alumina-HCl	activated alumina treated with HCl to protonate the surface
Alumina-HOH	activated alumina in neutral water-washed form
APHA	American Public Health Association
ArsenX	iron(III)-modified anion exchange resin available from Purolite, Inc.
As(III)	arsenic in the +3 oxidation state
As(Tot)	As(III) + As(V)
As(V)	arsenic in the +5 oxidation state
ASB2	Ionac ASB2 STY-DVB type 2 SBA resin available from Beyer-Sybron
BV	bed volume, volume of feed water = volume of media including voids
CSF	constant separation factor
CSS	conventional sulfate selective; also referred to simply as sulfate selective
DBP	disinfection by-product
DM	demineralization
DOC	dissolved organic carbon
Dowex 21K	STY-DVB type 1 gel SBA resin available from Dow Chemical Co.
EBCT	empty-bed contact time, minutes
EMCT	equilibrium multicomponent chromatography theory
EP	extraction procedure test (predecessor to TCLP test)
eq	gram equivalent, Avogadro's number of charges
FBR	fluidized-bed reactor
FeOOH	iron(III) oxyhydroxide adsorbent solid
GAC	granular activated carbon
Gel	standard-porosity IX resin, typically 8 percent DVB cross-linking
GFH	granular ferric hydroxide adsorbent, available from Siemens, Inc.
GFO	granular ferric oxide adsorbent, available from Severn Trent Services
gr	grain, unit of mass; 15.43 gr = 1.00 g
HRT	hydraulic retention time
IOCs	inorganic chemicals
Ionac A 641	STY-DVB type 1 gel SBA resin available from Lanxess
IonacA-642	STY-DVB macroporous type 1 SBA resin available from Lanxess
Ionac SR7	NSS STY-DVB SBA resin with tripropyl functional groups, available from Lanxess

IRA 404	STY-DVB SBA resin available from Dow-Rohm and Haas
IRA 458	polyacrylic SBA resin available from Dow-Rohm and Haas
IRA 958	polyacrylic macroporous SBA resin available from Dow-Rohm and Haas
IRA 996	NSS STY-DVB SBA resin with triethyl groups, available from Dow-Rohm and Haas
IX	ion exchange
kgr	kilograin, 1000 grains
M	molar, $\text{g} \cdot \text{mol/L}$
MCL	maximum contaminant level
meq	milliequivalent, 1/1000 of Avogadro's number of charges
mgd	millions of gallons per day flow rate
MnOOH	manganese oxyhydroxide adsorbent solid
MP 500 A	Lewatit macroporous type 1 STY-DVB SBA, Beyer Chemical Co.
MR	macroporous or macroreticular resin
N	normal, $\text{g} \cdot \text{eq/L}$
NOM	natural organic matter
NSS	nitrate over sulfate selective; also referred to simply as nitrate selective
pCi	picocuries (10^{-12} Ci)
POE	point of entry
POU	point of use
R ₃ N:	tertiary weak-base functional group in the free-base form
R ₄ N ⁺	quaternary functional group anion exchange site
RCOOH	weak-acid cation resin functional site in hydrogen form
RSSCT	rapid small-scale column test
SBA	strong-base anion
SBR	sequencing batch reactor
SFR	service flow rate or exhaustion rate = 1/EBCT, $\text{L/m}^3/\text{min}$, gpm/ft^3
SLV	superficial linear velocity, flow rate/area, cm/min , gpm/ft^2
SMCL	secondary maximum contaminant level
STY-DVB	polystyrene polymer cross-linked with divinylbenzene
TCLP	toxicity characteristic leaching procedure
TDS	total dissolved solids
THMFP	trihalomethane formation potential
TOC	total organic carbon in water
USEPA	U.S. Environmental Protection Agency
WAC	weak-acid cation
WBA	weak-base anion
ZPC	zero point of charge on an adsorbent surface

NOTATION FOR EQUATIONS

α_{ij}	separation factor of ion i with respect to j , dimensionless
$\alpha_{N/Cl}$	separation factor of nitrate with respect to chloride, dimensionless
BV_H	bed volumes of feed water treatment to hardness breakthrough
C	total concentration of ions, eq/L
C_B	concentration of contaminant in bypass water, eq/L
C_E	concentration of contaminant in column effluent, eq/L
f_F	fraction of feed water that must be treated
K_{ij}	selectivity coefficient of ion i with respect to j , variable units
n	number of exchanging species
Q	flow rate, L/min (gpm)
Q_B	bypass water flow rate, L/min (gpm)
Q_F	column feed flow rate, L/min (gpm)
q_H	hardness capacity of resin, eq/L
q_i	resin-phase equivalent concentration of ion i , eq/L
Q_P	blended product water flow rate, L/min (gpm)
t	time, h
t_{BW}	time required for backwash, h
t_{FR}	time required for fast rinse, h
t_H	time to hardness breakthrough, h
t_{os}	out-of-service time during backwashing regeneration and rinsing, h
t_R	time required for regeneration, h
t_{SR}	time required for slow rinse, h
v_0	approach velocity of mobile phase, m/h (gpm/ft ²)
V_F	volume of water fed to column prior to contaminant breakthrough, L, gal
V_R	volume of resin, m ³ (ft ³)
x_i	equivalent fraction of ion i in water, C_i/C , dimensionless
x_N	equivalent fraction of nitrate in water, C_N/C , dimensionless
y_i	equivalent fraction of species i in resin, q_i/q , dimensionless
y_N	equivalent fraction of nitrate in resin, q_N/q dimensionless
Q_F	column feed flow rate, L/min (gpm)
q_H	hardness capacity of resin, eq/L
q_i	resin-phase equivalent concentration of ion i , eq/L
Q_P	blended product water flow rate, L/min (gpm)
t	time, h
t_{BW}	time required for backwash, h
t_{FR}	time required for fast rinse, h
t_H	Time to hardness breakthrough, h
t_{os}	out-of-service time during backwashing regeneration and rinsing, h

t_R	time required for regeneration, h
t_{SR}	time required for slow rinse, h
v_0	approach velocity of mobile phase, m/h (gpm/ft ²)
V_F	volume water fed to column before contaminant breakthrough, L (gal)
V_R	volume of resin, m ³ (ft ³)
x_i	equivalent fraction of ion i in water, C_i/C , dimensionless
x_N	equivalent fraction of nitrate in water, C_N/C , dimensionless
y_i	equivalent fraction of species i in resin, q_i/q , dimensionless
y_N	equivalent fraction of nitrate in resin, q_N/q dimensionless

INTRODUCTION

Precipitation and coprecipitation provide a means of removing certain dissolved contaminants from solution by transforming or transferring them to a solid phase (particles) that can then be removed from solution using processes described in other chapters of this handbook, such as coagulation, flocculation, sedimentation, flotation, and filtration. Contaminants that can be effectively removed in this manner include calcium and magnesium ions (hardness); a portion of the *natural organic matter* (NOM) that reacts with disinfectants to form *disinfection by-products* (DBPs); a limited number of trace organic constituents; and various inorganic contaminants, especially metal ions.

This chapter begins with a discussion of the principles of precipitation and coprecipitation and then describes practical applications of these principles in drinking water treatment. The major focus of this chapter is on precipitative softening, which is employed at approximately 15 percent of water treatment plants in the United States. Other applications of precipitative processes are briefly summarized. Precipitation and coprecipitation are also involved in other processes addressed in this handbook, including coagulation with metal salts, which involves precipitation of aluminum and iron hydroxides and coprecipitation of various dissolved contaminants (Chap. 8); precipitation of iron and manganese after their dissolved forms have been oxidized (Chap. 7); and scale formation, which is important in filters (Chap. 10), membrane processes (Chap. 11), and distribution systems (Chap. 20).

PRINCIPLES

Precipitation

Precipitation occurs when dissolved constituents in a supersaturated solution interact to form a solid. The dissolved constituents and solids may be ionic or nonionic, but further discussion will be limited to those that are ionic, since precipitative processes are used in water treatment applications to remove ionic contaminants. An ionic contaminant can be removed if the concentration of another (oppositely charged) ion can be increased sufficiently to precipitate the contaminant ion out of solution, forming an ionic solid. It is also possible for ionic contaminants present in concentrations below the point of supersaturation to be removed by being incorporated into a precipitate formed by other ions. This process, known as *coprecipitation*, is described below. Treatment processes that remove contaminants by precipitation or coprecipitation are referred to as precipitative processes.

Precipitation of an ionic solid is both a physical and chemical process. It is commonly viewed as occurring in three stages, nucleation, crystal growth, and aging, in which ions in a supersaturated solution join together to form three-dimensional coordination compounds that develop into a solid phase. Coordination is the binding of a central atom (the cation in an ionic solid) by molecules (known as ligands) containing free pairs of electrons. Coordination is a fundamental phenomenon involved in complex formation, precipitation of ionic solids, chemisorption of ions, and coprecipitation. The ions that react to form an ionic solid (or crystal lattice) are referred to as the *lattice ions*; and other ions incorporated into an ionic solid by coprecipitation are referred to as *impurities*.

Nucleation is the coordination of lattice ions to form clusters (nuclei) of sufficiently large size that spontaneous deposition of additional lattice ions (crystal growth) can occur, which is possible only if the solution is supersaturated with respect to the solid being formed. Nucleation can occur through random collisions of lattice ions in solution (homogeneous nucleation) or through adsorption (accumulation at an interface) and nucleus formation on the surfaces of foreign particles (heterogeneous nucleation). Homogeneous and heterogeneous nucleation both require supersaturated solutions, but a higher degree of supersaturation is required for homogeneous nucleation. For this reason, and because foreign particles are present even in relatively clear water supplies, heterogeneous nucleation is expected to occur in precipitative drinking water treatment processes. But, if a high degree of supersaturation is achieved, for example, by adding a relatively large dose of lime or alum, then homogeneous nucleation may also occur.

Nucleation typically occurs instantly in highly supersaturated solutions. In solutions that are only slightly supersaturated, an extended period of time, referred to as an *induction period*, may pass before solids visibly appear. When precipitation is not desired, for example in the concentrate stream in a membrane process, the induction period can be extended,

perhaps indefinitely, by adding a chemical that interferes with nucleation or crystallization. Such chemicals, commonly referred to as *antiscalants* or *threshold inhibitors*, can adsorb onto nuclei or small crystals and interfere with adsorption of lattice ions, slowing or halting crystal growth. Solids formed in the presence of an antiscalant will contain antiscalant molecules as impurities; such impurities usually affect the properties of the solids, sometimes dramatically, and may interfere with options for their disposal, use, or reuse.

Crystallization involves (1) transport (diffusion) of lattice ions to the crystal-solution interface, (2) adsorption of lattice ions on the surface, and (3) incorporation of lattice ions into the lattice. Hence, the rate of crystallization can be diffusion controlled or interface controlled. For precipitation of $\text{CaCO}_3(\text{s})$ in a lime softening process, the reaction may be diffusion controlled during the initial moments of the reaction, for example, in the rapid mixing unit; but the reaction soon becomes interface controlled with the rate of crystallization being proportional to the degree of supersaturation. This can be expressed mathematically as follows:

$$\frac{d(\text{Ca}^{+2})}{dt} = -kS[(\{\text{Ca}^{2+}\} \times \{\text{CO}_3^{2-}\}) - K_{s0}] \quad (13-1)$$

where k = rate constant
 S = available surface area
 $\{\text{Ca}^{2+}\}$ = calcium ion activity
 $\{\text{CO}_3^{2-}\}$ = carbonate ion activity
 K_{s0} = solubility product constant for CaCO_3

Solids recirculation increases the surface area available for crystallization, favoring crystallization over nucleation. This results in the formation of larger particles, which may be of significant benefit if the solids are to be removed by sedimentation or if they will be dewatered prior to disposal or reuse.

Freshly precipitated ionic solids may be noncrystalline (amorphous) or microcrystalline (composed of crystals less than 1 or 2 μm in size), or they may consist of small crystallites in a polymorphous form. As such solids age, they tend to rearrange themselves so as to achieve a more satisfactory (stable) coordination status, forming larger, more well-formed, and less soluble crystals. Smaller, more soluble crystals may dissolve as larger crystals grow. This phenomenon is referred to as *Ostwald ripening* and results in a larger average particle size and a decrease in the total crystal surface area. For aging to occur, the crystals must remain in contact with the solution from which they were precipitated, referred to as the *mother liquor*. Some precipitates, such as calcite crystals composed of $\text{CaCO}_3(\text{s})$, age very rapidly, whereas others, such as magnesium, iron, and aluminum hydroxides, age extremely slowly and remain amorphous under water treatment conditions.

Factors influencing contaminant removal by precipitation include the concentration of the other ion forming the solid, the solubility of the solid formed, temperature, and the presence of species able to form complexes with the contaminant ion. For example, to remove a metal ion from solution, the ligand concentration must be high enough to induce precipitation, and the higher the ligand concentration remaining in solution, the lower the metal ion concentration will be at equilibrium. The solubility of many solids increases as water temperature increases, but there are notable exceptions, including $\text{CaCO}_3(\text{s})$. Complex formation increases the total solubility of a substance when the concentrations of the complexed species are included in the total.

Coprecipitation

Coprecipitation is the contamination of a precipitate by a substance that would otherwise have remained in solution had the precipitate not formed. Four mechanisms of coprecipitation

have been identified (Skoog and West, 1969), each involving adsorption of impurities during crystal growth.

1. *Surface adsorption*, whereby impurities are not incorporated into the crystal lattice but are adsorbed on the external surfaces of the crystals, for example, due to interactions with counter ions in the electrical double layer surrounding crystals having a surface charge
2. *Isomorphic inclusion*, also known as *inclusion* and as *mixed crystal formation*, in which impurities substitute for some of the lattice ions
3. *Nonisomorphic inclusion*, or *solid solution formation*, in which impurities appear to be dissolved in the precipitate and are not part of the crystal lattice
4. *Occlusion*, which occurs when impurities are adsorbed, then entrapped by growing crystals, creating crystal imperfections as they are covered over by lattice ions

Coprecipitation may greatly retard the rate of crystallization and can significantly influence crystal morphology (shape), structure, solubility, and surface properties.

Coprecipitation differs from postprecipitation, surface precipitation, and adsorption. Postprecipitation occurs when a second, more slowly precipitating substance precipitates on the surface of a previously formed precipitate. Postprecipitation is not considered coprecipitation because the solution must be supersaturated with respect to the second precipitate for postprecipitation to occur (Kolthoff, 1932; Skoog and West, 1969). Surface precipitation occurs when a substance adsorbs on a surface and accumulates to the extent that a precipitate forms on the surface (Benjamin, 2002). If a precipitate is formed and is later added to another solution, contaminants may adsorb onto the precipitate, but this is normally considered adsorption (Chap. 14) or ion exchange (Chap. 12) rather than coprecipitation.

If two distinct solid phases are precipitated simultaneously, it is possible for some of the ions associated with one precipitate to become incorporated into the other precipitate. For example, in the excess lime softening process, both $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$ are formed simultaneously. A small amount of Mg^{2+} would be expected to be incorporated into the rapidly precipitating $\text{CaCO}_3(\text{s})$. Since the solution is also supersaturated with respect to the Mg^{2+} ion, this would not fall within the classic definition of coprecipitation, but it should nevertheless be considered as coprecipitation.

Factors influencing the removal of contaminants by coprecipitation include

- *The rate of precipitation.* Crystals are purer when they grow more slowly.
- *The amount of precipitate formed.* Coprecipitation involves adsorption, and for crystals of a given size a larger mass of precipitate provides a larger surface on which adsorption can take place.
- *Time.* Crystal purity increases during the aging process and a coprecipitated contaminant can diffuse out of a precipitate over time, though the rate of diffusion may be negligible, e.g., for large molecules removed by occlusion.
- *Crystal size.* Contaminants diffuse more slowly out of larger crystals, but recirculating solids to grow larger crystals is expected to reduce contaminant removal because the crystals will remain in contact with the solution longer and will grow more slowly due to the increase in available surface area. For a given amount of solids, a smaller crystal size corresponds to a larger surface area, which will enhance contaminant removal by surface adsorption.
- *Crystal structure.* Contaminants diffuse more slowly out of well-crystallized solids, whereas a contaminant adsorbed on an amorphous solid is expected to be in equilibrium with the concentration of the contaminant in solution.
- *Crystal surface potential.* As an ionic solid precipitates, it may contain an excess of anions or cations due to differences in the initial lattice ion concentrations in solution,

or it may be positively or negatively charged due to the presence of certain potential determining ions, which typically include H^+ and OH^- . Contaminants having a charge opposite to that of the ion present in excess or to that of the crystal surface are expected to be preferentially adsorbed and coprecipitated.

- *The properties of the contaminant.* Adsorption of a contaminant on a growing crystal depends on the particular contaminant species actually present, its charge and degree of hydration, its ability to coordinate with one of the lattice ions, and its size relative to the lattice ions.
- *Complex formation.* Complexation can decrease coprecipitation by holding the contaminant in solution, and it can increase coprecipitation if the complex adsorbs more strongly to the solid than the uncomplexed contaminant.
- *pH.* The pH of the solution usually affects the charge and speciation of the contaminant, the surface charge of the solid (hence its ability to adsorb ionic impurities), and the behavior of complexing agents, so coprecipitation can be strongly pH dependent.
- *Temperature and ionic strength.* These factors influence the activity of the contaminant ion and can influence its adsorption on charged surfaces as well as the action of other factors listed.

Solubility Equilibria

To determine if a contaminant can potentially be removed by precipitation (or if removal is occurring by precipitation or coprecipitation) and to better understand the factors influencing contaminant removal by precipitation or coprecipitation, it is often helpful to examine solubility equilibria relevant to the contaminant of interest, to other ions present, and to various solids that may be formed under a given set of conditions. The basic concepts and nomenclature pertaining to chemical equilibria and to precipitation and dissolution of metal solids were introduced in Chap. 3.

The dissolution reaction for a sparingly soluble ionic solid may be expressed as

where A and B are the lattice ions and x and y are stoichiometric coefficients. This is similar in form to the dissolution reaction for metal solids shown in Chap. 3 with Eq. 3-35. The solubility product constant (K_{s0}) for the reaction shown in Eq. 13-2 is

$$K_{s0} = [A^{y+}]^x [B^{x-}]^y \quad (13-3)$$

where the square brackets indicate molar concentrations. Table 13-1 provides K_{s0} values for selected sparingly soluble ionic solids containing substances potentially relevant to water treatment or analysis.

In Eq. 13-3, activities must be used instead of molar concentrations to make accurate calculations when ionic strength effects are significant, and a temperature correction must be applied if the actual water temperature differs from the temperature at which the value of K_{s0} was determined. Corrections for ionic strength and temperature were introduced in Chap. 3 and are described in many textbooks, including those by Snoeyink and Jenkins (1980), Stumm and Morgan (1996), Butler (1998), Benjamin (2002), and Jensen (2003). Examples are included in a later section of this chapter. The Davies equation (described in Chap. 3) is valid for ionic strengths up to 0.5 M; ionic strength corrections can be made using Pitzer's specific ion interaction model (Plummer et al., 1988; Pitzer, 1991; Langmuir, 1997; Benjamin, 2002) for ionic strengths up to 1.0 M (or higher if additional terms are included).

TABLE 13-1 Selected Solubility Product Constants

Solid	Formula	K_{s0}^\dagger	Reference
Aluminum hydroxide	Al(OH) ₃	2×10^{-32}	NIST, 2004

[†]Values of K_{s0} are at 25°C and zero ionic strength, except those from *Lange's Handbook* (2005), which are for 18 to 25°C. Solubility calculations that fail to consider complexation and other factors can be highly inaccurate. Since the second ionization constant for H₂S is poorly known, it is more useful to examine sulfide solubility as described in the *CRC Handbook* (2008).

If the concentrations of the lattice ions are known, their ion product (Q), also referred to as their *reaction quotient* (Chap. 3), may be calculated as follows (ignoring ionic strength effects):

$$Q = [A^{y+}]^x [B^{z-}]^y \quad (13-4)$$

If $Q > K_{s0}$, the solution is supersaturated with respect to A_xB_y(s) and precipitation can occur, provided that any assumptions made are correct and that all appropriate corrections have been applied. Similarly, if $Q < K_{s0}$, precipitation of A_xB_y(s) is not possible. If $Q = K_{s0}$, the solution is in equilibrium with the solid. These same relationships may also be expressed using the saturation ratio (SR), the saturation index (SI), or the free energy of reaction (ΔG_{rxn}^0), as illustrated in Table 13-2. The Langelier saturation index (LSI) is a special case of the saturation index that applies specifically to precipitation of CaCO₃(s). It is widely used in the field of water supply and treatment and is described in Chap. 20.

TABLE 13-2 Relationships Among Parameters Used to Indicate the Saturation State of a Solution

Parameter	Equivalent expression	For a solution that is		
		Supersaturated	At equilibrium	Undersaturated
Q	See Eq. 13-4	$Q > K_{s0}$	$Q = K_{s0}$	$Q < K_{s0}$
SR	Q/K_{s0}	$SR > 1$	$SR = 1$	$SR < 1$
SI	$\log(Q/K_{s0})$	$SI > 0$	$SI = 0$	$SI < 0$
ΔG_{rxn}^0	$2.3RT \times SI^{\ddagger}$	$\Delta G_{rxn}^0 > 0$	$\Delta G_{rxn}^0 = 0$	$\Delta G_{rxn}^0 < 0$

[†] R is the gas constant (1.987 cal/mol-K), T is absolute temperature in degrees kelvin, and the reaction is written as a dissolution reaction as shown in Eq. 13-2.

It is important to recognize that the solubility of a substance in pure water may differ greatly from its solubility in water containing other dissolved substances. Some handbooks provide information on the solubility of various substances in pure solutions, and such information can be quite helpful when preparing reagents in pure water in the laboratory or when dissolving relatively soluble materials in water to prepare chemical feeding solutions. However, when a sparingly soluble substance is added to water containing dissolved substances, its dissolution may be hindered or promoted by ions already present. For example, if $\text{CaSO}_4(\text{s})$ is added to water already containing 1,000 mg/L of sodium sulfate, much less $\text{CaSO}_4(\text{s})$ will dissolve into the water than indicated in Example 3-3. This is expected on the basis of LeChâtelier's principle and is referred to, in the context of precipitation and dissolution, as the *common-ion effect*—the suppression of the solubility of one salt by another when they share a common ion. At equilibrium, the ion product Q will still equal K_{s0} for $\text{CaSO}_4(\text{s})$, but the Ca^{2+} concentration will be relatively low because dissolution of $\text{CaSO}_4(\text{s})$ will be limited by the high sulfate concentration.

A contrasting example is the dissolution of $\text{CaCO}_3(\text{s})$ in water containing a small amount of an acid, for example, ground water containing CO_2 . More $\text{CaCO}_3(\text{s})$ will dissolve into this water than into pure water because the acid will react with carbonate ions, CO_3^{2-} , converting them to bicarbonate ions, HCO_3^- . Thus, additional $\text{CaCO}_3(\text{s})$ must dissolve before the value of Q equals K_{s0} for $\text{CaCO}_3(\text{s})$.

In the field of water quality and treatment, questions frequently arise concerning the solubility of a contaminant ion in a water having a given pH, alkalinity, and ionic composition. If the solid limiting the solubility of the contaminant ion is known, the maximum concentration of the contaminant ion can often be estimated as illustrated in Example 13-1.

Example 13-1 Residual Mg^{2+} in Lime-Treated Water

Estimate the residual Mg^{2+} concentration in lime-treated water assuming it is limited by the solubility of magnesium hydroxide, $\text{Mg}(\text{OH})_2(\text{s})$, and that the pH is 11.0, the temperature is 25°C, and ionic strength effects can be ignored.

Solution

1. Write the appropriate chemical reaction.

$\text{Mg}(\text{OH})_2(\text{s})$ produced in a lime softening process will be amorphous; thus, from Table 13-1, K_{s0} for this reaction is 3.91×10^{-11} .

2. Determine the hydroxide ion concentration using the expression for K_w (Chap. 3).

$$K_w = [\text{H}^+][\text{OH}^-] = 10^{-14} \text{ at } 25^\circ\text{C}$$

Since

$$[\text{H}^+] = 10^{-\text{pH}} = 10^{-11} \text{ mol/L}$$

the concentration of OH^- is

$$[\text{OH}^-] = K_w/[\text{H}^+] = 10^{-14}/10^{-11} = 10^{-3} \text{ mol/L}$$

3. Establish the solubility product constant expression and solve for the Mg^{2+} concentration.

$$K_{s0} = [\text{Mg}^{2+}][\text{OH}^-]^2 = 3.91 \times 10^{-11}$$

Rearranging and solving for $[\text{Mg}^{2+}]$,

$$[\text{Mg}^{2+}] = K_{s0}/[\text{OH}^-]^2 = \frac{3.91 \times 10^{-11}}{(10^{-3})^2} = 3.91 \times 10^{-5} \text{ mol/L (or 0.95 mg/L)}$$

Since hardness ion concentrations are frequently expressed as CaCO_3 , multiply the concentration in mg/L by the ratio of the equivalent weights of CaCO_3 and Mg^{2+} .

$$\text{Mg}^{2+} = 0.95 \text{ mg/L} \times \frac{50 \text{ mg CaCO}_3/\text{eq}}{12.15 \text{ mg Mg/eq}} = 3.9 \text{ mg/L as CaCO}_3 \quad \blacktriangle$$

A hypothetical problem, such as Example 13-1, may be straightforward and have an exact solution. Problems encountered in practice may be complex, perhaps more so than those addressing them realize, and simplifying assumptions are often made to facilitate calculations. Such calculations may provide useful quantitative information, but they are subject to a number of limitations and can produce estimates that are inaccurate or even grossly in error. Potential sources of error include

- *Temperature and ionic strength effects.* These effects are commonly ignored when making preliminary estimates, but they can significantly influence contaminant solubility. Failing to apply appropriate corrections may make little difference at low ionic strength or at a temperature close to that at which the reported value of K_{s0} was determined, but can make a great difference when dealing with solutions of higher ionic strength, multi-valent contaminants, or solids whose solubility is strongly affected by temperature. The best way to determine whether such effects are significant is to correct for them to see what difference the corrections make. However, most corrections are also approximate, in that they are usually based on correlations of measured values having limited accuracy, and they are sometimes extended, knowingly or unknowingly, beyond the range of ionic strength or temperature for which they were developed.
- *Incorrect assumptions regarding contaminant speciation.* For a particular solid, the value of K_{s0} is valid only for the specific ions forming the solid, but a contaminant may be present in more than one form and many analytical methods measure only the total amount present rather than the individual species. For example, mercury may be present as a free ion (Hg^{1+} or Hg^{2+}); as an inorganic complex, with HgCl_2^0 being the dominant dissolved form in most freshwaters (Sawyer et al., 2003); as elemental mercury, for example, if it leaked out of an obsolete pump seal; complexed with natural organic matter; adsorbed on particles; coprecipitated with various solids; or as a component of one or more mercury containing solids. Furthermore, speciation can change during treatment in response to a change in pH, oxidant concentration, temperature, or the concentrations and properties of other dissolved species and solids. If the speciation of the contaminant is not known, the limits of its solubility can be hypothetically estimated or experimentally measured, but they cannot usually be calculated with a reasonable degree of certainty.
- *Complex formation.* Complex formation increases the total concentration of a contaminant that can be held in solution in equilibrium with a particular solid, and it can also increase removal of a contaminant by coprecipitation if the complex is more readily removed than the free ion. Anions commonly present in water supplies that can complex metal ions include carbonate and bicarbonate, hydroxide, sulfate, and as noted above for mercury, chloride and NOM. The solubility of lead in tap water can be significantly influenced by formation of the carbonato-lead(II) complex, PbCO_3^0 (Chap. 20). Trivalent aluminum and iron form relatively insoluble hydroxides when used as coagulants (Chap. 8), but at higher pH values their solubility can increase significantly due to tetrahydroxo complex formation, as shown in Figs. 8-8 and 8-9. However, aluminum concentrations as high as those shown in Fig. 8-8 are generally not observed in practice when alum is

added as a coagulant in the lime softening process, presumably because one or more aluminum-containing solids of unknown composition is formed under these conditions. Sulfate interacts with Ca^{2+} to form a sulfato-calcium(II) complex, CaSO_4^0 , an ion pair that can significantly influence the solubility of $\text{CaSO}_4(\text{s})$ and $\text{CaCO}_3(\text{s})$. For example, the solubility of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}(\text{s})$ at zero ionic strength was calculated in Example 3-3 at 694 mg/L (total of calcium and sulfate), but increases to about 1,500 mg/L when the CaSO_4^0 complex is taken into consideration. Rules for naming complexes can be found in many water chemistry textbooks, such as those by Snoeyink and Jenkins (1980) and Sawyer et al. (2003).

- *The presence of threshold inhibitors (antiscalants).* These substances may be present naturally (e.g., certain types of natural organic matter) or added intentionally (e.g., polyphosphates and other commercially available antiscalants). In either case, they can retard or prevent precipitation and, if precipitation does occur, they can greatly alter the properties of the precipitate, including its solubility. Calculations based on the assumption that these compounds are absent may not be valid when they are actually present.
- *Incorrect assumptions regarding the solid phase.* If the solid phase actually present differs in composition from the solid assumed to be present, the calculation will be void and will need to be redone using a K_{s0} value corresponding to the correct solid. Solubility can also be significantly influenced by crystal morphology and size, and by the presence of impurities. At least six different crystal forms of $\text{CaCO}_3(\text{s})$ are known, each having a different solubility. It is also possible for two or more solids to precipitate simultaneously, or for a metastable phase to form. A metastable phase is less thermodynamically stable and more soluble than the phase that will exist at equilibrium, but it may form more rapidly and persist for an indefinite period of time before the more stable phase forms.
- *Failure to reach equilibrium.* Precipitation can occur when $Q > K_{s0}$, but a solution can remain supersaturated for an extended period of time. Once precipitation commences, the system may approach equilibrium very slowly, especially if an amorphous or metastable phase precipitates first and is then slowly transformed into a more stable phase. Precipitation and dissolution involve the physical transfer of matter (ions) from one phase to another, which can also proceed slowly. For example, if water is left standing in a lead service line, it can take hours or days for the lead concentration in solution to reach equilibrium with the lead pipe (Chap. 20), especially if the lead ions must pass through a layer of scale or a biofilm. If other reactions occur simultaneously, such as oxygen consumption and pH changes (commonly associated with both corrosion reactions and biofilm growth), it may take far longer to reach equilibrium.
- *An inaccurate solubility product constant.* Experimentally determined K_{s0} values vary. Some values have been accurately determined and then verified by later investigators, whereas other values may be slightly in error. The most authoritative sources of K_{s0} values, for example, NIST (2004), are those whose authors have critically reviewed the available data and selected one or more values judged to have been accurately determined.

The solubility behavior of most sparingly soluble ionic solids in natural and treated waters is complicated due to numerous competing solubility and acid-base equilibria, complex formation, and other factors including those already noted. Simple calculations can provide much useful information. But, when accurate results and a deeper understanding of contaminant behavior are needed, many investigators find it helpful to conduct empirical studies or to employ a computer-based chemical equilibrium model able to simultaneously address a large number (perhaps hundreds or thousands) of dissolved species and numerous solid phases. Commonly used models include MINEQL+, an updated version of MINEQL (Westall et al., 1976); MINTEQA2 (Allison et al., 1991), a revised version of MINTEQ, which combined MINEQL with WATEQ (Truesdell and Jones, 1973 and 1974); Visual

MINTEQ (Gustafsson, 2009); and PHREEQC, a program based on the work of Parkhurst (1992) and Plummer et al. (1988) that includes redox equilibria and the ability to handle high-ionic-strength environments. Cogley (1998) and Jensen (2003) have summarized the capabilities and use of a number of computer-based chemical equilibrium models. Some suppliers of antiscalants also provide software programs that estimate the dose required to inhibit precipitation of a given salt under a specific set of conditions.

PRECIPITATIVE SOFTENING

Precipitative softening, commonly referred to as *lime softening* (since lime is the chemical most commonly used for this purpose), is primarily used to remove calcium and magnesium hardness from water supplies. It also removes other contaminants commonly found in hard waters including NOM, iron and manganese, and various other inorganic contaminants, especially metal ions. Precipitative softening processes typically include coagulation, flocculation, and sedimentation, in which case they also remove particles, as described in Chaps. 8 and 9. Softening units operated as crystallizers without coagulant addition do not remove particles but can be followed by coagulation and filtration if particle removal is desired.

Water Hardness

Water is considered hard if it forms scale, especially on heating, if it makes soap difficult to lather, if it precipitates soap (forming curdles or soap scum), or if it requires extra detergent for proper cleaning action. Water hardness is caused by dissolved divalent metal cations. In natural waters, Ca^{2+} and Mg^{2+} are the predominant cations causing hardness, since most other divalent cations are typically present at concentrations below 1 mg/L. Trivalent cations can also contribute to water hardness, but their concentrations in drinking water supplies are usually negligible. For analytical purposes, total hardness (TH) is defined as the sum of dissolved Ca^{2+} and Mg^{2+} (APHA, AWWA, and WEF, 2005). Other hardness-causing cations are either ignored or are measured and reported individually.

Units of Expression. When measured separately, Ca^{2+} and Mg^{2+} concentrations are usually reported in units of mg/L (as Ca or Mg) or mg/L as CaCO_3 . Total hardness, whether determined by direct measurement (titration) or by summing the individually measured concentrations of calcium and magnesium, is usually reported in mg/L as CaCO_3 . It is not useful or appropriate to report total hardness in mg/L because the atomic weight of Ca differs from that of Mg.

Hardness can also be reported in units of milliequivalents per liter (meq/L) or millimoles per liter (mM). Units of meq/L are most often used when determining the types and concentrations of hardness present; and units of mM are commonly used when calculating chemical dosages. For calculations involving the use of solubility product constants or complex stability constants, the concentrations of Ca^{2+} and Mg^{2+} must be expressed in units of moles per liter (M), corrected for the effects of ionic strength and complex formation when appropriate. For ion exchange softening (Chap. 12), chemists typically prefer units of meq/L for the liquid phase and units such as meq/mL, eq/L, or eq/g for the solid phase. But the units of grains per gallon and kilograins per cubic foot are often used by practitioners.

Example 13-2 Units of Expression

A water sample is analyzed and found to contain 84.2 mg/L of Ca^{2+} (as Ca) and 9.7 mg/L of Mg^{2+} (as Mg). What are the concentrations of calcium, magnesium, and total hardness in mM, meq/L, and mg/L as CaCO_3 ?

Solution

1. Determine the molecular and equivalent weights of Ca, Mg and CaCO_3 . From Appendix A, the atomic weights of Ca and Mg are 40.1 and 24.3. These values are rounded to three significant figures because the concentrations were reported to three significant figures. (Hardness concentrations are typically reported only to the nearest mg/L.) Ca^{2+} and Mg^{2+} are divalent and will react with two equivalents of base to precipitate CaCO_3 or $\text{Mg}(\text{OH})_2(\text{s})$, respectively. Thus, their equivalent weight is their atomic weight divided by 2, or 20.05 for Ca and 12.15 for Mg. The equivalent weight of CaCO_3 is its molecular weight (100) divided by 2, or 50 mg/meq (Chap. 3).

2. Determine calcium, magnesium, and total hardness in units of mM.

$$\text{Calcium hardness} = (84.2 \text{ mg/L}) / (40.1 \text{ mg/mmol}) = 2.10 \text{ mM}$$

$$\text{Magnesium hardness} = (9.7 \text{ mg/L}) / (24.3 \text{ mg/mmol}) = 0.40 \text{ mM}$$

$$\text{Total hardness} = 2.10 + 0.40 = 2.50 \text{ mM}$$

3. Determine calcium, magnesium, and total hardness in units of meq/L.

$$\text{Calcium hardness} = (84.2 \text{ mg/L}) / (20.05 \text{ mg/meq}) = 4.20 \text{ meq/L}$$

$$\text{Magnesium hardness} = (9.7 \text{ mg/L}) / (12.15 \text{ mg/meq}) = 0.80 \text{ meq/L}$$

$$\text{Total hardness} = 4.20 + 0.80 = 5.00 \text{ meq/L}$$

4. Determine calcium, magnesium, and total hardness in units of mg/L as CaCO_3 .

$$\text{Calcium hardness} = (4.20 \text{ meq/L}) \times (50 \text{ mg/meq}) = 210 \text{ mg/L as CaCO}_3$$

$$\text{Magnesium hardness} = (0.80 \text{ meq/L}) \times (50 \text{ mg/meq}) = 40 \text{ mg/L as CaCO}_3$$

$$\text{Total hardness} = 210 + 40 = 250 \text{ mg/L as CaCO}_3 \quad \blacktriangle$$

Types of Hardness. Hardness can be classified as calcium or magnesium hardness, with the sum being defined as total hardness as just discussed. The concentration of alkalinity is also important, since lime addition converts carbonate alkalinity (present predominantly in the form of bicarbonate in most natural waters) to carbonate (CO_3^{2-}), which reacts with Ca^{2+} to precipitate $\text{CaCO}_3(\text{s})$. Noncarbonate hardness (NCH) is hardness for which a corresponding (equivalent) amount of carbonate alkalinity is not naturally present in the water. NCH cannot be removed by lime addition, but it can be removed by sodium carbonate addition. Thus, when selecting a precipitative softening process (from among the alternative processes) and when determining the chemical dose requirements, there are four types of hardness to consider.

- Calcium carbonate hardness (CCH)
- Magnesium carbonate hardness (MCH)
- Calcium noncarbonate hardness (CNH)
- Magnesium noncarbonate hardness (MNH)

In some circles, primarily those associated with industrial applications, carbonate hardness is referred to as *temporary hardness*, since its concentration can be substantially

reduced by boiling (to precipitate CaCO_3); and noncarbonate hardness is referred to as *permanent hardness*, since boiling does not reduce its concentration.

Reasons for Removing Hardness. The decision to remove hardness from drinking water is typically made solely for economic and aesthetic reasons. The two most commonly cited reasons are (1) reduced scaling of boilers, water heaters, washing machines, coffee pots, and other appliances that heat water or come in contact with hot water, which can significantly extend their useful life and reduce energy costs, and (2) conservation of soaps and detergents, resulting in cost savings as well as reduced impacts on wastewater treatment facilities and receiving waters. Other commonly cited reasons include improved taste of food and beverages, improved lathering of soap, reduced formation of soap scums and bathtub rings, and improved laundering, resulting in improved appearance and increased life of clothing. The taste of water can be adversely affected by hardness levels that are too high or too low (Durand and Dietrich, 2009). It is rare for hardness to be removed primarily to improve the taste of water, but hardness and alkalinity are often added to demineralized waters to improve their taste and reduce their corrosivity.

Many years ago, hardness was measured using the soap test method (Durfor and Becker, 1964). Modern detergents provide superior lathering and cleaning action compared to the soaps commonly used in the past and they are also much less prone to forming soap scums, but detergent use is still related to water hardness since some detergent products contain chemicals (referred to as *binders*) that complex hardness-causing ions to facilitate proper cleaning action. van der Veen and Graveland (1988) reported that the total cost of centralized softening in Amsterdam was \$4 (U.S.) per household per year, while the savings in detergent, soaps, energy, and maintenance were estimated to be \$25 to \$40 per household per year. Such savings vary geographically and temporally, but many communities in the United States and elsewhere continue to find centralized softening economically attractive.

Questions sometimes arise regarding the potential human health effects associated with hardness removal, but there appears to be no convincing evidence that hardness in drinking water causes or protects against adverse health effects in humans (World Health Organization, 1996). Although Ca and Mg are essential nutrients, water consumption typically accounts for only a small fraction (5–20%) of total dietary intake. For these reasons, the World Health Organization (1996) and regulatory agencies such as the U.S. Environmental Protection Agency (USEPA) decided not to establish health-related guidelines for water hardness. Using soda ash to remove noncarbonate hardness, or using ion exchange to soften water (Chap. 12), increases the sodium concentration in the finished water. Sodium is also an essential nutrient, but if guidance or advisory levels are exceeded, this may raise concerns. Water consumption is typically not a significant source of dietary sodium when compared to the salt intake goal of less than 2,400 mg/day recommended by several government and health agencies (USEPA, 2003), but it may be significant for those on salt-restricted diets (<500 mg/day). See Chap. 2 for additional information on sodium and health effects.

Although there are no regulatory limits on water hardness, precipitative softening offers a convenient and effective means for removing various other constituents for which maximum contaminant levels (MCLs) or secondary maximum contaminant levels (SMCLs) have been established, including barium, radium, iron, manganese, and color. It also removes or inactivates pathogens (qualifying for disinfection credit when used in conjunction with coagulation and filtration), partially removes DBP precursors, reduces total dissolved solids (TDS), and facilitates stabilization of the finished water.

Typical Treatment Objectives. Complete removal of hardness may be appropriate for certain industrial applications but is undesirable for a public water supply. Scaling problems are usually minimal at hardness concentrations below about 80 to 100 mg/L as CaCO_3 if the water is properly stabilized. For stabilization (Chap. 20), minimum calcium and alkalinity

concentrations of at least 40 mg/L as CaCO_3 are generally recommended. Lower hardness levels can reduce consumption of soaps and detergents, but some hardness is needed to help rinse off soap, for example, when showering. In 1968, AWWA adopted water quality goals that included a goal for hardness of 80 mg/L as CaCO_3 , stating that this represented a balance between scaling and corrosion and that a goal of 90 or 100 mg/L as CaCO_3 might be desirable for some water supplies (AWWA, 1968). Utilities that soften typically use this goal as a starting point and then establish local treatment objectives taking into consideration some or all of the following factors:

- Local estimates of the aforementioned economic and aesthetic benefits
- The cost of treatment and residuals handling and disposal, which will depend in part on raw water hardness, the relative amounts of Ca and Mg, and the relative amounts of carbonate and noncarbonate hardness
- The wishes of the consumers (including industrial users) and their willingness to pay for treatment, which can depend greatly on what the consumers are accustomed to
- The silica concentration in the raw water, which can be lowered if magnesium is also removed and which can contribute to scaling of water heaters and boilers
- Whether a higher level of softening (higher chemical dosages) will help meet selected MCLs or SMCLs

Taking these and perhaps other factors into consideration, most utilities that soften produce a finished water hardness between 75 and 150 mg/L as CaCO_3 , corresponding to moderately hard water based on the classification described below. Treatment objectives are typically relaxed to avoid the use of soda ash or the need to remove magnesium. Soda ash usually costs much more than lime and contributes sodium to the finished water, and the capital cost of equipment needed to store and feed soda ash may not be justified if only a small dosage is needed to achieve an ideal hardness concentration. Many utilities that soften avoid removing magnesium, except for the small amount that coprecipitates with CaCO_3 (s). Magnesium removal is often not necessary and, compared to calcium removal, requires a significantly higher lime dose, often requires soda ash addition, produces a greater quantity of residuals that are significantly more difficult to dewater, and requires higher chemical dosages to stabilize the finished water. However, magnesium removal also results in silica removal, which can offer significant benefits to both industrial and residential customers.

Some utilities establish a separate goal for magnesium hardness, especially if magnesium hydroxide or magnesium silicate scales have been found in their customers' water heaters. A typical goal is a maximum magnesium hardness in the range of 40 to 65 mg/L as CaCO_3 . A maximum finished water pH value is often established as well because the solubility of $\text{Mg}(\text{OH})_2$ (s) depends strongly on pH (Example 13-1). In selecting the pH value of finished water, the temperature of the heated water should be taken into consideration because water dissociates more as its temperature increases and, although its pH decreases, its hydroxide ion concentration actually increases; this can cause precipitation of metal hydroxides, carbonates, and silicates. On the basis of magnesium concentrations at the inlet and outlet of a 60°C (140°F) water heater, Tuepker and Hartung (1960) determined the maximum magnesium concentration at which precipitation would not occur at various pH values (Table 13-3). However,

TABLE 13-3 Approximate Maximum Magnesium Concentrations in Lime-Softened Meramec River Water That Will Not Precipitate in 60°C (140°F) Domestic Water Heaters

pH of Water at 25°C	Mg (mg/L as CaCO_3)

their results were based on a limited number of experiments using a single source water, and the scale composition and silica concentrations were not reported. Therefore, Table 13-3 should be viewed not as a general guideline applicable to all source waters but as an example of the type of information needed to establish appropriate goals.

Other investigators, including Ryznar et al. (1946), Larson (1951), and Larson et al. (1959), have examined the solubility of $Mg(OH)_2(s)$ at temperatures relevant to domestic water heaters; but, although they recognized the importance of silica in scaling water heaters, they did not consider silica in their calculations. Larson et al. (1959) summarized their recommendations for avoiding $Mg(OH)_2(s)$ precipitation in water heaters and hot water pipes in the form of a magnesium index (MI) based on field data and calculated as follows:

$$MI = (2 \times pH) + \log Mg + (0.02 \times t) - 21.2 \tag{13-5}$$

where pH is the measured pH of the treated water at its ambient temperature, Mg is the magnesium hardness in mg/L as $CaCO_3$, and t is the ambient temperature of the treated water in degrees Fahrenheit. This equation was developed for waters having approximately 50 mg/L of alkalinity and a TDS of 200 mg/L. Larson et al. (1959) found that magnesium hydroxide scaling problems were unlikely for $MI \leq 0$, isolated for values of 0.1 to 0.3 over an extended period of time, significant for values of 0.4 to 0.7, and numerous after several months for $MI \geq 0.7$.

It is difficult to precisely estimate the magnesium and pH limits that will prevent magnesium scaling problems because it may be possible for more than one magnesium containing solid phase to be formed; the relevant equilibrium constants, including solubility product constants and the ionization constants of water (K_w) and carbonic acid, vary with both temperature and ionic strength; the temperature of a heated surface in a water heater will be considerably higher than the operating water temperature; and the change in the pH of water as its temperature increases is a function of alkalinity. The solubility of magnesium-based solids formed in water heaters may not be well understood or easily calculated, but the options for controlling magnesium scales are straightforward: reduce the magnesium concentration, and possibly the silica concentration as well; lower the pH; reduce the water temperature; or add a scale inhibitor.

Classification and Geographic Distribution of Hard and Soft Waters. Water supplies can be classified on the basis of hardness, and the classification shown in Table 13-4 is

TABLE 13-4 Classification of Water Supplies by Degree of Hardness

Hardness (mg/L as $CaCO_3$)	Degree of Hardness
0–75	Soft
75–150	Moderately hard
150–300	Hard
>300	Very hard

Source: Sawyer et al. (2003 and earlier editions), with permission of McGraw Hill, Copyright 2003.

widely used. The concentration ranges shown in Table 13-4 are arbitrary, and other authors have chosen slightly different ranges, especially when presenting previously published data grouped into other concentration ranges.

Figure 13-1 shows the average raw water hardness for each of 48 states in the United States, based on a survey of 1315 large cities (Lohr and Love, 1954). On average, raw water supplies in the United States are relatively soft in Hawaii, the Pacific Northwest, the Northeast, and

several southeastern states; moderately hard in Alaska, Colorado, and a number of eastern and southeastern states; and relatively hard in Florida and most southwestern and midwestern states. Maps based on other surveys show similar patterns for both raw and finished water hardness (Collins et al., 1934; Lohr and Love, 1954; Durfor and Becker, 1964; Briggs and Ficke, 1977). In Canada, water supplies in provinces near the Pacific or Atlantic Ocean tend to be softer, while those in the central provinces tend to

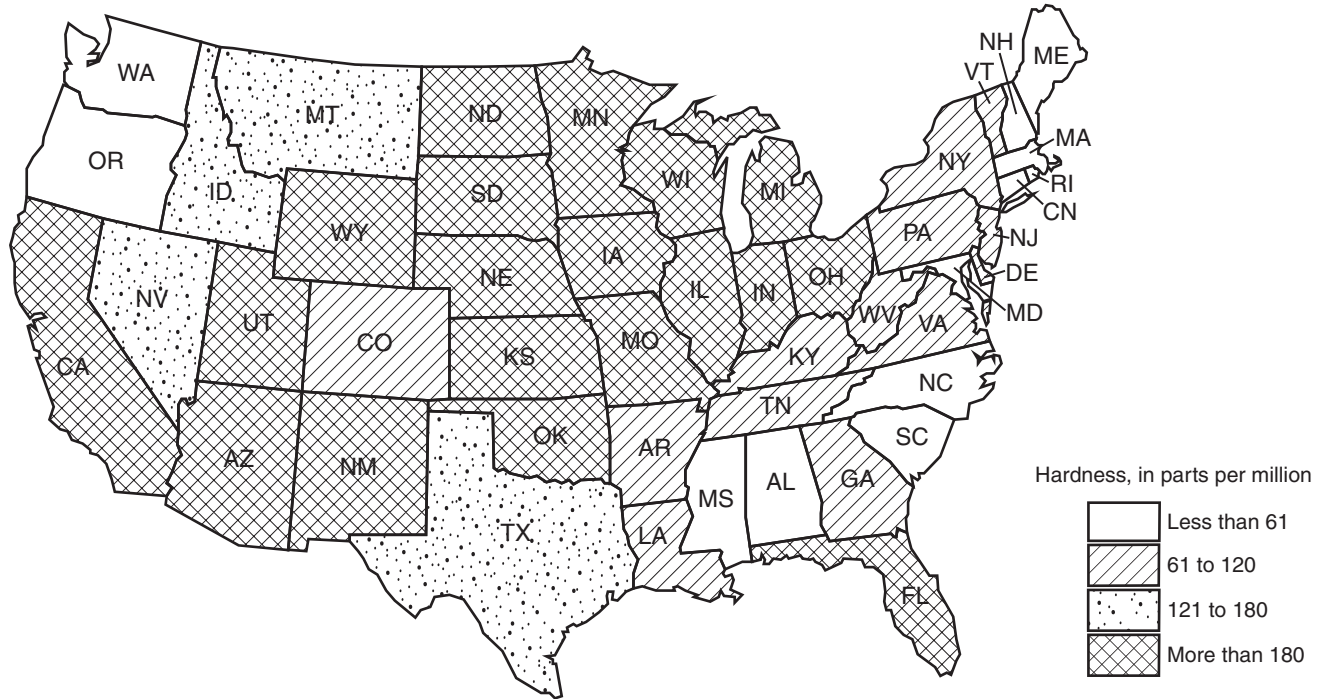

FIGURE 13-1 Average hardness, by state, of raw water from public supplies, drawn from groundwater and surface water sources, for 1,315 of the larger cities in the United States in 1952. (Adapted from Lohr and Love, 1954.)

be harder. In some parts of the world, hard surface water supplies are much less common than they are in North America.

Maps such as the one shown in Fig. 13-1 can be helpful for some purposes, such as designing surveys, selecting sampling sites, or identifying regions likely to be impacted by proposed regulations. However, caution should be exercised in drawing conclusions from such maps, as there can be great variations from site to site within a state, especially between surface water and groundwater supplies. The surveys cited focused on larger cities, so the results are biased toward surface water supplies, which Lohr and Love (1954) found to average less than half the hardness concentration of the groundwater supplies surveyed. Although alkalinity tends to vary in patterns similar to those exhibited by hardness, some hard waters contain mostly noncarbonate hardness, which affects the cost of treatment and may influence both the treatment objectives and the choice of a treatment process. Decisions for a specific community or treatment facility should be based on the documented quality of the source water being treated.

Chemistry of Precipitative Softening

In precipitative softening, Ca^{2+} is precipitated as $\text{CaCO}_3(\text{s})$, and Mg^{2+} is precipitated as $\text{Mg}(\text{OH})_2(\text{s})$. A limited amount of Mg^{2+} may be coprecipitated with (incorporated into or adsorbed onto) $\text{CaCO}_3(\text{s})$ (Liao and Randtke, 1985; Russell et al., 2009); thus, some Mg^{2+} may be removed even when the solubility of $\text{Mg}(\text{OH})_2(\text{s})$ is not exceeded. The equilibrium reaction equations for precipitation of $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$, written as dissolution reactions, are

According to LeChâtelier's principle, these reactions can be driven to the left by increasing the concentrations of carbonate (CO_3^{2-}) and hydroxide (OH^-) ions, respectively. This is done by adding a base, usually lime, to the water being treated. Base addition increases the OH^- concentration, which reacts with the carbonate system (described in Chap. 3) to increase the CO_3^{2-} concentration and precipitate $\text{CaCO}_3(\text{s})$. A portion of the base is consumed as it reacts with the carbonate system; but if the OH^- concentration increases sufficiently, $\text{Mg}(\text{OH})_2(\text{s})$ also precipitates.

Removing Carbonate Hardness Using Lime. Either quicklime or hydrated lime may be used for lime softening. When quicklime, $\text{CaO}(\text{s})$, is used, it must first be slaked (combined with water) to form hydrated lime, $\text{Ca}(\text{OH})_2(\text{s})$, as follows:

(A note about arrows in chemical equations: When expressing an equilibrium relationship, a double arrow (\rightleftharpoons) is used; when showing a reaction that is essentially complete or when only the forward reaction is considered, a single, forward arrow (\rightarrow) is used.)

Excess water is used in the slaking process, but hydrated lime is only slightly soluble in water, so slaking produces either a lime slurry or a lime paste, depending on the type of slaker used. The slurry or paste is fed by diluting it to produce milk of lime containing up to 180 g/L hydrated lime (AWWA and ASCE, 2005). Quicklime used for water softening must be the fast-slaking type because lime that is incompletely slaked may settle to the bottom of the softening basins and be wasted or cause operational problems. The purity

of quicklime varies considerably, ranging from 75 percent to over 90 percent in shipments meeting ANSI/AWWA Standard B202 (AWWA, 2007). Lime purity must be factored in when estimating chemical dosages, and slakers must be designed to handle the impurities that fail to dissolve, referred to as *grit*.

Dissolution of hydrated lime in water is described by the following equilibrium reaction:

The solubility product constant for $\text{Ca(OH)}_2(\text{s})$ is 5.02×10^{-6} at 25°C (CRC Handbook, 2008), so the solubility of $\text{Ca(OH)}_2(\text{s})$ in pure water at 25°C is 798 mg/L if complex formation is ignored. Thus, only a small fraction of the lime in milk of lime is dissolved; but the lime should dissolve completely when added to water being treated with the dosages typically associated with lime softening, releasing 2 moles of OH^- ions per mole of lime added. These OH^- ions react with bicarbonate ions associated with carbonate hardness to form carbonate ions.

One mole of carbonate ions can precipitate up to 1 mole of Ca^{2+} ions initially present in the water, and the other mole of carbonate ions can precipitate up to 1 mole of the Ca^{2+} ions that were released into solution as the lime dissolved. Thus, the overall reaction for removal of CCH using quicklime, obtained by summing Eqs. 13-8, 13-9, and 13-10 with the reverse of Eq 13-6 multiplied by 2 is

or, when using hydrated lime,

Precipitation of Mg^{2+} proceeds in similar fashion, with three important differences. First, Mg^{2+} is precipitated as $\text{Mg(OH)}_2(\text{s})$, and not as a carbonate salt, with 1 mole of lime producing enough OH^- ions to precipitate up to 1 mole of Mg^{2+} .

Second, as shown in Eq 13-13, precipitation of $\text{Mg(OH)}_2(\text{s})$ with lime results in no net removal of hardness, since dissolution of the lime leaves an equivalent concentration of Ca^{2+} in the water, so a second mole of lime must be added to remove these additional Ca^{2+} ions. Assuming that sufficient alkalinity is available, that is, that the Mg^{2+} is present as MCH, the overall reaction for Mg^{2+} removal using quicklime is

Thus, on a stoichiometric basis, the lime dose required to remove MCH is twice that required to remove CCH. Third, precipitation of $\text{Mg(OH)}_2(\text{s})$ requires a relatively high pH, higher than that achieved by stoichiometric addition of lime. Therefore, excess lime must be added to raise the pH to the point that the desired amount of $\text{Mg(OH)}_2(\text{s})$ actually precipitates. This process is referred to as excess lime softening.

Removing Noncarbonate Hardness. Lime is unable to remove NCH because it is not possible to precipitate $\text{CaCO}_3(\text{s})$ in the absence of carbonate. Carbonate must be added to remove NCH, and the usual chemical of choice for this purpose is sodium carbonate,

Na_2CO_3 , commonly known as soda ash. The overall stoichiometric reactions for removal of CNH and MNH are

Some authors include anions, usually sulfate or chloride, in equations describing these reactions, often referring to these ions as being associated with CNH or MNH. Others show the NCH to be initially present in the form of a salt, such as $\text{CaSO}_4(\text{s})$ or $\text{MgCl}_2(\text{s})$. These practices stem from the fact that softening was practiced for well over a century before it was first recognized that salts can release dissolved ions into solution, and it took many more years for this to be generally accepted by most chemists. Prior to that time, chemical reactions in water were expressed as reactions between salts. Today it is recognized that anions such as chloride and sulfate do not play a direct role in the softening process, though they may influence softening reactions by contributing to ionic strength or, in the case of sulfate, by forming complexes.

Softening with Sodium Hydroxide. If at least half of the calcium hardness is carbonate hardness, sodium hydroxide (NaOH, also known as caustic soda) can be used to remove both calcium and magnesium hardness. The stoichiometric reactions for removal of Ca^{2+} and Mg^{2+} using NaOH are

As can be seen by comparing Eq. 13-17 with the reaction shown in Eq. 13-11, only half as much carbonate (in the form of HCO_3^- ions) is consumed when using caustic soda instead of lime to remove CCH. This is potentially advantageous when CNH is present, since removing 2 moles of CCH using caustic soda effectively converts 1 mole of CNH to CCH. Also, only half as much $\text{CaCO}_3(\text{s})$ is produced; this reduces the cost of residuals disposal. To remove Mg^{2+} , excess NaOH must be added to raise the pH sufficiently to precipitate $\text{Mg}(\text{OH})_2(\text{s})$, but this requires conversion of most of the remaining bicarbonate to carbonate, so using caustic soda to remove magnesium is not an attractive option when the magnesium is present as MCH.

Since caustic soda is typically much more expensive than lime or soda ash and since it also increases the sodium concentration in the finished water (which can create a public relations issue), it is rarely used for water softening in the United States. Caustic soda softening is practiced at a number of treatment plants in Europe (see, for example, van Dijk and Wilms, 1991) and elsewhere, especially those employing pellet reactors to soften waters containing NCH. From an operational standpoint, it is easier to inject a solution of NaOH into the inlet of a pellet reactor than to inject lime slurry, and NaOH reacts more rapidly than lime because it is already in solution and does not require time to dissolve. Sodium hydroxide is also easier to store, handle, and feed than lime, especially at smaller treatment plants.

Removing Carbonic Acid. Many hard waters, especially groundwaters and those drawn from the hypolimnion of a lake or reservoir, contain a significant amount of dissolved carbon dioxide (CO_2) along with a much smaller amount of carbonic acid (H_2CO_3). As described in Chap. 3, these species exist in equilibrium with one another. Their sum is commonly designated as H_2CO_3^* (Eq. 3-23), which is referred to as carbonic acid. Carbonic acid reacts instantly with lime, or any other base used to soften water, so carbonic acid must

be considered when estimating chemical doses for precipitative softening. For lime, the stoichiometric reaction with H_2CO_3^* is as follows:

If the concentration of carbonic acid is relatively high, it may be cost-effective to use air stripping (Chap. 6) to reduce its concentration to below 10 mg/L as CO_2 (Horsley et al., 2005).

Recarbonation and Final Stabilization of Lime-Softened Water. During precipitative softening, the water may approach equilibrium with the solid phases being formed, but in most cases it will still be scale-forming; that is, it will have the potential to encrust basins, conduits, valves, filter media, underdrains, clearwells, and wetted surfaces throughout the storage and distribution system. This is especially a problem when adding excess lime to remove Mg^{2+} , since excess lime not removed by adding soda ash can react with residual Ca^{2+} and with CO_2 (adsorbed from the air into the water as it flows over weirs and through open channels) to precipitate additional $\text{CaCO}_3\text{(s)}$. To minimize or eliminate its scale-forming potential, lime-softened water must be properly stabilized. This is usually accomplished by (1) substantially lowering the pH of the water, prior to filtration, by recarbonation or mineral acid addition; (2) adjusting the pH of the finished water, if necessary, to obtain the desired value of the LSI (Chap. 20); and (3) adding a scale inhibitor, such as phosphoric acid or sodium hexametaphosphate.

Recarbonation is the addition of CO_2 to water from which carbonate has been removed by lime softening or by another process such as membrane softening, reverse osmosis, or ion-exchange demineralization. Recarbonation of lime-softened water restores a portion of the total carbonate concentration lost during the softening process; it also lowers the pH of the treated water, reducing scale formation. The pH of lime-softened water can also be lowered using a strong mineral acid, with sulfuric acid being the usual choice. Addition of a strong mineral acid is sometimes loosely referred to as recarbonation, but it does not change the total carbonate concentration and is more properly referred to as *acid addition* or *pH adjustment*.

Most softening plants practicing recarbonation employ *single-stage recarbonation*, a process in which all of the CO_2 needed to adjust the pH to the desired final value prior to filtration is added at once. However, when excess lime is used to remove Mg^{2+} , the Ca^{2+} associated with the excess lime will remain in the finished water if single-stage recarbonation is employed, since the excess lime in solution will react with CO_2 as follows:

If the Ca^{2+} associated with the excess lime must be removed to meet treatment objectives, one option is to remove it by adding soda ash along with the excess lime. However, soda ash is relatively expensive, increases the sodium concentration in the finished water (in essence converting calcium hydroxide into sodium hydroxide), and does not reduce the acid dose required to stabilize the treated water. An alternative is to employ *two-stage recarbonation*. In the first stage, CO_2 is added until the point of minimum $\text{CaCO}_3\text{(s)}$ solubility is reached, and the additional $\text{CaCO}_3\text{(s)}$ that is formed is allowed to precipitate and settle. In the second stage, more CO_2 is added to reduce the pH to the desired final value. Since two-stage recarbonation requires an additional recarbonation point and is usually not necessary to meet local treatment objectives, single-stage recarbonation is far more common.

The CO_2 doses required for single-stage and two-stage recarbonation can be calculated on the basis of chemical equilibrium relationships. These relationships and the equations describing them are complex; so, when precise calculations are needed, they are usually made with the aid of a computer program. However, precise estimates of the CO_2 dose are generally not needed in practice, since the dose actually applied by a chemical feeder is

only approximately known; some CO_2 is absorbed from the atmosphere; the exact composition and solubility of some of the solids carried over from the softening process may be unknown; and, regardless of the calculated dosage, the CO_2 feed system will be adjusted on the basis of measurements of finished water quality relative to the utility's treatment objectives. Estimates suitable for most purposes can be made using the following stoichiometric relationships:

As these equations indicate, recarbonation converts residual OH^- and CO_3^{2-} ions, whether free or complexed, to HCO_3^- ions. This prevents further precipitation of $\text{Mg}(\text{OH})_2(\text{s})$, dissolves $\text{Mg}(\text{OH})_2(\text{s})$ particles remaining in the settled water, and diminishes or eliminates the driving force for $\text{CaCO}_3(\text{s})$ precipitation. It is commonly believed that recarbonation also dissolves $\text{CaCO}_3(\text{s})$ particles carried over from the softening process, but this is expected to occur only if enough CO_2 is added to produce a negative LSI. If a positive LSI is maintained following recarbonation, $\text{CaCO}_3(\text{s})$ will have a tendency to precipitate rather than to dissolve; but small or impure $\text{CaCO}_3(\text{s})$ crystals, which may have a higher solubility than assumed in calculating the LSI, could potentially dissolve even though the calculated LSI value is positive.

In the first stage of two-stage recarbonation, CO_2 is added to convert OH^- ions to CO_3^{2-} ions, as shown in Eqs. 13-21 and 13-22; then, in the second stage, the remaining CO_3^{2-} ions are converted to HCO_3^- ions, as shown in Eq. 13-23. The carbonate ions formed in the first stage react with the Ca^{2+} ions associated with the excess lime to precipitate additional $\text{CaCO}_3(\text{s})$, which is flocculated and then removed by sedimentation. Since the water is already saturated with $\text{CaCO}_3(\text{s})$ prior to CO_2 addition, formation of CaCO_3 is approximately stoichiometric. Maximizing the carbonate concentration will maximize removal of calcium hardness, and the maximum carbonate concentration will be obtained when the CO_2 dosage increases the acidity from a negative value to 0 mg/L as CaCO_3 (Merrill, 1978). Assuming that the concentrations of H_2CO_3^* and H^+ are negligible (an excellent approximation at $\text{pH} > 10$), this corresponds to the point where the concentrations of HCO_3^- and OH^- are equal, or to a pH value of about 10.0 to 10.6 depending on temperature, ionic strength, and alkalinity. This also corresponds to the point where phenolphthalein alkalinity equals one half of the total alkalinity (APHA, AWWA, and WEF, 2005; Schierholz et al., 1976), so alkalinity titrations are sometimes used for process control.

Although these stoichiometric equations ignore important equilibrium relationships involved in recarbonation, CO_2 dose estimates based on stoichiometry are reasonably accurate because inaccuracies introduced by key approximations offset one another. For example, in the first stage of two-stage recarbonation, not all of the hydroxide is converted to carbonate (since the target pH is above 10), but this is offset by the fact that some of the carbonate is converted to bicarbonate as the pH drops. Stoichiometric and equilibrium calculations of CO_2 doses are expected to yield similar results if similar assumptions are made regarding the species present in the settled water.

Following recarbonation, a filter aid is typically added to improve particle capture during filtration. Other chemicals added before or after filtration, including chlorine, ammonia, fluoride, and scale inhibitors, can also influence the pH of the finished water. Therefore, the pH of the finished water should be monitored and adjusted as needed to maintain the desired value. The target value is often selected, in concert with the target values of calcium hardness and alkalinity, to maintain a specified LSI value; but it may also be selected on the basis of

empirical observations of scaling and corrosion in the distribution system, tap-water lead levels, or other criteria. The pH of the finished water can be controlled by adjusting the CO_2 dose used for recarbonation or by adding a supplemental dose of acid or base prior to distribution.

Many years ago, CO_2 was often produced on site by the combustion of oil or gas in an external burner, or by gas combustion in an underwater burner. Today, most plants use liquefied CO_2 , since its use significantly reduces operation and maintenance problems. Liquefied CO_2 can be vaporized and fed as a gas, using diffusers, or dissolved under pressure into a side stream of water that is then injected back into the settled water prior to filtration. Chemicals and chemical feed systems used for recarbonation, acid addition, and feeding other chemicals used to stabilize water are described in detail by AWWA and ASCE (2005).

Horsley et al. (2005) and Recommended Standards (2007) indicate that a contact time of at least 20 min should be provided for stabilization. The basis for this recommendation is not stated, but it presumably provides time for mixing, for conditioning of the remaining particles at a lower pH value, and in some cases for another opportunity for any remaining particles to settle. Some contend that this detention period is not needed when using side-stream injection because dissolved CO_2 reacts more rapidly than gas-phase CO_2 and because the pH quickly stabilizes following pH addition. However, such arguments do not make sense. Gas-phase CO_2 dissolves rapidly into water, becoming $\text{CO}_2(\text{aq})$, and $\text{CO}_2(\text{aq})$ reacts with water to form H_2CO_3 ; but, in this hydration reaction, equilibrium strongly favors $\text{CO}_2(\text{aq})$. More than 99 percent of dissolved CO_2 in water is present in the form $\text{CO}_2(\text{aq})$ rather than carbonic acid, H_2CO_3 (see Chap. 3 and Snoeyink & Jenkins (1980); and this is true regardless of the manner in which the CO_2 is dissolved into the water. The hydration reaction is relatively slow from a chemist's perspective, but fast enough for the CO_2 in a recarbonation basin to be consumed in a few seconds in cold water. The reaction of H_2CO_3 (the active species in acid-base reactions involving CO_2) with dissolved carbonate and hydroxide ions is virtually instantaneous, so the pH would be expected to stabilize rapidly regardless of the method of CO_2 addition. The important question is how rapidly any remaining particles react with the CO_2 , recognizing that heterogeneous reactions (those involving reactants in two different phases) can be quite slow, and whether this affects the filterability of the particles. A much shorter detention period may suffice, especially given the increased use of polymeric filter aids since the criterion of 20 min was first developed; and it was recognized long ago (ASCE, AWWA, and CSSE, 1969) that "some plants are known to be operating [recarbonation basins] with practically no retention time whatsoever." Today it is common to use a recarbonation basin for single-stage recarbonation; to follow the first stage of two-stage recarbonation with flocculation and clarification (or a solids contact basin) rather than a recarbonation basin; and to omit a recarbonation basin following the second stage of two-stage recarbonation.

Chemical Dose Estimates Based on Stoichiometry. Chemical doses for lime softening and recarbonation can be estimated using simple stoichiometric relationships, such as those shown in a number of the preceding equations, or by performing calculations that take equilibrium relationships into consideration. Both approaches have advantages and limitations, and both must be applied with judgment to obtain reasonable results. Chemical dosages can also be determined empirically, at full scale or by conducting jar tests.

Chemical dose estimates based on stoichiometry are easy to understand, can be made very quickly, and require minimal computational resources and ability. However, their accuracy is limited because important equilibrium relationships are either ignored or replaced with simple approximations. For example, the stoichiometry reflected in Eq. 13-11 indicates that 1 mole of lime will convert 1 mole of Ca^{2+} ions to $\text{CaCO}_3(\text{s})$, but a portion of the Ca^{2+} will remain in solution in equilibrium with $\text{CaCO}_3(\text{s})$, as shown in Eq. 13-6, and some

Ca^{2+} will remain in solution in the form of ion pairs, such as CaCO_3^0 and CaSO_4^0 , or other complexes. To compensate for this, an expected residual Ca^{2+} concentration (or a specific treatment objective) can be assumed and the chemical doses can be adjusted accordingly.

Chemical dose estimates based on stoichiometry are suitable for most purposes, such as setting initial chemical feed rates, sizing chemical handling and storage facilities, estimating solids production, and estimating costs. In practice, operators must adjust chemical doses up or down to achieve specific treatment objectives, but this would be the case even if each chemical dose could be determined very precisely, since there would still be changes in water quality and flow rate, and perhaps in chemical concentration or purity.

The required excess lime dosage, typically about 0.3 to 0.7 mM (Horsley et al., 2005), or 30 to 70 mg/L as CaCO_3 , is difficult to estimate accurately using stoichiometry alone. One approach is to simply pick a dosage within the typical range and to then adjust it to meet the treatment objective for magnesium. However, the dosage actually required will depend on temperature, ionic strength, and the concentration of magnesium hardness desired in the finished water. The required dosage can be more accurately estimated by introducing simple equilibrium calculations, first to estimate the pH value corresponding to the desired finished-water magnesium concentration, assuming equilibrium with amorphous $\text{Mg}(\text{OH})_2$ (s), and then to estimate the lime dose required to reach the calculated pH value. Such calculations are included in Example 13-4.

Estimating Chemical Doses Using Equilibrium Models. Equilibrium models can be used to determine the chemical doses required for lime softening and recarbonation; to evaluate the LSI and calcium carbonate precipitation potential (CCPP) of treated water, as described in Chap. 20; and for other purposes, such as estimating the pH of a water following chemical addition or blending with another water. Equilibrium models used to estimate chemical doses for lime softening and recarbonation incorporate equilibrium constants for dissolution (and precipitation) of CaCO_3 (s) and $\text{Mg}(\text{OH})_2$ (s), for the carbonate system, and usually for a limited number of metal-ion complexes, along with a means of adjusting each constant to account for the effects of temperature and ionic strength. Equilibrium relationships and other equations needed to construct a basic equilibrium model of the lime softening process are described in the subsection Calcium Carbonate and Magnesium Hydroxide Equilibria.

The equations in simpler models can be solved using only a handheld calculator, as demonstrated in Example 13-5; but a spreadsheet or other computer program is normally used so the calculations can be more easily repeated or refined, and software programs are commercially available for those who lack the time or knowledge to write their own. Prior to the availability of personal computers, many water treatment professionals used Caldwell-Lawrence diagrams to estimate chemical dosages for precipitative softening and water stabilization, and for other purposes, such as determining the pH of blended waters or the pH of a water following chemical addition. These diagrams, prepared using a mainframe computer, provide nomographic representations of CaCO_3 (s) and $\text{Mg}(\text{OH})_2$ (s) solubility as a function of temperature and ionic strength. Use of these diagrams was described and demonstrated in the previous edition of this handbook (Benefield and Morgan, 1999) and by Caldwell and Lawrence (1953), Merrill and Sanks (1969), Loewenthal and Marais (1976), and Merrill (1978). Since these diagrams are rarely used today, they are not described further in this edition.

When developing or using an equilibrium model, the user should note that although some of the calculations may be more accurate than those based on stoichiometric calculations, their accuracy will be limited by the accuracy of the equilibrium constants used, the corrections applied, and the assumptions regarding the physical and chemical nature of the system. Values of equilibrium constants are based on experimental measurements and are subject to both analytical and procedural errors, so it is important to choose values from

reliable sources and to recognize that their accuracy is limited by the accuracy of the data from which they were calculated and by the ability of the investigator to correctly perform the calculations. Furthermore, solubility product constants are usually determined using pure solutions of known composition that are allowed to reach equilibrium before measurements are made. Waters that are lime softened may contain impurities, such as DOC, phosphate, silicic acid, and coagulants, that influence the solubility of $\text{CaCO}_3(\text{s})$ and may form complexes not included in the model; and equilibrium may not be attained before the solids are removed. Temperature and ionic strength corrections are based on correlations of measured values. Temperature corrections are often based on the van't Hoff equation (Chap. 3, Eq. 3-16), which in turn is based on the assumption that the enthalpy change does not vary significantly with temperature, which may or may not be the case. Temperature corrections made using correlations based on only a few data points, linear correlations of nonlinear data, or data outside the temperature range of interest may introduce significant error. The Davies equation, commonly used to estimate activity coefficients as a function of ionic strength, was originally developed to estimate the activity coefficients of selected ions to within ± 2 percent at 25°C in a 0.1 M solution, so it is presumably less accurate under other conditions. Many models introduce small errors by failing to account for changes in ionic strength that occur as solids precipitate or dissolve, and most models fail to account for the reduction in ionic strength that results from ion-pair formation. Chemical equilibrium models are often based on the assumption of a closed system, but treatment systems are usually not completely closed; thus, gains and losses of CO_2 are often ignored whether or not they are significant.

Calcium Carbonate and Magnesium Hydroxide Equilibria. The solubility product constant for dissolution of $\text{CaCO}_3(\text{s})$, shown in Eq. 13-6, can be written as follows when ionic strength effects are considered:

$$K_{s_0, \text{CaCO}_3} = \gamma_d [\text{Ca}^{2+}] \gamma_d [\text{CO}_3^{2-}] \quad (13-24)$$

where K_{s_0, CaCO_3} is the solubility product constant for $\text{CaCO}_3(\text{s})$, γ_d is the activity coefficient for divalent ions, and the square brackets denote molar concentrations. In very dilute solutions, that is, at very low ionic strengths, activity coefficients have a value of approximately 1 and the activity of an ion is approximately equal to its molar concentration. As ionic strength increases, activity decreases, and activity coefficients must be applied to obtain accurate results. For very precise work involving pure solutions, empirically derived single-ion activity coefficients are commonly used (as described by Butler, 1998). Activity coefficients that vary only with ionic charge are normally used in calculations pertaining to natural (and treated) waters, which contain mixtures of different ions of unlike charge. Using ion-specific activity coefficients would be complicated and would contribute little to the overall accuracy of the calculations given other uncertainties involved in most calculations. Activity coefficients may be estimated using one of several equations in widespread use, including the Davies equation (Davies, 1938) modified as recommended by Davies (1962), and using the Debye-Hückel limiting law to account for the effect of temperature.

$$\log \gamma_z = -Az^2 \left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I \right) \quad (13-25)$$

where z is the ionic charge, I is the ionic strength (see Chap. 3), $A = 1.82 \times 10^6 (\epsilon T)^{-3/2}$, and ϵ is the dielectric constant of water (78.38 at 25°C). The value of the dielectric constant varies with temperature and is commonly estimated using the following correlation:

$$\epsilon = \frac{60,594}{T+116} - 68.937 \quad (13-26)$$

where T is absolute temperature (K). Rossum and Merrill (1983) presented this correlation without indicating its source. Compared to accurately determined values of ϵ from 0 to 100°C (Archer and Wang, 1990; CRC Handbook, 2008), Eq. 13-26 estimates ϵ with an average error of 0.17 percent and a maximum error of 0.30 percent. The following equation, obtained by fitting an exponential expression to the data of Archer and Wang from 0 to 100°C, estimates ϵ more accurately, with an average error of only 0.013 percent and a maximum error of 0.025 percent:

$$\epsilon = 308.67 e^{-0.0045976(T)} \quad (13-27)$$

where T is absolute temperature (K).

Comparing activity coefficients calculated using Eq. 13-25 (with $A = 0.5$) against 50 values determined experimentally at an ionic strength of 0.1 M and 25°C, Davies (1962) found the average deviation to be 1.6 percent, with three of the deviations being twice that large. Butler (1998) found that activity coefficients estimated using Eq. 13-25 have a possible error of 3 percent when $I = 0.1$ M, and 10 percent when $I = 0.5$ M. Stumm and Morgan (1996) indicated that Eq. 13-25 is appropriate for $I < 0.5$ M, and Butler (1982) stated that it applies from 0 to 50°C.

The value of K_{s0} for $\text{CaCO}_3(\text{s})$ depends on the form precipitated and on temperature. Known forms of $\text{CaCO}_3(\text{s})$ include calcite, aragonite, vaterite, and several hydrated forms (Randtke et al., 1982). Calcite is the most thermodynamically stable form in most natural freshwaters, and it is the sole or dominant form normally present in lime-softening residuals. Aragonite has been found, typically as a minor component, in some samples of lime-softening residuals, and its formation is favored in seawater under certain conditions. Slack (1980) reported the formation of calcium carbonate hexahydrate ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$) at several lime-soda softening plants in England and found that cold temperatures, high phosphate concentrations, and perhaps DOC contributed to its formation. Randtke et al. (1982) observed vaterite formation in laboratory experiments when sodium carbonate was added to Ca^{2+} solutions, but on standing, the solids transformed into calcite and calcite was the only product formed when using quicklime or hydrated lime. Slack found that adding calcite inhibited formation of $\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$, as expected. Since solids are normally recirculated at lime-softening plants and since calcite is more thermodynamically stable than other forms under typical water treatment conditions, calcite formation is strongly favored, fortunately so, since other forms are considerably more soluble than calcite and therefore inhibit the softening process.

The solubility of $\text{CaCO}_3(\text{s})$ in water is of interest to investigators in diverse fields and has been extensively studied. Reported values of K_{s0} for $\text{CaCO}_3(\text{s})$ vary, but the following equations developed by Plummer and Busenberg (1982) are thought to provide the best available estimates of K_{s0} for calcite, aragonite, and vaterite under conditions relevant to water treatment and distribution (APHA, AWWA, and WEF, 2005):

$$pK_{sc} = 171.9065 + 0.077993T - 2839.319/T - 71.595 \log_{10}T \quad (13-28)$$

$$pK_{sa} = 171.9773 + 0.077993T - 2903.292/T - 71.595 \log_{10}T \quad (13-29)$$

$$pK_{sv} = 172.1295 + 0.077993T - 3074.688/T - 71.595 \log_{10}T \quad (13-30)$$

where $pK = -\log(K)$, K_{sc} = solubility product constant for calcite, K_{sa} = solubility product constant for aragonite, K_{sv} = solubility product constant for vaterite, and T = absolute temperature, K ($273.15 + ^\circ\text{C}$). Equations 13-28 through 13-30 are applicable over the temperature range 0 to 90°C (273 to 363K).

The following correlation was widely used in the past to estimate K_{s0} , but although it is still included in some texts today, it should now be considered obsolete:

$$pK_{s0, \text{CaCO}_3} = 8.03 + 0.01183t \quad (13-31)$$

where t = temperature in degrees Celsius. This correlation was developed for a temperature range of 0 to 80°C (Loewenthal and Marais, 1976), but it is based on K_{s0} values summarized by Larson and Buswell (1942), which were extrapolated for temperatures above 30°C and which were determined without taking complex formation into consideration.

The solubility product constant expression for dissolution of $\text{Mg}(\text{OH})_2(\text{s})$, shown in Eq. 13-7, is as follows when corrected for ion strength effects:

$$K_{s0,\text{Mg}(\text{OH})_2} = \gamma_d [\text{Mg}^{2+}] \gamma_m^2 [\text{OH}^-]^2 \quad (13-32)$$

When $\text{Mg}(\text{OH})_2(\text{s})$ precipitates in a lime-soda softening process, it forms amorphous or microcrystalline solids that have a much higher solubility than crystalline $\text{Mg}(\text{OH})_2(\text{s})$, a mineral known as brucite. Therefore, the values of K_{s0} listed in the chemical and geochemical literature for brucite are not applicable to $\text{Mg}(\text{OH})_2(\text{s})$ formed in the lime softening process. Using the data of earlier investigators, Loewenthal and Marais (1976) developed the following equation to describe the solubility of freshly precipitated $\text{Mg}(\text{OH})_2(\text{s})$ over a temperature range of 0 to 80°C:

$$pK_{s0,\text{Mg}(\text{OH})_2} = 0.0175t + 9.97 \quad (13-33)$$

where t = temperature in degrees Celsius.

Solubility product constants based on molar concentrations ($^c K_{s0}$) may be written for $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$ by rearranging Eqs. 13-24 and 13-32 as follows:

$$^c K_{s0,\text{CaCO}_3} = \frac{K_{s0,\text{CaCO}_3}}{\gamma_d^2} = [\text{Ca}^{2+}][\text{CO}_3^{2-}] \quad (13-34)$$

$$^c K_{s0,\text{Mg}(\text{OH})_2} = \frac{K_{s0,\text{Mg}(\text{OH})_2}}{(\gamma_d \gamma_m^2)} = [\text{Mg}^{2+}][\text{OH}^-]^2 \quad (13-35)$$

In these expressions and those presented earlier, only free (uncomplexed) Ca^{2+} and Mg^{2+} ions are taken into consideration. To more accurately estimate the total residual concentrations of dissolved Ca and Mg^{2+} , their complexed forms must also be considered. Numerous metal-ligand complexes can potentially form in natural waters. Most can usually be ignored, but some may be present in concentrations that are significant relative to those of the free ions. Ca and Mg complexes commonly included in chemical equilibrium models are listed in Table 13-5, along with expressions for their formation constants and equations that can be used to estimate the values of their formation constants as a function of temperature. The effect of complex ion formation on $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$ solubility can be included in equilibrium calculations by including the complexes in mass balance relationships for total residual calcium and total residual magnesium. For the complexes listed in Table 13-5, these relationships are

$$[\text{Ca}]_T = [\text{Ca}^{2+}] + [\text{CaOH}^+] + [\text{CaHCO}_3^+] + [\text{CaCO}_3^0] + [\text{CaSO}_4^0] \quad (13-36)$$

and

$$[\text{Mg}]_T = [\text{Mg}^{2+}] + [\text{MgOH}^+] + [\text{MgHCO}_3^+] + [\text{MgCO}_3^0] + [\text{MgSO}_4^0] \quad (13-37)$$

At low ionic strength (ignoring activity corrections), Eqs. 13-36 and 13-37 can be reduced to

$$[\text{Ca}]_T = \frac{K_{s0,\text{CaCO}_3}}{\alpha_2 C_{T,C}} \left(1 + \frac{K_w K_3}{[\text{H}^+]} + K_4 \alpha_1 C_{T,C} + K_5 \alpha_2 C_{TT} C^+ + K_6 [\text{SO}_4^{2-}] \right) \quad (13-38)$$

TABLE 13-5 Complex Formation Reactions of Ca^{2+} and Mg^{2+} with Selected Ligands

Complex formation reaction	Equilibrium expression	$\log K$ (25°C)	ΔH_r^0 (kcal/mole)
$\text{Ca}^{2+} + \text{OH}^- \leftrightarrow \text{CaOH}^+$	$K_3 = [\text{CaOH}^+]/([\text{Ca}^{2+}][\text{OH}^-])$	1.30	2.0
$\text{Ca}^{2+} + \text{HCO}_3^- \leftrightarrow \text{CaHCO}_3^+$	$K_4 = [\text{CaHCO}_3^+]/([\text{Ca}^{2+}][\text{HCO}_3^-])$	1.20	4.6
$\text{Ca}^{2+} + \text{CO}_3^{2-} \leftrightarrow \text{CaCO}_3^0$	$K_5 = [\text{CaCO}_3^0]/([\text{Ca}^{2+}][\text{CO}_3^{2-}])$	3.22	3.6
$\text{Ca}^{2+} + \text{SO}_4^{2-} \leftrightarrow \text{CaSO}_4^0$	$K_6 = [\text{CaSO}_4^0]/([\text{Ca}^{2+}][\text{SO}_4^{2-}])$	2.36	1.7
$\text{Mg}^{2+} + \text{OH}^- \leftrightarrow \text{MgOH}^+$	$K_7 = [\text{MgOH}^+]/([\text{Mg}^{2+}][\text{OH}^-])$	2.58	3.0
$\text{Mg}^{2+} + \text{HCO}_3^- \leftrightarrow \text{MgHCO}_3^+$	$K_8 = [\text{MgHCO}_3^+]/([\text{Mg}^{2+}][\text{HCO}_3^-])$	1.01	1.2
$\text{Mg}^{2+} + \text{CO}_3^{2-} \leftrightarrow \text{MgCO}_3^0$	$K_9 = [\text{MgCO}_3^0]/([\text{Mg}^{2+}][\text{CO}_3^{2-}])$	2.92	2.6
$\text{Mg}^{2+} + \text{SO}_4^{2-} \leftrightarrow \text{MgSO}_4^0$	$K_{10} = [\text{MgSO}_4^0]/([\text{Mg}^{2+}][\text{SO}_4^{2-}])$	2.26	1.4

General equation for estimating $\log K$ at absolute temperature T (in degrees K)

$$\log K(T) = \log K(\text{at } 298.15\text{K}) - [0.73295 \times \Delta H_r^0 \times (298.15 - T)/(298.15)]$$

Complex-specific temperature correlations for T in degrees K

$$\log K_4 = 1209.12 + 0.31294T - 34,765.05/T - 478.782 \log T$$

$$\log K_5 = -1228.732 - 0.299444T + 35,512.75/T + 485.818 \log T$$

$$\log K_8 = 2.319 - 0.011056T + 2.2812 \times 10^{-5}T^2$$

$$\log K_9 = 0.991 + 0.00667T$$

Note: The equilibrium expressions are written in terms of molar concentrations, but activities must be used when ionic strength effects are significant. Values of $\log K$ and ΔH_r^0 are from NIST (2004). The general equation for estimating $\log K$ as a function of temperature is based on a rearrangement of the Van't Hoff equation, which is accurate only if ΔH_r^0 does not vary with temperature over the temperature range of interest. The complex-specific temperature correlations for K_4 and K_5 are those found by Plummer and Busenberg (1982). Those for K_8 and K_9 are from Plummer, Jones, and Truesdell (1976) and yield $\log K$ values at 25°C that differ slightly from those reported by NIST (2004).

and

$$[\text{Mg}]_T = \frac{K_{s0,\text{Mg}(\text{OH})_2} [\text{H}^+]^2}{(K_w)^2} \left(1 + \frac{K_w K_7}{[\text{H}^+]} + K_8 \alpha_1 C_{T,C} + K_8 \alpha_2 C_{T,C} + K_{10} [\text{SO}_4^{2-}] \right) \quad (13-39)$$

where $C_{T,C}$ is the total molar inorganic carbon concentration, K_w is the ion product of water, and K_1 and K_2 are the acid dissociation constants for carbonic acid (see Chap. 3). The value of K_w can be calculated using the following expression:

$$pK_w = \frac{4470.99}{T} + 0.017060(T) - 6.0875 \quad (13-40)$$

where T = temperature in degrees kelvin ($273.15 + ^\circ\text{C}$). Equation 13-40 was developed by Harned and Owen (1958) for temperatures of 273 to 333K (0 to 60°C), but it provides good estimates of K_w at much higher temperatures. To correct for activity, replace the thermodynamic equilibrium constants in Eqs. 13-38 and 13-39 with their corresponding concentration-based constants:

$${}^c K_{s0,\text{CaCO}_3} \text{ and } {}^c K_{s0,\text{Mg}(\text{OH})_2}$$

(as shown in Eqs. 13-34 and 13-35)

$${}^cK_w = K_w/(\gamma_m)^2$$

$$\begin{aligned} {}^cK_3 &= \gamma_d K_3 & {}^cK_4 &= \gamma_d K_4 & {}^cK_5 &= (\gamma_d)^2 K_5 & {}^cK_6 &= (\gamma_d)^2 K_6 \\ {}^cK_7 &= \gamma_d K_7 & {}^cK_8 &= \gamma_d K_8 & {}^cK_9 &= (\gamma_d)^2 K_9 & {}^cK_{10} &= (\gamma_d)^2 K_{10} \end{aligned}$$

Several of these expressions assume an activity of 1 for uncharged molecules such as the CaCO_3^0 ion pair. This is generally considered to be a reasonable assumption for solutions having an ionic strength less than 0.1 M (Snoeyink and Jenkins, 1980). In general, an activity coefficient for an uncharged molecule (γ_0) can be expressed as a simple function of ionic strength up to $I \sim 5\text{M}$.

$$\log \gamma_0 = bI \quad (13-41)$$

where b is an empirically determined constant that may be small (or zero) for uncharged ion pairs (Butler, 1998). Note that activity coefficients for uncharged molecules are greater than or equal to 1 (not equal to or less than 1, as they are for ions). Uncharged molecules are salted out of water as ionic strength increases, since ions interact much more strongly with water. Also note that pH equals the negative logarithm of *hydrogen ion activity*, not hydrogen ion concentration. Thus,

$$[\text{H}^+] = \frac{10^{-\text{pH}}}{\gamma_m} = 10^{-\text{pH} - \log(\gamma_m)} \quad (13-42)$$

In many waters, the concentrations of complexed forms of Ca and Mg are small relative to the concentrations of uncomplexed Ca^{2+} and Mg^{2+} and can therefore be ignored. In fact, when the water is cold, the contact time is short, or the solids concentration is low, the errors associated with failure to approach equilibrium are likely to greatly exceed those associated with ignoring complex formation. Complexes are most likely to be important when attempting to accurately model the softening of water high in sulfate or carbonate that is being treated under conditions where equilibrium is approached.

Cadena et al. (1974) concluded that the CaCO_3^0 ion pair accounted for a significant amount of the residual calcium remaining after lime softening, but they used a value of K_5 about 17 times higher than values reported by other investigators. Pisigan and Singley (1985) found that the concentration of CaCO_3^0 is insignificant in fresh water in the pH range of 6.20 to 9.20. An example by Snoeyink and Jenkins (1980) illustrated that, for a water having $C_{T,C} = 10^{-3}$ at pH 12, the sum of the carbonate, bicarbonate, and hydroxo complexes of Ca^{2+} in equilibrium with CaCO_3 is less than 1 mg/L as CaCO_3 ; however, the concentration of free (uncomplexed) Ca^{2+} present at equilibrium was found to be only 0.5 mg/L under these conditions. Thus, in this example, the error introduced by ignoring complexes would be relatively large even though the total concentration of soluble Ca species is quite small.

Process Variations

There are a number of process variations that can be employed to accomplish precipitative softening, several of which are illustrated in Fig. 13-2. Factors considered in process selection include raw water quality, treatment objectives (possibly including the need to remove other contaminants besides those causing hardness), costs (including chemical, solids disposal, and other operating costs), and the preferences of both the consumers and those managing the treatment facilities. Straight lime softening is the process most commonly

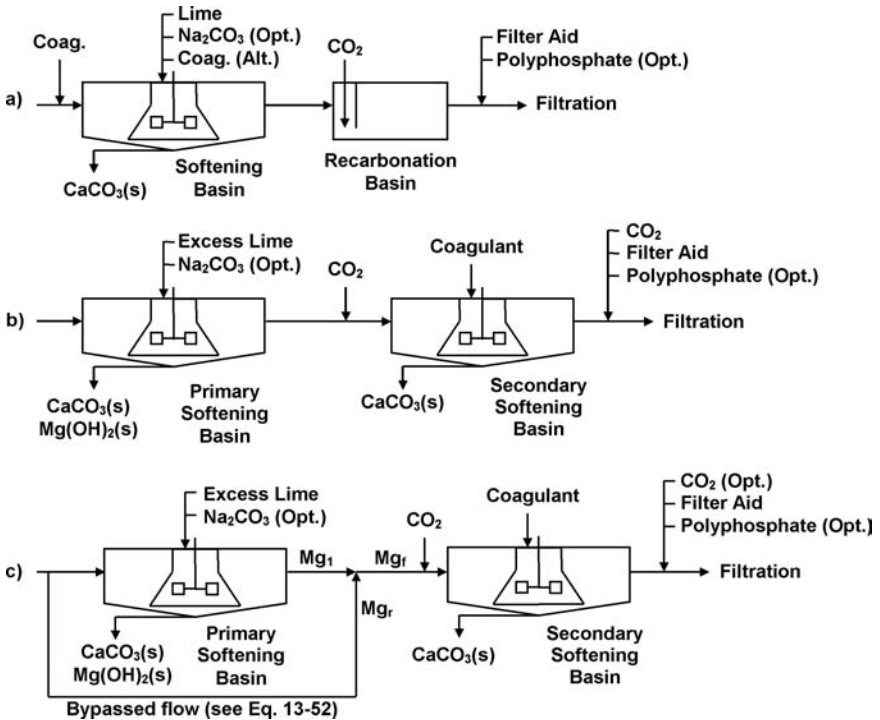

FIGURE 13-2 Common lime-softening process variations. (a) Straight single-stage lime or lime-soda softening. (b) Excess lime or lime-soda softening with two-stage recarbonation (also known as two-stage softening). (c) Split treatment softening.

employed for precipitative softening of public water supplies in North America, but other processes are sometimes found to be advantageous under site-specific conditions.

Straight Lime Softening. *Straight lime softening*, also referred to as *conventional lime softening*, removes carbonic acid and CCH, though a small amount of Mg may be removed by means of coprecipitation. On a stoichiometric basis, the lime dose required is the sum of the doses required to remove carbonic acid and CCH. There are two possible cases.

Case 1. All of the calcium hardness is CCH. In this case, the required lime dose, in units of moles per liter, may be estimated as follows:

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + [\text{CCH}] = [\text{H}_2\text{CO}_3^*] + [\text{Ca}^{2+}] \quad (13-43)$$

Case 2. Both CCH and CNH are present. In this case, only the CCH can be removed. Assuming the pH of the raw water is less than 9 and all of the carbonate alkalinity is initially present in the form of HCO_3^- , then the required lime dose may be estimated as follows:

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + [\text{CCH}] = [\text{H}_2\text{CO}_3^*] + \frac{1}{2}[\text{HCO}_3^-] \quad (13-44)$$

In either case, the lime dosage may be increased to accelerate the reaction or decreased if a higher finished water calcium hardness is acceptable.

Many years ago, waters treated using straight lime or lime–soda softening were sometimes not recarbonated because the water was considered to be reasonably close to equilibrium with respect to precipitation of $\text{CaCO}_3(\text{s})$. However, some utilities found it necessary or desirable to lower the pH of the finished water or to add a scale inhibitor, such as sodium hexametaphosphate, to avoid $\text{CaCO}_3(\text{s})$ deposition in filters, in the distribution system, and especially in water heaters. Utilities gradually came to recognize the importance of water stabilization and its long-term impacts on the condition of a distribution system, as well as its potential impacts on lead concentrations in tap water. Today most utilities practicing straight lime or lime–soda softening carefully evaluate the stability of the finished water and adjust pH, alkalinity, and hardness as needed to protect the distribution system (Chap. 20) and comply with the Lead and Copper Rule (Chap. 1).

Straight Lime–Soda Softening. *Straight lime–Soda softening*, also referred to as *conventional lime–soda softening*, removes both CCH and CNH, but not magnesium hardness, except for a small amount of magnesium that may be coprecipitated with $\text{CaCO}_3(\text{s})$. If all of the carbonate alkalinity is initially present in the form of HCO_3^- , the stoichiometric lime dose is calculated as in Case 2, and the dose of soda ash required to remove CNH is

$$[\text{Na}_2\text{CO}_3] = [\text{CNH}] = [\text{Ca}^{2+}] - \frac{1}{2}[\text{HCO}_3^-] \quad (13-45)$$

Example 13-3 Straight Lime and Lime–Soda Softening

A groundwater having a pH of 7.50, an alkalinity of 180 mg/L as CaCO_3 , and a temperature of 25°C is analyzed and found to have the following major ion concentrations:

$$\begin{aligned} \text{Ca}^{2+} &= 84.2 \text{ mg/L} & \text{Mg}^{2+} &= 9.7 \text{ mg/L} & \text{Na}^+ &= 23.0 \text{ mg/L} \\ \text{SO}_4^{2-} &= 96.1 \text{ mg/L} & \text{Cl}^- &= 14.2 \text{ mg/L} \end{aligned}$$

Determine the concentration of each type of hardness and the chemical doses required to soften and recarbonate this water using straight lime and lime–soda softening (Fig. 13-2a). Draw bar diagrams to illustrate the ionic composition of the water after each step of treatment, and ignore ionic strength effects. Assume that a polymer is used as a coagulant. If alum were used instead, an equivalent amount of lime would be needed to neutralize the acidity contributed by the alum, and there would be a corresponding increase in CNH.

Solution

1. Determine the initial HCO_3^- and CO_3^{2-} concentrations.

Since pH is between 6 and 9, the CO_3^{2-} concentration is negligible, thus $\text{HCO}_3^- \approx$ alkalinity = 180 mg/L as CaCO_3 . Dividing by the equivalent weight of CaCO_3 ,

$$\text{HCO}_3^- \approx (180 \text{ mg/L as CaCO}_3)/(50 \text{ mg/meq}) = 3.60 \text{ meq/L}$$

Since HCO_3^- has one acid-base equivalent per mole,

$$\text{HCO}_3^- \approx (3.60 \text{ meq/L})/(1 \text{ meq/mmol}) = 3.60 \text{ mM}$$

2. Determine the H_2CO_3^* concentration.

At 25°C, $\text{pK}_1 = 6.35$ (Table 3-7). Therefore,

$$\text{K}_1 = 10^{-6.35} = \frac{[\text{HCO}_3^-][\text{H}^+]}{[\text{H}_2\text{CO}_3^*]} = \frac{(3.60 \times 10^{-3})(10^{-7.50})}{[\text{H}_2\text{CO}_3^*]}$$

Solving for H_2CO_3^* ,

$$[\text{H}_2\text{CO}_3^*] \approx 0.25 \times 10^{-3} \text{ M} = 0.25 \text{ mM}$$

Since H_2CO_3^* has two acid-base equivalents per mole,

$$\text{H}_2\text{CO}_3^* \approx (0.25 \text{ mM}) (2 \text{ meq/mmol}) (50 \text{ mg/meq}) = 25 \text{ mg/L as CaCO}_3$$

This concentration is high enough to justify evaluating the cost effectiveness of removing CO_2 by air stripping, but it will be removed using lime in this example.

3. Determine the types of hardness present.

A good way to do this is to begin by constructing a bar diagram showing the ionic composition of the water in meq/L. Carbonic acid can also be included in the bar diagram, as a reminder that it must also be considered when estimating chemical dosages. The first step in constructing a bar diagram is to determine the concentration of each constituent in meq/L. The concentrations in mM can also be determined to facilitate calculating dosages in mM.

Constituent	mg/L	Mol. wt.	mM	meq/mmol	meq/L
H_2CO_3^*	25 [†]	NA	0.25	2	0.50
Ca^{2+}	84.2	40.1	2.10	2	4.20
Mg^{2+}	9.7	24.3	0.40	2	0.80
Na^+	23.0	23.0	1.00	1	1.00
HCO_3^-	180 [†]	NA	3.60	1	3.60
SO_4^{2-}	96.1	96.1	1.00	2	2.00
Cl^-	14.2	35.45	0.40	1	0.40

[†]mg/L as CaCO_3 ; units must be converted using equivalent weight.

Construct a bar diagram showing ion concentrations in meq/L. (This bar diagram and those that follow are not drawn to scale.)

The concentration of each type of hardness can be read from the bar diagram. Recall that carbonate hardness is hardness for which an equivalent amount of HCO_3^- is available, and that removal of calcium hardness with lime requires 2 moles of HCO_3^- per mole of Ca^{2+} (Eqs. 13-11 and 13-12), or one equivalent of HCO_3^- per equivalent Ca^{2+} . Since the concentration of Ca^{2+} in meq/L exceeds the concentration of HCO_3^- , both CCH and CNH are present, whereas all of the Mg^{2+} is NCH. Thus,

$$\text{CCH} = 3.60 \text{ meq/L} = 1.80 \text{ mM} = 180 \text{ mg/L as CaCO}_3$$

$$\text{CNH} = 4.2 - 3.6 = 0.6 \text{ meq/L} = 0.3 \text{ mM} = 30 \text{ mg/L as CaCO}_3$$

$$\text{MCH} = 0$$

$$\text{MNH} = 5.0 - 4.2 = 0.8 \text{ meq/L} = 0.4 \text{ mM} = 40 \text{ mg/L as CaCO}_3$$

Sodium, sulfate, chloride, and other ions besides Ca^{2+} , Mg^{2+} , and HCO_3^- are not important with respect to softening, except insofar as they influence ionic strength and form complexes. Thus, they can be omitted from the bar diagram or grouped together as other ions. However, their inclusion in the bar diagram provides a check on the quality of the data, since the sums of the cation and anion concentrations, in meq/L, should be approximately equal (APHA et al., 2005), and checking the balance also helps guard against common errors made when converting concentrations from one set of units to another.

- Determine the chemical doses for straight lime softening followed by recarbonation. Straight lime softening will remove only CCH. Using Eq 13-43,

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + [\text{CCH}] = 0.25 \text{ mM} + 1.80 \text{ mM} = 2.05 \text{ mM}$$

Assuming lime purity of 90 percent, the lime dose in mg/L will be

$$(2.05 \text{ mM}) \times (56 \text{ mg/mmol}) / (0.90) = 128 \text{ mg/L as 90 percent pure CaO}$$

After softening, before recarbonation, the ionic composition of the water will be as follows, assuming that 40 mg/L of CaCO_3 (0.4 mM or 0.8 meq/L) remains in solution and that OH^- is negligible:

	1.4	2.2	3.2
Ca ²⁺	Mg ²⁺	Na ⁺	
CO ₃ ²⁻	SO ₄ ²⁻		Cl ⁻
0	0.8	2.8	3.2

The approximate CO_2 dose required for recarbonation, as shown in Eq. 13-23, equals the residual CO_3^{2-} concentration. Thus,

$$\text{CO}_2 = 0.8 \text{ meq/L} = 0.4 \text{ mM} \times 44 \text{ mg/mmol} = 17.6 \text{ mg/L as CO}_2$$

In practice, the CO_2 dose must be adjusted to achieve the desired treated-water pH value. The treated water will have a calcium hardness of 70 mg/L as CaCO_3 , a magnesium hardness of 40 mg/L as CaCO_3 , a total hardness of 110 mg/L, and the following ionic composition:

	1.4	2.2	3.2
Ca ²⁺	Mg ²⁺	Na ⁺	
HCO ₃ ⁻	SO ₄ ²⁻		Cl ⁻
0	0.8	2.8	3.2

- Determine the chemical doses for straight lime-soda softening followed by recarbonation.

Soda ash will be added to remove CNH; and the dose, using Eq. 13-45, will be

$$[\text{Na}_2\text{CO}_3] = [\text{CNH}] = 0.6 \text{ meq/L} = 0.3 \text{ mM}$$

Assuming a soda ash purity of 98 percent, the dose in mg/L will be

$$(0.30 \text{ mM}) \times (106 \text{ mg/mmol}) / (0.98) = 32 \text{ mg/L}$$

as 98 percent pure Na_2CO_3 .

The doses of lime and CO_2 will remain unchanged from those used for straight lime softening. After softening and recarbonation, assuming that 40 mg/L of CaCO_3 remains in solution, the treated water will have a calcium hardness of 40 mg/L as CaCO_3 , a magnesium hardness of 40 mg/L as CaCO_3 , a total hardness of 80 mg/L, and the following ionic composition:

0	0.8	1.6	3.2
Ca^{2+}	Mg^{2+}	Na^+	
HCO_3^-	SO_4^{2-}		Cl^-
0	0.8	2.8	3.2

Soda ash addition removed the CNH, but caused a slight increase in TDS (<2 mg/L), since each Ca^{2+} ion removed was replaced with two sodium ions. However, lime addition removed 2.8 meq/L of Ca^{2+} and HCO_3^- ions, significantly reducing TDS. ▲

Excess Lime or Lime–Soda Softening. Excess lime softening removes both calcium and magnesium hardness. As noted above, excess lime is needed to raise the pH high enough to reduce the magnesium concentration to the desired value. Soda ash is used to remove NCH. Depending on the relative concentrations of alkalinity and hardness in the water being treated, there are two possible cases.

Case 1. All of the hardness is carbonate hardness. In this case, the stoichiometric lime dose, in moles per liter, may be estimated as follows:

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + [\text{CCH}] + 2 [\text{MCH}] + \text{Excess} \quad (13-46)$$

In this equation, the excess includes the lime required to convert most of the remaining HCO_3^- to CO_3^{2-} as well as the lime required to increase the OH^- concentration sufficiently to reach the target pH value. When making stoichiometric estimates, it is generally assumed that all of the HCO_3^- is converted to CO_3^{2-} at the target pH value, which is typically about 0.7 to 1.0 pH units higher than the value of pK_2 . The reaction of lime with excess HCO_3^- , that is, HCO_3^- not associated with hardness, can be expressed as follows:

Assuming that all of the HCO_3^- will be converted to CO_3^{2-} , the stoichiometric lime dosage can also be estimated using the following equation:

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + \frac{1}{2}[\text{HCO}_3^-] + [\text{MCH}] + \text{excess} \quad (13-48)$$

In this equation, the lime required to convert HCO_3^- to CO_3^{2-} is included in the bicarbonate term and not in the excess.

In practice, an excess lime dosage of 0.3 to 0.7 mM is typically required to reduce magnesium hardness to the desired value (Horsley et al., 2005). When estimating lime dosages stoichiometrically, the excess can be estimated on the basis of experience or by choosing a dosage in the typical range. Dosages of 0.50 to 0.65 mM are commonly assumed by those wishing to make a reasonably conservative estimate without performing equilibrium calculations. However, the excess actually required depends on alkalinity, water temperature, ionic strength, the treatment objective for magnesium, and

the dissolved silica concentration. (Dissolved silica will be present in the raw water as H_4SiO_4 , or silicic acid, which has a pK_1 value of about 9.83 and will consume base as the pH is raised to remove magnesium.) A common approach is to introduce a simple equilibrium calculation, that is, to estimate the pH value corresponding to the solubility of the desired finished water magnesium concentration and to then estimate the lime dose required to achieve the target pH value, as illustrated in Example 13-4.

Case 2. NCH is present. Assuming all of the carbonate alkalinity is initially present in the form of HCO_3^- , the required doses of lime and soda ash may be estimated as follows:

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + [\text{CCH}] + 2[\text{MCH}] + [\text{MNH}] + \text{excess} \quad (13-49)$$

$$[\text{Na}_2\text{CO}_3] = [\text{NCH}] = [\text{Ca}^{2+}] + [\text{Mg}^{2+}] - \frac{1}{2}[\text{HCO}_3^-] \quad (13-50)$$

Alternatively, the lime dosage may be estimated as follows:

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + \frac{1}{2}[\text{HCO}_3^-] + [\text{MCH}] + [\text{MNH}] + \text{excess} \quad (13-51)$$

Since all of the HCO_3^- is consumed in this case, the excess shown in Eqs. 13-49 and 13-51 includes only the caustic alkalinity needed to raise the pH to the target value.

Soda ash can be added to precipitate the Ca^{2+} associated with the excess lime, but one of three other options is often chosen: (1) allow the Ca^{2+} associated with the excess lime to remain in the finished water, which is the logical option when its removal is not necessary to meet the treatment objectives for calcium hardness and total hardness; (2) remove the Ca^{2+} associated with the excess lime by adding CO_2 in the first stage of two-stage recarbonation; or (3) practice split treatment, treating only a portion of the water with excess lime softening. The first option is most commonly chosen when the entire flow receives excess lime treatment. The second option is generally selected when the goal is to reduce total hardness to a very low level and the utility also desires to avoid increasing the sodium concentration, and to save on chemical costs, as the cost of CO_2 is typically much lower than that of soda ash. The third option is typically chosen when only a fraction of the water requires excess lime softening and the chemical savings associated with split treatment are sufficient to offset its increased capital cost.

Example 13-4 Excess Lime–Soda Softening (Stoichiometric Calculations)

A groundwater having a pH of 7.32, an alkalinity of 200 mg/L as CaCO_3 , and a temperature of 15°C is analyzed and found to have the following major ion concentrations:

$$\text{Ca}^{2+} = 68.2 \text{ mg/L} \quad \text{Mg}^{2+} = 19.4 \text{ mg/L} \quad \text{Na}^+ = 46.0 \text{ mg/L}$$

$$\text{SO}_4^{2-} = 96.1 \text{ mg/L} \quad \text{Cl}^- = 35.5 \text{ mg/L}$$

Determine the concentration of each type of hardness. Estimate the chemical doses required to soften this water to the maximum practical extent (i.e., a calcium hardness of 30 mg/L as CaCO_3 and a magnesium hardness of 10 mg/L as CaCO_3) using lime–soda softening followed by two-stage recarbonation (Fig. 13-2b). Determine the quantity of softening solids produced, and draw bar diagrams to illustrate the ionic composition of the water after each treatment step. Assume that $\text{Mg}(\text{OH})_2(\text{s})$ acts as a coagulant in the first stage and a polymer is used in the second stage. Ignore ionic strength effects. Municipal supplies are normally not softened to obtain maximum hardness removal, but may be when it significantly benefits industrial customers or if the softened water is blended with unsoftened water, with the blended water meeting the desired treatment objectives. When only partial removal of Mg^{2+} is desired, some utilities practice split treatment softening, illustrated in Example 13-6.

Solution

1. Estimate the initial HCO_3^- and CO_3^{2-} concentrations.

Since pH is between 6 and 9, the CO_3^{2-} concentration is negligible, thus, $\text{HCO}_3^- \approx \text{alkalinity} = 180 \text{ mg/L as CaCO}_3$. Dividing by the equivalent weight of CaCO_3 ,

$$\text{HCO}_3^- \approx (200 \text{ mg/L as CaCO}_3)/(50 \text{ mg/meq}) = 4.00 \text{ meq/L}$$

Since HCO_3^- has one acid-base equivalent per mole,

$$\text{HCO}_3^- \approx (4.00 \text{ meq/L})/(1 \text{ meq/mmol}) = 4.00 \text{ mM}$$

2. Estimate the initial H_2CO_3^* concentration.

At 15°C , $\text{p}K_1 = 6.42$ (Table 3-7). Therefore,

$$K_1 = 10^{-6.42} = \frac{[\text{HCO}_3^-][\text{H}^+]}{[\text{H}_2\text{CO}_3^*]} = \frac{(4.00 \times 10^{-3})(10^{-7.32})}{[\text{H}_2\text{CO}_3^*]}$$

Solving for H_2CO_3^* ,

$$[\text{H}_2\text{CO}_3^*] = 0.50 \times 10^{-3} \text{ M} = 0.50 \text{ mM}$$

Since H_2CO_3^* has two acid-base equivalents per mole,

$$\text{H}_2\text{CO}_3^* = (0.50 \text{ mM}) (2 \text{ meq/mmol}) (50 \text{ mg/meq}) = 50 \text{ mg/L as CaCO}_3$$

This concentration is relatively high, so it will be assumed that air stripping is used to reduce the H_2CO_3^* concentration to $10 \text{ mg/L as CaCO}_3$. (Complete removal is not economical.)

3. Determine the types of hardness present.

As shown in Example 13-3, determine the concentration of each constituent in meq/L , then construct a bar diagram. (Note that air stripping to remove CO_2 will convert a small fraction of carbonate hardness to noncarbonate hardness. In this case the change is less than 0.5 percent, so it will be ignored.)

Constituent	mg/L	Mol. wt.	mM	meq/mmol	meq/L
H_2CO_3^*	10 [†]	NA	0.10	2	0.20
Ca^{2+}	68.2	40.1	1.70	2	3.40
Mg^{2+}	19.4	24.3	0.80	2	1.60
Na^+	32.2	23.0	1.40	1	1.40
HCO_3^-	200 [†]	NA	4.00	1	4.00
SO_4^{2-}	76.9	96.1	0.80	2	1.60
Cl^-	28.4	35.45	0.80	1	0.80

[†]mg/L as CaCO_3 ; units must be converted using equivalent weight.

The concentration of each type of hardness can be read from the bar diagram.

$$\text{CCH} = 3.40 \text{ meq/L} = 1.70 \text{ mM} = 170 \text{ mg/L as CaCO}_3$$

$$\text{CNH} = 0$$

$$\text{MCH} = 4.0 - 3.4 = 0.6 \text{ meq/L} = 0.3 \text{ mM} = 30 \text{ mg/L as CaCO}_3$$

$$\text{MNH} = 5.0 - 4.0 = 1.0 \text{ meq/L} = 0.5 \text{ mM} = 50 \text{ mg/L as CaCO}_3$$

4. Estimate the pH needed to reduce Mg^{2+} to less than 10 mg/L as CaCO_3 , or 0.1 mM. Estimate pK_{s0} for $\text{Mg}(\text{OH})_2(\text{s})$ at 15°C using Eq. 13-33.

$$\text{pK}_{s0} = 0.0175 (15) + 9.97 = 10.23$$

Determine the pH corresponding to a Mg^{2+} solubility of 0.1 mM (Eq 13-7).

$$[\text{OH}^-]^2 = K_{s0}/[\text{Mg}^{2+}] = 10^{-10.23}/(0.1 \times 10^{-3}) = 10^{-6.23}$$

$$[\text{OH}^-] = 10^{-3.12} \text{ M}$$

To help drive the reaction to completion, and to neutralize silicic acid and any acidic chemicals added, such as alum or chlorine gas, a slightly higher OH^- concentration, 10^{-3} M , will be used. At 15°C, $K_w = 14.34$ (Eq. 13-40 or Table 3-7). Thus,

$$\text{pH} = -\log (10^{-14.34}/10^{-3.0}) = 11.34$$

5. Estimate chemical doses and solids production for excess lime–soda softening. A good way to do this is to prepare a table summarizing the reactions involved.

Constituent	Conc. (mM)	Equation	Dose (mM)		Solids (mM)		
			CaO	Na_2CO_3	$\text{CaCO}_3(\text{s})$	$\text{Mg}(\text{OH})_2(\text{s})$	
H_2CO_3^*	0.10	13-19	0.10	0.00	0.10	0.00	
CCH	1.70	13-11	1.70	0.00	3.40	0.00	
CNH	0.00	13-15	0.00	0.00	0.00	0.00	
MCH	0.30	13-14	0.60	0.00	0.60	0.30	
MNH	0.50	13-16	0.50	0.50	0.50	0.50	
Excess	—	†	0.50	†	0.50	0.00	
Subtotal						5.10	0.80
Solids remaining in solution						-0.30	-0.10
Total			3.40	0.50	4.80	0.70	

*Since all of the HCO_3^- will be consumed by stoichiometric lime addition, the excess lime dose is that needed to achieve the desired pH value of 11.34, which corresponds to an OH^- concentration of 1.00 mM. Since each mole of lime produces 2 moles of OH^- , an excess lime dose of 0.50 mM is needed. An equivalent amount of Na_2CO_3 could be added to remove the Ca^{2+} ions associated with the excess lime. But in this example, the excess Ca^{2+} ions will be removed during the first stage of two-stage recarbonation and the $\text{CaCO}_3(\text{s})$ solids produced during recarbonation (0.50 mM) are included in the table.

Alternatively the CaO dose can be estimated using Eq. 13-49.

$$[\text{CaO}] = [\text{H}_2\text{CO}_3^*] + [\text{CCH}] + 2[\text{MCH}] + [\text{MNH}] + \text{excess}$$

$$[\text{CaO}] = 0.10 + 1.70 + 2(0.30) + 0.50 + 0.50 = 3.40 \text{ mM}$$

$$(3.40 \text{ mM}) \times (56 \text{ mg/mmol}) = 190 \text{ mg/L}$$

as 100 percent pure CaO. The Na₂CO₃ dose can be estimated using Eq. 13-50.

$$[\text{Na}_2\text{CO}_3] = [\text{NCH}] = 0.50 \text{ mM}$$

$$(0.50 \text{ mM}) \times (106 \text{ mg/mmol}) = 53 \text{ mg/L}$$

as 100 percent pure Na₂CO₃.

Since CaCO₃ and Mg(OH)₂ have different molecular weights, adding their concentrations together in mM or equivalents is of little practical value. The estimated solids production in mg/L of dry solids is

$$\text{CaCO}_3(\text{s}) = (4.80 \text{ mM}) \times (100 \text{ mg/mmol}) = 480 \text{ mg/L}$$

$$\text{Mg}(\text{OH})_2(\text{s}) = (0.70 \text{ mM}) \times (58.3 \text{ mg/mmol}) = 41 \text{ mg/L}$$

$$\text{Total solids (dry weight basis)} = 480 + 41 = 521 \text{ mg/L}$$

Estimates of solids production based on stoichiometric calculations have been found to be reasonably accurate, provided that appropriate adjustments are made when suspended solids, PAC, organic matter, and coagulants also contribute to solids production. See Chap. 22 for additional information regarding the characteristics and handling of lime softening solids.

Prior to recarbonation, the ionic composition of the softened water will be as follows:

0	0.6	1.6	1.8	4.2
Ca ²⁺	Ca ²⁺	Mg ²⁺	Na ⁺	
CO ₃ ²⁻	OH ⁻	OH ⁻	SO ₄ ²⁻	Cl ⁻
0	0.6	1.6	1.8	3.4 4.2

6. Estimate the CO₂ dose required for each stage of two-stage recarbonation.

In the first stage of two-stage recarbonation, the excess lime and Mg(OH)₂ remaining in solution will be converted to CaCO₃(s) and MgCO₃, respectively. From the bar diagram, the required CO₂ dosage will be (Eqs. 13-21 and 13-22)

$$\text{CO}_2 = 1.0 + 0.2 \text{ meq/L} = 1.2 \text{ meq/L}$$

$$(1.2 \text{ meq/L}) \times (22 \text{ mg/meq}) = 26.4 \text{ mg/L as CO}_2$$

A slightly lower CO₂ dose will be needed if an acidic coagulant, such as alum or ferric sulfate, is added to coagulate the CaCO₃(s) produced during the first stage of recarbonation, or if chlorine gas is added to disinfect the water at this point. Following the first stage of recarbonation, the ionic composition will be

0	0.6	0.8	3.2
Ca ²⁺	Mg ²⁺	Na ⁺	
CO ₃ ²⁻		SO ₄ ²⁻	Cl ⁻
0	0.8	2.4	3.2

In the second stage of two-stage recarbonation, the residual CO₃²⁻ will be converted to HCO₃⁻. From the bar diagram, the required CO₂ dosage will be (Eq. 13-23)

$$\text{CO}_2 = (0.8 \text{ meq/L}) \times (22 \text{ mg/meq}) = 17.6 \text{ mg/L as CO}_2$$

The total CO₂ dose for two-stage recarbonation will be

$$\text{Total CO}_2 \text{ required} = 26.4 + 17.6 = 44 \text{ mg/L as CO}_2$$

After the second stage of recarbonation, the ionic composition of the water will be

	0.6	0.8	
Ca ²⁺	Mg ²⁺	Na ⁺	
HCO ₃ ⁻		SO ₄ ²⁻	Cl ⁻
0	0.8	2.4	3.2

If single-stage recarbonation had been used, the excess lime would have been converted to Ca(HCO₃)₂, which would have required an additional 1.0 meq/L of CO₂ (22 mg/L as CO₂), and the finished water would have had the following ionic composition:

	0.6	1.6	1.8	
Ca ²⁺	Ca ²⁺	Mg ²⁺	Na ⁺	
HCO ₃ ⁻			SO ₄ ²⁻	Cl ⁻
0	1.8	3.4	4.2	

Example 13-5 Excess Lime–Soda Softening (Equilibrium Calculations)

For the groundwater described in Example 13-4, estimate the chemical doses on the basis of chemical equilibrium relationships, taking into consideration the effects of ionic strength, temperature, and complex formation.

Solution

1. Determine the initial ionic strength of the water using Eq. 3-6.

Using the ion concentrations determined in Step 3 of Example 13-4, converting the units from mM to M, and substituting into Eq 3-6,

$$\begin{aligned}
 I &= \frac{1}{2} [0.0017(2^2) + 0.0008(2^2) + 0.0014(1^2) + 0.004(1^2) \\
 &\quad + 0.0008(2^2) + 0.0008(1^2)] \\
 &= 0.0097 \text{ M}
 \end{aligned}$$

2. Determine the activity coefficients γ_m and γ_d using Eqs. 13-27 and 13-25.

$$\epsilon = 308.67e^{-0.0045976(273.15 + 15)} = 82.062$$

$$A = 1.82 \times 10^6 (\epsilon T)^{-3/2} = 1.82 \times 10^6 [82.062 \times (273.15 + 15)]^{-3/2} = 0.501$$

$$\log \gamma_z = -Az^2 \left(\frac{\sqrt{I}}{1 + \sqrt{I}} - 0.3I \right) = -0.501z^2 \left(\frac{\sqrt{0.0097}}{1 + \sqrt{0.0097}} - 0.3(0.0097) \right) = -0.0435z^2$$

Thus, $\log \gamma_m = -0.0435$, so $\gamma_m = 0.905$; and $\log \gamma_d = -0.174$, so $\gamma_d = 0.670$

3. Determine pK₁ and pK₂ for the carbonate system and K_w for water at 15°C (288.15K).

The values of pK_1 and pK_2 can be determined using the equations developed by Plummer and Busenberg (1982).

$$pK_1 = 356.3094 + 0.06091964T - 21,834.37/T - 126.8339(\log_{10} T) + 1,684,915/T^2$$

$$pK_2 = 107.8871 + 0.03252849T - 5151.79/T - 38.92561(\log_{10} T) + 563,713 - 9/T^2$$

where T = absolute temperature (kelvin).

At 288.15 K, $pK_1 = 6.419$ and $pK_2 = 10.428$ (consistent with the values shown in Table 3-7).

Using Eq 13-40,

$$pK_w = 4470.99/T + 0.017060T - 6.0875 = 14.345$$

4. Adjust the values of the equilibrium constants determined in Step 3 for ionic strength to obtain concentration-based equilibrium constants.

$$p^cK_1 = -\log \left[\frac{10^{-K_1}}{(\gamma_m)^2} \right] = -\log \left[\frac{10^{-6.419}}{(0.905)^2} \right] = -6.332$$

$$p^cK_2 = -\log \left[\frac{10^{-K_2}}{\gamma_d} \right] = -\log \left[\frac{10^{-10.4228}}{(0.670)} \right] = -10.254$$

$$p^cK_w = -\log \left[\frac{10^{-K_w}}{(\gamma_m)^2} \right] = -\log \left[\frac{10^{-14.345}}{(0.905)^2} \right] = -14.258$$

(A note about rounding: Some of the numbers calculated in this example are technically not accurate to the number of decimal places shown, but rounding numbers prematurely, especially logarithmic values used in subsequent calculations, can cause mass, ion, or species balances to be slightly off, leading to confusion as to the correctness of the calculations.)

5. Determine the concentrations of $H_2CO_3^*$, HCO_3^- , CO_3^{2-} , and $C_{T,C}$.

First determine the hydrogen ion concentration, recognizing that pH is a measure of hydrogen ion activity, not its molar concentration. Thus,

$$[H^+] = (10^{-7.32})/0.905 = 10^{-7.277} \text{ M}$$

Then determine the ionization fractions for the carbonate system using Eqs. 3-48, 3-49, and 3-50 with the concentration-based equilibrium constants obtained in step 4.

$$\alpha_0 = \frac{[H_2A]}{C_{T,C}} = \frac{1}{1 + \frac{cK_1}{[H^+]} + \frac{cK_1 cK_2}{[H^+]^2}} = \frac{1}{1 + \frac{10^{-6.332}}{10^{-7.277}} + \frac{10^{-6.332} 10^{-10.254}}{(10^{-7.277})^2}} = 0.1018$$

$$\alpha_1 = \frac{[HA^-]}{C_{T,C}} = \frac{1}{1 + \frac{[H^+]}{cK_1} + \frac{cK_2}{[H^+]}} = \frac{1}{1 + \frac{10^{-7.277}}{10^{-6.332}} + \frac{10^{-10.254}}{10^{-7.277}}} = 0.8972$$

$$\alpha_2 = \frac{[A^{2-}]}{C_{T,C}} = \frac{1}{1 + \frac{[H^+]}{cK_2} + \frac{[H^+]^2}{cK_1 cK_2}} = \frac{1}{1 + \frac{10^{-7.277}}{10^{-10.254}} + \frac{(10^{-7.277})^2}{10^{-6.332} 10^{-10.254}}} = 0.000946$$

Check the sum of the ionization fractions, which should equal 1.

$$\alpha_0 + \alpha_1 + \alpha_2 = 0.1018 + 0.8972 + 0.000946 = 0.999946 \approx 1$$

Solve for C_{TC} by rearranging Eq. 3-52 and substituting $K_w/[H^+]$ for $[OH^-]$, then, knowing C_{TC} , determine the individual carbonate species from the ionization fractions.

$$\begin{aligned} C_{TC} &= [\text{Alk} - ({}^cK_w/[H^+]) - [H^+]]/(\alpha_1 + 2\alpha_2) \\ &= [(200/50,000 - (10^{-14.258}/10^{-7.277}) - 10^{-7.277})]/[0.8972 + 2(0.000946)] \\ &= 0.004449 \text{ M (or 4.449 mM)} \end{aligned}$$

$$H_2CO_3^* = \alpha_0 C_{TC} = 0.1018(4.449) = 0.453 \text{ mM (or 45.3 mg/L as CaCO}_3\text{)}$$

$$HCO_3^- = \alpha_1 C_{TC} = 0.8972(4.449) = 3.992 \text{ mM}$$

$$CO_3^{2-} = \alpha_2 C_{TC} = 0.000946(4.449) = 0.004 \text{ mM}$$

Check to see that the alkalinity equals 4.00 mM, assuming $[H^+]$ and $[OH^-]$ are negligible.

$$\text{Alk} = HCO_3^- + 2CO_3^{2-} = 3.992 + 2(0.004) = 4.00 \text{ mM}$$

6. Determine C_{TC} and the concentrations of the individual carbonate species after air stripping.

Air stripping to reduce the concentration of $H_2CO_3^*$ to 10 mg/L as $CaCO_3$ (or 0.100 mM) will reduce C_{TC} , increase pH, and increase CO_3^{2-} . The alkalinity will remain unchanged, but it cannot be assumed that C_{TC} will be reduced by the exact difference between the initial and final CO_2 concentrations, since speciation will also change as a result of CO_2 loss and the increase in pH. An accurate calculation can be made using a trial-and-error approach, which is typically done by assuming a pH value, then proceeding as in Step 5 until the desired $H_2CO_3^*$ concentration is obtained and the alkalinity check is correct. For pH values between 6 and 9, as expected here, a good first guess can be made by rearranging the expression for K_1 and substituting the known value (after air stripping) of $H_2CO_3^*$ of 0.1 mM (or $10^{-4.00}$ M) and the approximate molar concentration of HCO_3^- .

$$[H^+] \approx \frac{K_1 [H_2CO_3^*]}{[HCO_3^-]} = \frac{(10^{-6.332})(10^{-4.00})}{\sim 0.00399} \approx 1.17 \times 10^{-8} \text{ M}$$

$$p[H^+] \approx -\log (1.17 \times 10^{-8}) = 7.932$$

$$pH \approx -\log [(1.17 \times 10^{-8})(0.905)] = 7.975$$

Using this pH value as a starting point, it was found, by trial and error using a spread sheet, that a pH of 7.973 gave the best results, which were as follows (calculated as shown in Step 5):

$$[H^+] = (10^{-7.973})/0.905 = 10^{-7.930} \text{ M}$$

$$\alpha_0 = 0.0245 \quad \alpha_1 = 0.9709 \quad \text{and} \quad \alpha_2 = 0.0046$$

$$\alpha_0 + \alpha_1 + \alpha_2 = 1.000$$

$$C_{TC} = 4.081 \text{ mM}$$

$$H_2CO_3^* = \alpha_0 C_{TC} = (0.0245)(4.081) = 0.100 \text{ mM (or 10 mg/L as CaCO}_3\text{)}$$

$$HCO_3^- = \alpha_1 C_{TC} = (0.9709)(4.081) = 3.962 \text{ mM}$$

$$CO_3^{2-} = \alpha_2 C_{TC} = (0.0046)(4.081) = 0.019 \text{ mM}$$

Check to see that the alkalinity equals 4.00 mM, assuming $[H^+]$ and $[OH^-]$ are negligible.

$$\text{Alk} = \text{HCO}_3^- + 2\text{CO}_3^{2-} = 3.962 + 2(0.019) = 4.00 \text{ mM}$$

Calculate acidity (for use in Step 8).

$$\text{Acidity} = 2(0.100) + 3.962 = 4.162 \text{ mM}$$

7. Determine the pH value needed to reduce the soluble Mg concentration to 10 mg/L as CaCO_3 .

This was straightforward in Example 13-4 because only a single Mg species, Mg^{2+} , was considered and ionic strength effects and complexation were ignored. When ionic strength and complex formation are taken into consideration, a computer is typically employed to make iterative calculations since, as the chemical dose is increased to raise the pH, precipitates form and the ionic composition of the water changes, resulting in changes in ionic strength and the concentrations of the species interacting to form complexes. For manual calculations, a good starting point is the approximate composition on the water following lime and soda ash addition, as determined in Step 5 of Example 13-4.

0	0.6	1.6	1.8	4.2	
	Ca^{2+}	Ca^{2+}	Mg^{2+}	Na^+	
	CO_3^{2-}	OH^-	OH^-	SO_4^{2-}	Cl^-
0	0.6	1.6	1.8	3.4	4.2

This water has an ionic strength of 0.0124 M. However, some of the ions shown will actually be present in the form of complexes or solids that have not settled, so it is reasonable to assume that there has been no significant change in ionic strength at this point in the process. Accordingly, the values of the parameters calculated that depend only on temperature and ionic strength will be assumed to be unchanged.

The pH needed to reduce Mg to 10 mg/L as CaCO_3 (10^{-4} M) can be determined using Eq. 13-39 after determining the values of the constants, corrected for the effects of ionic strength and temperature and assuming an appropriate value of $C_{T,C}$. Using Eq 13-33,

$$pK_{s0,\text{Mg}(\text{OH})_2} = 0.0175(15) + 9.97 = 10.233$$

Using Eq 13-35,

$${}^cK_{s0,\text{Mg}(\text{OH})_2} = K_{s0,\text{Mg}(\text{OH})_2} / (\gamma_d \gamma_m^2) = 10^{-10.233} / [(0.670)(0.905)^2] = 1.067 \times 10^{-10}$$

Using the equations in Table 13-5 to obtain temperature-corrected Mg^{2+} complex formation constants, then correcting them for ionic strength as described following Eq 13-40,

$$\begin{aligned} K_7 &= 10^{2.51} & {}^cK_7 &= \gamma_d K_7 = 0.670(10^{2.51}) = 10^{2.33} \\ K_8 &= 10^{1.03} & {}^cK_8 &= \gamma_d K_8 = 0.670(10^{1.03}) = 10^{0.85} \\ K_9 &= 10^{2.91} & {}^cK_9 &= \gamma_d^2 K_9 = 0.670^2(10^{2.91}) = 10^{2.57} \\ K_{10} &= 10^{2.23} & {}^cK_{10} &= \gamma_d^2 K_{10} = 0.670^2(10^{2.23}) = 10^{1.88} \end{aligned}$$

The value of $C_{T,C}$ will depend on the doses of lime and soda ash. Since a practical solubility of $\text{CaCO}_3(\text{s})$ of 30 mg/L was assumed in the problem statement, it will be

assumed that the residual concentration of CO_3^{2-} prior to recarbonation is 30 mg/L as CaCO_3 (or 0.3 mM) and that the small amount of HCO_3^- present is included in the assumed CO_3^{2-} concentration; that is, that $C_{T,C} = 0.3$ mM. Other reasonable assumptions can be made, but some of them result in iterative solutions that are best made using a computer-based model. Assuming that $C_{T,C}$ remains unchanged until after $\text{Mg}(\text{OH})_2(\text{s})$ has precipitated is not a good assumption because $\text{CaCO}_3(\text{s})$ precipitates at the same time and ignoring this fact will cause the concentrations of carbonate and bicarbonate complexes to be significantly overestimated.

Substituting the corrected constants into Eq. 13-39,

$$[\text{Mg}]_T = \frac{{}^c K_{s0,\text{Mg}(\text{OH})_2} [\text{H}^+]^2}{{}^c K_w^2} (1 + {}^c K_w {}^c K_7 / [\text{H}^+] + {}^c K_8 \alpha_1 C_{T,C} + {}^c K_9 \alpha_2 C_{T,C} + {}^c K_{10} [\text{SO}_4^{2-}])$$

$$(0.0001) = \frac{(1.067 \times 10^{-10}) [\text{H}^+]^2}{(10^{-14.258})^2} [1 + (10^{-14.258})(10^{2.33}) / [\text{H}^+] + 10^{0.85} \alpha_1 (0.0003) + 10^{2.57} \alpha_2 (0.0003) + 10^{1.88} (0.0008)]$$

Using a computer to solve for $[\text{H}^+]$, recognizing that α_1 and α_2 are functions of $[\text{H}^+]$,

$$[\text{H}^+] = 10^{-11.35} \quad \text{pH} = -\log[(0.905)(10^{-11.35})] = 11.39$$

$$\alpha_0 = 0.0000 \quad \alpha_1 = 0.0743 \quad \text{and} \quad \alpha_2 = 0.9257$$

and the concentrations of the individual Mg species are

$$\begin{aligned} \text{Mg}^{2+} &= 0.0700 \text{ mM} \\ \text{MgOH}^+ &= 0.0185 \text{ mM} \\ \text{MgHCO}_3^+ &= 0.00001 \text{ mM} \\ \text{MgCO}_3^0 &= 0.0072 \text{ mM} \\ \text{MgSO}_4^0 &= 0.0043 \text{ mM} \end{aligned}$$

The sum of these species is the target Mg concentration of 0.0001 M (10 mg/L as CaCO_3). The most significant Mg complex of those considered, under these conditions, is MgOH^+ (18.5% of the total). Although this complex is commonly added in to obtain the total Mg concentration, it is not clear that this approach is correct. In the studies on which Eq. 13-33 is based, the investigators attempted to exclude CO_2 and foreign substances, including sulfate, from the samples. Thus, the concentrations of MgHCO_3^+ , MgCO_3^0 , and CaSO_4^0 should have been zero or negligible. However, MgOH^+ would have been present in these samples, and it is not clear that it was accounted for separately from Mg^{2+} , since MgOH^+ was commonly ignored in the time period when the experiments were conducted. If MgOH^+ is already included in the calculated Mg^{2+} concentration, then adding it in again will make the pH calculation above slightly inaccurate, though the difference will be small given the other assumptions involved.

8. Determine the doses of lime and soda ash needed to treat this water.

The lime and soda ash doses can be determined by performing chemical balances on the changes in Ca^{2+} , Mg^{2+} , $C_{T,C}$, and acidity during softening, and the calculations can be checked using a balance on alkalinity. The first step is to characterize the carbonate system. Assuming, as before, that $C_{T,C} = 0.0003$ M, and using the pH

of 11.39 and the ionizations fractions obtained in Step 7, chemical equilibrium calculations yield

$$\text{H}_2\text{CO}_3^* = 0.0000 \text{ M} \quad \text{HCO}_3^- = 0.022 \text{ mM} \quad \text{CO}_3^{2-} = 0.278 \text{ mM}$$

$$[\text{H}^+] = -\log[(10^{-11.39})/(0.905)] = 10^{-11.35} \text{ M}$$

$$[\text{OH}^-] = K_w/[\text{H}^+] = (10^{-14.258})/(10^{-11.35}) = 1.234 \text{ mM}$$

$$\text{Alk} = 1.812 \text{ mM} \quad \text{Acidity} = -1.212 \text{ mM} \quad C_{TC} = 0.300 \text{ mM}$$

Thus, lime and soda ash addition, coupled with precipitation of $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$, resulted in the following water quality changes (ignoring complexed OH^- ions):

$$\text{Loss of acidity} = 4.162 - (-1.212) = 5.374 \text{ mM}$$

$$\text{Loss of } C_{TC} = 4.081 - (0.300) = 3.781 \text{ mM}$$

$$\text{Loss of } \text{Ca}^{2+} = 1.70 - 0.8 = 0.90 \text{ mM}$$

$$\text{Loss of } \text{Mg}^{2+} = 0.8 - 0.10 = 0.70 \text{ mM}$$

$$\text{Loss of alkalinity} = 4.000 - 1.812 = 2.188 \text{ mM}$$

The loss of acidity was caused by lime addition, since each mole of lime removes 2 moles (or equivalents) of acidity, and lime was also the source of the OH^- ions removed from the system by precipitation of $\text{Mg}(\text{OH})_2(\text{s})$. Precipitation of $\text{CaCO}_3(\text{s})$ and addition of Na_2CO_3 cause no change in acidity. Thus,

$$\text{CaO dose} = 0.5[(5.374 + 2(0.70))] = 3.387 \text{ mM}$$

The loss of Ca^{2+} was the net result of the increase in Ca^{2+} caused by lime addition and loss of Ca^{2+} associated with precipitation of $\text{CaCO}_3(\text{s})$. Thus,

$$\text{CaCO}_3(\text{s}) \text{ precipitated} = 1.70 - 0.80 + 3.387 = 4.287 \text{ mM}$$

The change in C_{TC} was the net result of adding soda ash and precipitating $\text{CaCO}_3(\text{s})$. Thus,

$$\text{Na}_2\text{CO}_3 \text{ dose} = -(4.081 - 0.300) + 4.287 = 0.506 \text{ mM}$$

These calculations can be confirmed by checking them against the change in alkalinity, recognizing that each mole of lime or soda ash adds 2 moles (equivalents) of alkalinity to the system, while precipitation of a mole of $\text{CaCO}_3(\text{s})$ or $\text{Mg}(\text{OH})_2(\text{s})$ removes 2 moles of alkalinity from the system. Thus,

$$\text{Change in alkalinity} = 2[\text{CaO}] + 2[\text{Na}_2\text{CO}_3] - 2[\text{CaCO}_3(\text{s})] - 2[\text{Mg}(\text{OH})_2(\text{s})]$$

$$= 2(3.387) + 2(0.506) - 2(4.287) - 2(0.7) = -2.188 \text{ mM}$$

This agrees with the value previously calculated; therefore, the calculations are internally consistent.

9. Calculate the CO_2 dose for the first stage of two-stage recarbonation and the resulting pH.

To maximize Ca^{2+} removal in the first stage of two-stage recarbonation (without adding additional Na_2CO_3), the acidity should be increased from a negative value to zero. The acidity of the water leaving excess lime softening is -1.212 mM and each mole of CO_2 (H_2CO_3^*) contributes two moles of acidity. Thus,

$$\text{CO}_2 \text{ dose} = 1.212/2 = 0.606 \text{ mM (or } 26.7 \text{ mg/L as } \text{CO}_2\text{)}$$

Adding CO_2 will not directly affect alkalinity, but will increase $C_{T,C}$ on a 1:1 basis. For each mole of $\text{CaCO}_3(\text{s})$ precipitated, there will be a 2-mole (equivalent) decrease in alkalinity as well as a 1-mole decrease in $C_{T,C}$. Assuming precipitation of 0.60 mM of $\text{CaCO}_3(\text{s})$, leaving a residual calcium hardness of 0.30 mM, or 30 mg/L as $\text{CaCO}_3(\text{s})$, the water leaving the first stage of two-stage recarbonation will have the following characteristics:

$$\text{Alkalinity} = 1.812 - 2(0.60) = 0.612 \text{ mM}$$

$$C_{T,C} = 0.300 + 0.606 - 0.60 = 0.306 \text{ mM}$$

$$\text{Check: } C_{T,C} = \frac{1}{2}(\text{alkalinity} + \text{acidity}) = \frac{1}{2}(0.612 + 0) = 0.306 \text{ mM}$$

The composition of this water is very similar to that shown following the first stage of recarbonation in Step 6 of Example 13-4, the main difference being that HCO_3^- and OH^- are present, whereas only CO_3^{2-} is shown in Example 13-4. Complexes are also present, but are not included in the bar diagram, though they can readily be accounted for in ion, mass, and other balances when using a computer program. The ionic strength of this water is $\sim 0.0048 \text{ M}$, or about half the value prior to softening. Therefore, the constants influenced by ionic strength must be recalculated to accurately estimate the pH value of the water leaving this stage of treatment. Using a spreadsheet to make these corrections and to solve, by trial and error, for a pH value that simultaneously satisfies the constraints on alkalinity, acidity, and $C_{T,C}$ shown, the pH value was found to be 10.44, which is in the expected range.

The effluent from the first stage of recarbonation will be unstable, and more CO_2 will be needed to reach the desired final value of pH, LSI, or CCPP. See Chap. 20 for details.

10. Verify that the desired Ca hardness concentration can be obtained.

In this example, it seems intuitively obvious that the desired residual hardness concentration can be obtained; but in more extreme cases the solubility of $\text{CaCO}_3(\text{s})$ may be sufficiently high, due to the effects of ionic strength, temperature, and complex formation, that the goal cannot be met. This can be checked, as described earlier in this chapter and in Chap. 3, by comparing the ion product Q with the solubility product constant ${}^cK_{s0}$, after making appropriate corrections. The value of $\text{p}K_{s,c}$ at 15°C (288.15K) can be found using Eq. 13-28.

$$\begin{aligned} \text{p}K_{s,c} &= 171.9065 + 0.077993(288.15) - 2839.319/(288.15) - 71.595[\log_{10}(288.15)] \\ &= 8.430 \end{aligned}$$

Using Eq. 13-34 with a value of γ_d of 0.747 (for $I = 0.0048$ and $T = 288.15 \text{ K}$),

$${}^cK_{s0,\text{CaCO}_3} = K_{s0,\text{CaCO}_3}/(\gamma_d^2) = (10^{-8.430})/[(0.747)^2] = 10^{-8.177}$$

Following recarbonation, Ca hardness = 0.300 mM and $C_{T,C} = 0.306 \text{ mM}$. Using a spreadsheet and assuming $I = 0.0048$ and $T = 288.15\text{K}$, the following values were obtained:

$$\alpha_0 = 0.0000 \quad \alpha_1 = 0.4385 \quad \text{and} \quad \alpha_2 = 0.5614$$

$$\text{HCO}_3^- = 0.134 \text{ mM} \quad \text{CO}_3^{2-} = 0.172 \text{ mM} \quad \text{and} \quad \text{OH}^- = 0.134 \text{ mM}$$

$$\gamma_m = 0.930 \quad \text{and} \quad \gamma_d = 0.747$$

Before determining the ion product Q , the concentrations of the Ca complexes must be deducted from the total Ca concentration, and the concentrations of the carbonate complexes must be deducted from the CO_3^{2-} concentration. The concentrations of

the Ca and Mg complexes were determined using the equations in Table 13-5, with the constants corrected for temperature and ionic strength as described earlier, and assuming $Ca_T = 0.30$ mM and $Mg_T = 0.10$ mM, consistent with the treatment objectives. Using a spreadsheet, the concentrations were found to be

$$\begin{array}{ll} Ca^{2+} = 0.253 \text{ mM} & Mg^{2+} = 0.0866 \text{ mM} \\ CaOH^+ = 0.00041 \text{ mM} & MgOH^+ = 0.0025 \text{ mM} \\ CaHCO_3^+ = 0.00024 \text{ mM} & MgHCO_3^+ = 0.00008 \text{ mM} \\ CaCO_3^0 = 0.028 \text{ mM} & MgCO_3^0 = 0.0055 \text{ mM} \\ CaSO_4^0 = 0.019 \text{ mM} & MgSO_4^0 = 0.0053 \text{ mM} \end{array}$$

(When using a more rigorous approach, these results would be used to adjust the concentrations of other species, such as the carbonate species, which would in turn result in changes in ionic strength, pH, and other parameters. Such an approach is greatly facilitated by using a computer model able to solve many equations simultaneously. Only the first iteration is shown here.)

The CO_3^{2-} concentration, when adjusted for the concentrations of the known carbonate complexes, is

$$CO_3^{2-} = 0.172 - 0.028 - 0.0055 = 0.139 \text{ mM}$$

Knowing the concentrations of Ca^{2+} and CO_3^{2-} , Q can be calculated.

$$Q = (0.253 \text{ mM} \times 0.001 \text{ mol/mmol})(0.139 \text{ mM} \times 0.001 \text{ mol/mmol}) = 10^{-7.454}$$

Since $Q > K_{s0}$, further precipitation of $CaCO_3(s)$ can occur, so the goal can be met; and these results suggest that a significantly lower final Ca concentration can be achieved or that the treatment goals could be met using slightly lower doses of CaO and Na_2CO_3 .

An alternative and widely used approach is to assume that the softening process produces an effluent Ca^{2+} concentration in equilibrium with $CaCO_3(s)$, using Eq. 13-38 to determine the lowest total soluble Ca concentration that can be achieved. This approach results in slightly lower estimated chemical doses, but higher dosages will usually be required in practice due to failure to reach equilibrium, the presence of suspended $CaCO_3(s)$ and $Mg(OH)_2(s)$ in the settled water, and the presence of other substances that complex hardness ions or otherwise increase the solubility of $CaCO_3(s)$ or $Mg(OH)_2(s)$. Both approaches, as well as the stoichiometric approach demonstrated in Example 13-4, produce reasonable and similar estimates of the required chemical doses. In practice the operator will in most cases have to use slightly different chemical doses to meet the treatment objectives while minimizing chemical costs. ▲

Two-Stage Softening. *Two-stage softening* consists of excess lime softening followed by a second stage of softening that is actually the first stage of two-stage recarbonation, as shown in Fig. 13-2b. This process variation carries an increased capital cost, relative to single-stage softening followed by single-stage recarbonation, but it offers several advantages including: (1) maximum hardness reduction; (2) reduced CO_2 consumption (since some of the CO_3^{2-} is precipitated as $CaCO_3(s)$ instead of being converted to HCO_3^-); (3) greater resistance to treatment upsets, since problems that arise in the first basin can potentially be addressed as the water passes through the second basin; and (4) a stable, high-quality effluent, due to the increased detention time and an additional opportunity to coagulate,

flocculate, and settle the water after the first stage of CO_2 addition. Two-stage softening is sometimes referred to as *two-stage treatment*, but the term *two-stage treatment* should be avoided because it may also refer to coagulation followed by softening or softening followed by coagulation. When the source water has a high concentration of organic matter, pretreating the water using coagulation, flocculation, and clarification may remove DBP precursors more effectively than softening alone, especially when using straight lime–soda softening rather than excess lime softening; and it may also enhance the softening process, since organic matter can inhibit $\text{CaCO}_3(\text{s})$ precipitation.

Split Treatment Softening. This process conserves chemicals and reduces solids production by fully softening only a portion of the flow. It is commonly considered when removing magnesium, since only a portion of the magnesium typically needs to be removed and the chemical dosages required for magnesium removal are relatively high. In this process, the flow is split, as illustrated in Fig. 13-2c, with one portion receiving excess lime or lime–soda softening and the other portion bypassing excess lime softening. The two streams are then recombined and treated using straight lime or lime–soda softening to remove additional calcium hardness. When the two streams are recombined, the excess lime reduces the lime dosage needed to soften the bypassed flow; CO_2 in the bypassed flow helps neutralize the excess lime carried over from the first stage of treatment, and any extra alkalinity (HCO_3^-) present in the bypassed flow can be used to remove CNH from the stream receiving excess lime treatment, thereby reducing or eliminating the need for soda ash. The first-stage softening basin and the bypass line may be sized to handle only a fraction of the flow, thereby reducing capital costs, but they may also be sized to handle the entire flow to increase operational flexibility. The fraction of the flow bypassing the first stage is determined by performing a mass-balance calculation on magnesium hardness at the point where the flows are recombined; this yields

$$x = \frac{\text{Mg}_f - \text{Mg}_1}{\text{Mg}_r - \text{Mg}_1} \quad (13-52)$$

where x = fraction of water bypassing the first stage

Mg_r = magnesium hardness in the raw (unsoftened) water

Mg_1 = magnesium hardness leaving the first-stage (excess lime) softening unit

Mg_f = magnesium hardness in the finished water (treatment objective)

Split treatment is rarely used to soften surface waters because variations in water quality can make it difficult to maintain the proper split ratio and chemical dosages and to reliably meet treatment objectives for hardness, turbidity, color, and taste and odor. Two-stage softening is more commonly recommended when treating surface waters.

The term *split treatment* is also used to describe situations in which only a portion of the flow is softened before being combined with the remaining flow, which may be treated in parallel, using a different process, or which may remain untreated until the flows are recombined. Such an arrangement is common when only partial softening is needed. The CO_2 in the bypassed flow is used to stabilize the softened water (perhaps only partially), and the combined flows are then coagulated and settled prior to filtration. When treating surface waters in this fashion, the entire flow must be properly coagulated at some point prior to filtration to comply with the requirements of the Surface Water Treatment Rule (Chap. 1). In such cases, recarbonation is often unnecessary, but the filtered water should still be properly stabilized before being pumped into the distribution system.

Example 13-6 Split Treatment Softening

For the groundwater described in Example 13-4, determine the chemical doses required for split treatment softening (Figure 13-2c) assuming the following treatment objectives: Mg hardness = 40 mg/L as CaCO_3 and Ca hardness = 60 mg/L as CaCO_3 .

Solution

1. Determine the fraction of flow bypassing the first stage of softening.

Using Eq 13-52,

$$x = \frac{Mg_f - Mg_i}{Mg_r - Mg_i} = \frac{40 - 10}{80 - 10} = 0.429 \text{ or } 42.9\%$$

Therefore, 57.1 percent of the flow will be treated using excess lime softening in the first stage of softening. In practice, a higher percentage of the flow is typically treated in the first stage to provide greater operational flexibility. Where air stripping is used to remove CO_2 , the bypass stream can also bypass the air stripping process if the utility wishes to use the CO_2 in the bypass stream to recarbonate the water leaving the first stage of softening; but this may not be feasible if air stripping is also used to remove other volatile contaminants from the water.

2. Determine the lime dose to be added to the first stage.

As found in Example 13-4, the lime dose added to the first stage of softening, that is, excess lime softening, will be 3.40 mM (190 mg/L as CaO). However, this dose will be added to only 57 percent of the flow. Based on the total plant flow rate,

$$\text{CaO dose (Stage 1)} = 0.571 \times 3.40 \text{ mM} = 1.94 \text{ mM (or 108 mg/L as CaO)}$$

3. Determine the excess lime leaving the excess lime softening process (Stage 1).

The excess lime dose, from Example 13-4, is 0.50 mM. This lime will be used in Stage 2 to remove $H_2CO_3^*$ and CCH from the bypassed flow. Based on the total plant flow rate, the excess caustic remaining in the effluent from the first stage of softening will be

$$\text{Excess} = 0.571 \times 0.50 \text{ mM} = 0.285 \text{ mM} = 0.571 \text{ meq/L} = 16 \text{ mg/L as CaO}$$

The residual $Mg(OH)_2$ leaving Stage 1 can also be used for softening in Stage 2. It is usually ignored, but will be included in this example to make the ion balance complete.

$$Mg(OH)_2 \text{ (from Stage 1)} = 0.571 \times 0.20 \text{ meq/L} = 0.114 \text{ meq/L}$$

4. Determine the composition of the blended flow entering second-stage softening.

The excess lime will be present in dissolved form, as Ca^{2+} and OH^- ions, at a concentration of 0.285 mM (0.571 meq/L), as found in Step 3. The concentrations of chloride and sulfate will remain unchanged; so will the sodium concentration, since no soda ash was added during the first stage of softening. The initial concentrations of the other constituents, at the blending point, can be determined by performing mass balances:

$$Ca^{2+} \text{ and } OH^- \text{ (from excess lime in Stage 1)} = 0.571 \times 1.0 \text{ meq/L} = 0.571 \text{ meq/L}$$

$$Ca^{2+} + CO_3^{2-} \text{ (not precipitated in Stage 1)} = 0.571 \times 0.6 \text{ meq/L} = 0.343 \text{ meq/L}$$

$$Mg^{2+} \text{ (from bypass)} = 0.429 \times 1.60 = 0.686 \text{ meq/L}$$

$$Mg^{2+} \text{ and } OH^- \text{ (not precipitated in Stage 1)} = 0.114 \text{ meq/L (from Step 3)}$$

$$\text{Total } Mg^{2+} = 0.114 + 0.686 = 0.800 \text{ meq/L (or 40 mg/L as } CaCO_3, \text{ as planned)}$$

$$H_2CO_3^* \text{ (from bypass)} = 0.429 \times 0.2 \text{ meq/L} = 0.086 \text{ meq/L}$$

$$HCO_3^- \text{ (from bypass)} = 0.429 \times 4.0 \text{ meq/L} = 1.716 \text{ meq/L}$$

$$Ca^{2+} \text{ (from the bypassed flow)} = 0.429 \times 3.4 \text{ meq/L} = 1.459 \text{ meq/L}$$

Thus, the composition of the blended water entering second-stage softening (with individual constituents not drawn to scale, for clarity) will be

0.086	↓	0	0.571	↓	0.685	1.028	3.058	3.744	5.144
H ₂ CO ₃ *	Ca ²⁺	Mg ²⁺	Ca ²⁺	Ca ²⁺ (0.571 + 1.459)		Mg ²⁺	Na ⁺		
OH ⁻	OH ⁻	CO ₃ ²⁻	HCO ₃ ⁻ (1.716)		SO ₄ ²⁻		Cl ⁻		
↑	0	0.571	↑	1.028	2.744	4.344	5.144	0.086	

However, the Ca(OH)₂ and Mg(OH)₂ carried over from Stage 1 will react with H₂CO₃* and CCH in the bypassed flow. First, allow the H₂CO₃* to react with excess lime to form CaCO₃.

$$\text{Ca(OH)}_2 = 0.571 - 0.086 = 0.485 \text{ meq/L}$$

Then use the remaining excess lime to remove CCH.

$$\text{Ca}^{2+} = (0.571 + 1.459) - 0.485 = 1.545 \text{ meq/L}$$

$$\text{HCO}_3^- = 1.716 - 0.485 = 1.231 \text{ meq/L}$$

Lastly, use the OH⁻ ions associated with Mg(OH)₂ to remove CCH, recognizing that one equivalent of OH⁻ will react with one equivalent of HCO₃⁻ to precipitate two equivalents of Ca²⁺. Thus,

$$\text{Ca}^{2+} = 1.545 - 2(0.114) = 1.317 \text{ meq/L}$$

$$\text{HCO}_3^- = 1.231 - 0.114 = 1.117 \text{ meq/L}$$

Assuming 0.3 mM of CaCO₃ (0.6 meq/L) remains in solution, the composition of the water after blending but before adding additional lime will be

0	0.600	1.917	2.717	4.117
Ca ²⁺	Ca ²⁺ (1.317)		Mg ²⁺	Na ⁺
CO ₃ ²⁻	HCO ₃ ⁻ (1.117)		SO ₄ ²⁻	
0	0.600	1.717	3.317	4.117

5. Determine the lime and soda ash doses required for the second stage of softening.

The blended water entering the second-stage softening unit contains 1.917 meq/L of Ca²⁺ hardness, or 96 mg/L as CaCO₃, so additional lime will be needed to meet the treatment objective of 60 mg/L as CaCO₃ (1.20 meq/L). Since the blended water is already saturated with CaCO₃(s), the additional dose required to meet the treatment objective is

$$\text{CaO} = 1.917 \text{ meq/L} - 1.20 \text{ meq/L} = 0.717 \text{ meq/L} = 0.36 \text{ mM} = 20 \text{ mg/L as CaO}$$

The additional lime can be added to either stage of treatment. Adding it to the first stage of treatment will reduce the number of lime feeders that must be kept in service.

Soda ash is not needed, since the treatment objective can be met without removing CNH. CNH is present in the blended water even though there was none in the raw water because lime was used to remove MNH in the first stage of softening. Depending on water quality, there may or may not be enough alkalinity available for

removing Ca^{2+} using only lime in the second stage of softening. If not, soda ash can be added or, if the utility wishes to avoid the use of soda ash, the treatment objective for calcium hardness can be relaxed. Soda ash is usually added to the first stage to simplify chemical feeding; but it can also be added to the second stage; this can help maintain the desired solids concentration in the second-stage softening process.

The total lime dose required for both stages of softening is $1.94 + 0.36 = 2.30$ mM, or 32 percent less than required for single-stage excess lime–soda softening in Example 13-4. Furthermore, no soda ash is required, and less CO_2 is required to stabilize the softened water.

- Determine the CO_2 dose required to stabilize the softened water.

The water leaving the second stage of softening has already been partially stabilized using the bypassed flow. It contains 0.6 meq/L of CaCO_3 , which can be converted to $\text{Ca}(\text{HCO}_3)_2$ using a CO_2 dose of 0.6 meq/L, or 13.2 mg/L as CO_2 . The finished water will have the following composition:

	1.20	2.00	3.40	
	Ca^{2+}	Mg^{2+}	Na^+	
	HCO_3^-	SO_4^{2-}		
0	1.00	2.60	3.40	▲

Process Variations Facilitating Lime Recovery. Lime softening plants produce large quantities of solids composed largely of $\text{CaCO}_3(\text{s})$, which can potentially be recovered and recalcined (or “burned,” in a calcining furnace) to produce lime and CO_2 which can be reused on site for softening and recarbonation. Since 2 moles of $\text{CaCO}_3(\text{s})$ are produced for each mole of CCH removed, lime recovery can produce excess lime and CO_2 , which can be sold to a neighboring plant. Furthermore, lime recovery greatly reduces the cost of residuals disposal, which can be substantial. Thus, at first glance, lime recovery appears to be an attractive option, and many utilities practicing lime softening have evaluated the feasibility of lime recovery.

For lime recovery to be feasible, the solids sent to the calcining furnace must consist of relatively pure $\text{CaCO}_3(\text{s})$; otherwise, impurities will build up in the system, adversely affecting finished water quality and making the process inefficient and uneconomical. Lime recovery is not feasible when softening turbid surface waters because $\text{CaCO}_3(\text{s})$ cannot be economically separated from the solids removed from the raw water, but this limitation can potentially be overcome using an appropriate pretreatment system. For low-turbidity waters, magnesium poses the greatest problem, but iron, silica, and other impurities can also interfere with lime recovery (Burris et al., 1976).

Magnesium hydroxide interferes with lime recovery for two reasons. First, it is light and hydrous, making the lime softening residuals difficult to dewater and the dewatered solids too wet for energy-efficient recalcining. A solids content of 70 percent or higher is recommended for recalcination (Pizzi, 1995). Second, recalcining of $\text{Mg}(\text{OH})_2(\text{s})$ produces MgO , which unlike CaO is not useful for softening because MgO simply reverts to $\text{Mg}(\text{OH})_2(\text{s})$ when added to water. Unless magnesium is removed from the system, it will accumulate in the system, making the system increasingly less efficient.

Process variations designed to facilitate lime recovery by removing magnesium from the solids stream sent to the recalcining furnace include (1) three-stage treatment; (2) the Lykken-Estabrook process (Aultman, 1939), which involves using split treatment, discarding the solids from the first stage and calcining solids recovered from the second stage, which is feasible only if a sufficient quantity of $\text{CaCO}_3(\text{s})$ is produced in the second stage; (3) centrifuging the solids to separate the denser $\text{CaCO}_3(\text{s})$ from the lighter solids composed primarily of $\text{Mg}(\text{OH})_2(\text{s})$, aluminum and iron oxides, and organic matter (Sheen and

Lammers, 1944; Burris et al., 1976); and (4) dissolving the $\text{Mg}(\text{OH})_2(\text{s})$ with CO_2 , as is done in the magnesium-carbonate process (Burris et al., 1976).

Lime recovery was practiced or evaluated at a number of lime softening plants in the past (see, for example, Dye and Tuepker, 1971), but by the mid-1990s, fewer than half a dozen were known to be doing so (Pizzi, 1995). The author is aware of two plants currently recovering lime: Miami-Dade County, Florida, employing a variation of three-stage treatment, and Dayton, Ohio, using the magnesium-carbonate process. Other utilities have stopped recovering lime, primarily because it has not been found to be practical or cost effective under local conditions.

Lime recovery requires a relatively large capital expenditure (for the calcining furnace and ancillary equipment); places an additional burden on the operating staff (who must also be trained to properly run a calcining furnace); requires a relatively pure supply of $\text{CaCO}_3(\text{s})$; and can produce poor quality lime if the facilities are not properly designed, constructed, operated, and maintained. Economy of scale is a significant factor, and a lime production rate of at least 45,400 kg/d (50 tons/d) has been cited as a desirable rate for a practical system (Pizzi, 1995). Many lime softening plants are located close enough to a lime supplier that lime recovery saves little in shipping costs. However, if transportation costs and solids disposal costs increase sufficiently, many utilities that soften may decide to take a fresh look at the economics of lime recovery.

Three-Stage Treatment. This process variation, also known as the *Hoover process* and as *two-stage treatment*, has been described by Aultman (1939), by Dye and Tuepker (1971), and in *Hoover's Water Supply and Treatment* (Pizzi, 1995 and earlier editions). Straight lime or lime-soda softening is practiced in the first stage, producing solids consisting primarily of $\text{CaCO}_3(\text{s})$, provided that the raw water is relatively free of turbidity. Excess lime softening is practiced in the second stage, producing both $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$, which are discharged to waste. Recarbonation is considered as the third stage. If two-stage recarbonation is used, relatively pure $\text{CaCO}_3(\text{s})$ solids are also produced in the first recarbonation stage. The solids from the first stage, combined with solids from the third stage, if applicable, are dewatered and recalcined.

The Miami-Dade County Water & Sewer Department recovers lime using a two-stage lime softening process (Segers, 2009). Straight lime softening is used to remove CCH in the first stage, and the solids are centrifuged to concentrate the $\text{CaCO}_3(\text{s})$ to about 70 percent solids, and to remove lighter solids. The concentrated solids are recalcined in one of two calcining furnaces serving a total of three treatment plants. The recalcined lime slakes satisfactorily and contains about 90 to 95 percent available CaO. In the second stage of lime softening, lime and other chemicals (coagulants) are added to increase the removal of color and organic matter (enhanced softening), but little or no magnesium is removed. Single-stage recarbonation is used to reduce the pH of the softened water to the desired value (about 8.9 to 9.1). The high cost of shipping lime to this location contributes significantly to the cost-effectiveness of the lime recovery process.

The Magnesium-Carbonate Process. In this process, also referred to as the *A.P. Black process* in honor of its developer, CO_2 (from the limekiln stack gas) is bubbled through the residual solids to dissolve $\text{Mg}(\text{OH})_2(\text{s})$, converting it into a clear solution of magnesium bicarbonate (Black et al., 1971; Thompson et al., 1972; USEPA, 1975). The CO_2 dosage is controlled to avoid dissolving the remaining $\text{CaCO}_3(\text{s})$ solids, which are concentrated, dewatered, and fed to the limekiln. The magnesium-carbonate solution is recycled back to the lime softening process, where it serves as a coagulant. Excess magnesium bicarbonate can be discharged downstream or converted to $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}(\text{s})$ and sold.

The city of Dayton, Ohio, has used the magnesium-carbonate process since about 1958 (Zell, 2009). The City's lime recovery facility reclaims CaCO_3 from its two large lime softening plants, producing enough lime to supply these plants plus two others and enough CO_2 to run the process and to recarbonate the softened water. Excess lime can be produced

by a lime recovery facility because 2 moles of $\text{CaCO}_3(\text{s})$ are produced for each mole of CCH removed. The city also produced and sold $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}(\text{s})$ in the 1970s, but ceased doing so because chemical prices were too low to justify this practice. Since chemical costs have increased recently, the city plans to reevaluate the economic feasibility magnesium-carbonate recovery.

Aeration Softening. *Aeration softening* is a term that has been used to describe the removal of hardness following air stripping, without lime or soda ash addition (Chao and Westerhoff, 2002). Removing CO_2 by air stripping can cause a water supply to become supersaturated with $\text{CaCO}_3(\text{s})$; this can lead to encrustation of air stripping towers, treatment basins, and filter media, but this also provides a means for removing a limited amount of CCH.

Hot-Process Softening. In hot-process softening the water is preheated, typically to 100°C or higher, in a pressure vessel. Heating the water significantly reduces the solubility of both $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2$, greatly increasing both the rate and extent of hardness removal. Silica is effectively adsorbed by $\text{Mg}(\text{OH})_2(\text{s})$, and a magnesium salt can be added if needed to increase silica removal. Heating also dramatically lowers the solubility of dissolved gases, such as carbon dioxide and oxygen, which can then be readily removed using a deaerator. Removing carbon dioxide results in a proportional reduction in the lime dose required for softening. This process is not used to treat public water supplies, but is commonly employed in certain industrial applications, such as pretreating boiler makeup water prior to demineralization. Anthracite filters are normally used to remove the solids carried over from a hot-process softener, since silica sand is relatively soluble in hot alkaline water and would, therefore, release silica back into the treated water.

Precipitative Softening Systems

Precipitative softening may be accomplished using conventional systems, solids contact basins, or pellet reactors. The best system for a particular application depends on a number of factors including raw-water quality, treatment objectives, and space limitations. See Chaps. 8 and 9 for additional information regarding rapid mixing, flocculation, and sedimentation, and Horsley et al. (2005) for additional information regarding the design of lime softening systems.

Conventional Systems. A conventional softening system includes rapid mixing, flocculation, and sedimentation in sequence, or rapid mixing followed by a flocculator-clarifier (see Chap. 9). Such systems closely resemble those used to coagulate and clarify surface water, but there are important design and operational differences in softening systems.

The purpose of rapid mixing in a lime softening system is to dissolve the lime and to disperse other chemicals, such as soda ash or a coagulant, into the water being treated. In softening systems, rapid mixers may require longer mixing times and can use lower mixing speeds than those used for coagulation. It is important to provide enough time for the lime to dissolve, especially in cold, hard water; and the mixing speed only needs to be high enough to keep the hydrated lime particles in suspension as they dissolve (Reh, 1978). A velocity gradient (G value) of 300 sec^{-1} is generally considered adequate, but higher values may be appropriate when a surface water supply is being simultaneously coagulated and softened.

Flocculators in lime softening systems are typically designed to have higher mixing speeds than those used for coagulation in the absence of softening. Higher speeds are needed to keep the flocculating solids in suspension, since they are typically much denser than those produced by coagulation alone. In systems that recirculate solids to promote growth

of $\text{CaCO}_3(\text{s})$ crystals, individual particles may also be quite large in size. Flocculation time depends not only on flocculation kinetics but also on the amount of time required for the softening reactions to approach equilibrium, which in turn depends on water temperature and on solids recirculation practices. A flocculation time of 30 to 45 min is typical (Horsley et al., 2005), but shorter times may be justified based on local conditions and experience.

Softening solids settle much more rapidly than those typically produced in a coagulation plant, so sedimentation basins in softening plants are typically designed to have significantly shorter contact times and higher surface loading rates, especially when treating groundwater supplies (Recommended Standards, 2007). The rake arms must be designed to withstand the much higher torque associated with high concentrations of dense solids. Larger solids withdrawal pipes are used to handle the larger quantity of solids, to avoid plugging problems, and to facilitate cleaning if plugging does occur. It is recommended that provisions be made to routinely flush the solids withdrawal pipes to prevent solids accumulation. Dissolved air flotation is not used in precipitative softening systems, since softening solids are relatively dense and thus easier to settle than to float, but $\text{CaCO}_3(\text{s})$ is floated in various industrial applications.

In coagulation plants, solids recirculation is generally avoided and may even be prohibited, but in lime softening plants it is generally recommended and widely practiced. Indeed, precipitation of $\text{CaCO}_3(\text{s})$ can be viewed as a crystallization process, and solids recirculation is perhaps the most obvious way to enhance a crystallization process. Advantages of recirculating solids (back to the rapid mixing basin) include

1. Faster reaction kinetics (since the growth rate of $\text{CaCO}_3(\text{s})$ crystals is proportional to the available surface area), resulting in a more stable effluent, improved magnesium removal (Larson et al. 1959; Tuepker and Hartung, 1960), reduced use of chemicals for recarbonation and stabilization, and reduced filter encrustation
2. Elimination of metastable forms of CaCO_3 , since they are unstable in the presence of calcite and once calcite is present it will remain in the system if solids are recirculated
3. Growth of larger, denser $\text{CaCO}_3(\text{s})$ crystals, which reduces the solubility of $\text{CaCO}_3(\text{s})$ and produces a more stable effluent and which also improves both the settleability and the dewaterability of the softening solids
4. Promotion of crystal growth over nucleation, resulting in significantly less scale formation on basin walls and mixing equipment

There are added capital and operations and maintenance (O&M) costs associated with the pumps and piping needed to recirculate solids, but the added costs are generally considered minor relative to the benefits provided.

Some conventional lime softening plants operate without solids recirculation. At some plants treating highly turbid, colored, or algae-laden source waters, recirculating settled solids may exacerbate taste and odor problems, especially if some of the settled solids become anoxic. In other cases, solids recirculation has been found to increase settled water turbidity, perhaps due to an unfavorable interaction between the coagulation and softening processes, which often take place concurrently in a lime softening plant. In such cases it is possible that a change in the coagulation process would rectify the problem. Another potential disadvantage of solids recirculation, one not widely recognized, is that it can potentially diminish removal of trace contaminants by coprecipitation, especially if the contaminants diffuse more slowly than the matrix ions, in this case Ca^{2+} and CO_3^{2-} . A softening system is in essence a crystallizer, and in a crystallizer, solids recirculation promotes the growth of crystals that are not only larger but also purer.

Some individuals have expressed concern that recirculating softening solids will reintroduce previously removed pathogens back into the system and might, therefore, give them

another chance to escape removal, as has been found to happen in some cases involving recycling of filter backwash water. However, lime softening systems and filtration systems are not analogous in this respect. Solids that accumulate in a lime softening system are discharged from the system at the same rate, on average, that they are produced. Solids recirculation is expected to increase the removal of pathogens by providing more opportunities for them to flocculate with other particles and to be removed by sedimentation and discharged with the solids. Pathogens and fine particles that accumulate on a filter do so because they were not previously removed by sedimentation, so there is a good chance they will again fail to settle out if they are recycled, unless they are recycled back to the rapid-mixing basin and given another chance to be coagulated, flocculated, and settled. (Recycling of filter backwash water, practices, regulations, and possible effects are covered in Chap. 10.)

Solids Contact Basins. Spaulding (1937) and other early investigators noted that lime-softened water could be rapidly stabilized by stirring it with finely divided $\text{CaCO}_3(\text{s})$ or by passing it through a rapid sand filter. Seeking ways to relieve supersaturation prior to filtration, Spaulding considered recycling softening solids back to the head of the plant, but rejected this option because in his experience it caused increased taste and odor problems. Reasoning that the stabilizing benefit of downward filtration could also be achieved by “upward filtration through suitable material, which might be calcium carbonate of desirable size or light material coated with calcium carbonate,” he developed a system he called the *Precipitator* (Fig. 13-3). He experimented with various types of media, including coal and activated carbon, which worked well, but found it unnecessary to add media, since $\text{CaCO}_3(\text{s})$ crystals could be effectively retained in a funnel-shaped upflow clarifier. Inside the clarifier he placed an inverted cone, providing space for mixing and flocculation in the same basin with the clarifier. Turbulence from the mixer kept the solids in suspension regardless of the flow rate through the system.

In modern upflow clarifiers of various types, flocculated water flows upward through a suspension of solids, being further flocculated and stabilized by what has been termed *sludge*

FIGURE 13-3 A solids contact clarifier (the Spaulding Precipitator, marketed by Permutit®, a division of Siemens Water Technologies). (Source: Hartung, 1951.)

FIGURE 13-4 A helical flow solids contact basin (the ClariCone®; drawing courtesy of CB&I, The Woodlands, Texas.)

blanket filtration but is more accurately described as *floc blanket clarification*. Such systems are generically referred to as floc blanket clarifiers. Floc blanket clarifiers were once used in both coagulation and softening applications, but the lime softening market has been dominated for many years by similar but distinctly different basins generically referred to as *solids contact basins*, *solids contact clarifiers*, or *reactor clarifiers*. Solids contact basins are designed to recirculate a high concentration of solids internally, typically using turbines and draft tubes. They thereby obtain all the benefits of solids recirculation noted above for conventional systems. Examples of solids contact basins are shown in Figs. 13-3, 13-4, and 9-17.

Although some prefer, for the purpose of discussion, to group floc blanket clarifiers with solids contact basins (e.g., Hartung, 1948), the term *solids contact basins* is used here to refer to systems that internally recirculate a high concentration of solids. Solids contact softening basins typically provide a flocculation time of 15 to 30 min (based on the volume under the cone), a sedimentation time of 1 to 2 hours when used to soften ground water, a sedimentation time of 2 to 4 hours when used to treat surface waters, and a rise rate of 0.4 to 0.72 m/hour (1.0 to 1.75 gpm/ft²), depending on local conditions (Horsley et al., 2005). Helical flow solids contact basins, such as the one shown in Fig. 13-4, share a few similarities with pellet reactors, but they are operated as solids contact basins with the solids kept in suspension hydraulically rather than mechanically.

Solids contact basins are generally more cost effective than conventional systems and are especially attractive when treating waters that do not require turbidity removal, since they can accommodate high loading rates. They generally produce a more stable effluent than a conventional system (Horsley et al., 2005), thereby reducing the chemical costs associated with recarbonation and stabilization, and they are less subject to problems associated

with icing and algae growth. Nevertheless, conventional softening basins are still used, especially for treating turbid surface waters and waters that vary considerably in quality. Conventional systems are commonly found in older plants and in larger facilities with basins built using common-wall construction. Floc blanket clarifiers and flocculator-clarifiers, rather than solids contact basins, are sometimes used for the second stage of two-stage softening, especially when relatively few solids are produced and the primary objective is to coagulate and settle the remaining suspended solids prior to filtration.

A question that frequently arises in connection with solids contact basins is whether separate rapid-mixing basins are needed, given that the chemicals can be added directly to the mixing zone within the basin. Rapid mixing basins are generally not needed for the purpose of softening, especially when treating groundwaters or when treating surface waters pretreated or posttreated using coagulation, flocculation, and sedimentation. However, when coagulating and softening surface waters in the same basin, rapid-mixing basins may be helpful or in some cases necessary. Regulatory agencies may require rapid-mixing basins unless the design engineer can demonstrate that adequate mixing and satisfactory process performance can be obtained without them. Operators may find that rapid mixing is not needed, but before turning off a rapid mixing device or otherwise altering coagulation practices, the appropriate regulatory agency should be consulted to confirm that the actions taken will not compromise the plant's compliance with the Surface Water Treatment Rule (summarized in Chap. 1).

Pellet Reactors. *Pellet reactors*, also known as *pelletizers* and as *fluidized bed crystallizers*, are designed to cause deposition of crystalline solids on a fluidized bed of granular media. They can be used to crystallize a variety of solid phases, but are best suited for those that produce hard, well-formed crystals. In the field of water supply and treatment, they are used primarily, if not exclusively, for softening, and are commonly referred to as *pellet softeners*. They are similar in concept to Spaulding's Precipitator and similar in some ways to solids contact basins, but differ in several important ways: (1) they are seeded with fine, dense media, usually quartz or garnet sand, rather than $\text{CaCO}_3(\text{s})$ or softening solids; (2) the softening chemicals are injected into the water as it enters the bottom of the reactor and are mixed hydraulically rather than mechanically (in a manner favoring crystal growth over nucleation); (3) the solids are withdrawn in the form of relatively large pellets, not as a slurry of finely divided solids; (4) rise rates are typically about 60 to 120 m/hour (25 to 50 gpm/ft²), much greater than those encountered in conventional softening systems and solids contact basins (thus, pellet softeners have a very small areal footprint); and (5) no coagulant is added to (or formed in) the reactor, so suspended solids are not removed.

The pellet reactor shown in Fig. 13-5 is a modified version of the system developed in 1938 by Dr. E. T. Zentner in Czechoslovakia (Powell, 1954). It consists of a conical tank initially loaded with a bed of fine sand, typically about 0.2 mm in diameter. The sand is often referred to as a catalyst because it accelerates crystallization kinetics by increasing the available surface area, but it is not a true catalyst in a chemical sense. The water and chemicals enter tangentially at the bottom of the cone and mix immediately. The water rises through the reactor in a swirling motion, with an upward velocity sufficient to maintain a fluidized bed. As $\text{CaCO}_3(\text{s})$ is deposited on the grains, they gradually grow in size, with each grain consisting of a single sand grain coated with $\text{CaCO}_3(\text{s})$. The larger grains (or pellets) settle toward the bottom of the reactor, where they are drawn off, and fresh seed grains are added to the top of the bed. Some older systems are operated in batch mode, with the entire bed being discharged at the end of a run, but in batch mode performance is reduced at the start and end of a run.

Pellet reactors do not need to have a conical shape. Other types of reactors have been described by Graveland et al., (1983), van der Veen and Graveland (1988), and van Dijk and Wilms (1991). The cylindrical reactor shown in Fig. 13-6 uses nozzles distributed over a

FIGURE 13-5 A conical pellet reactor (the Spiractor™, marketed by Permutit®, a division of Siemens Water Technologies). (Source: Powell, 1954.)

flat-bottomed floor to evenly mix chemicals with the inflowing water; this facilitates the use of caustic soda. As a fluidized bed expands, the settling rate of the particles reaches equilibrium with the interstitial velocity of the upflowing water, just as it does when backwashing a rapid sand filter, so the media will be retained provided that the top of the expanded bed is not allowed to approach the effluent weir. In practice, the rise rate is selected to maximize hardness removal and is significantly lower than the rate at which media loss would occur.

Pellet softeners work well when only calcium hardness is removed because $\text{CaCO}_3(\text{s})$ crystals are relatively hard and dense. A trace of magnesium may be removed by coprecipitation, but precipitation of $\text{Mg}(\text{OH})_2(\text{s})$ must be avoided by keeping the pH sufficiently low. Magnesium hydroxide precipitates as an amorphous or microcrystalline solid that is very light and hydrous, and it does not adhere well to sand or $\text{CaCO}_3(\text{s})$. As a result, it passes out of the reactor, creating a high solids loading on the filters (Harms and Robinson, 1992). For similar reasons, coagulants are not added, so the process is not well suited for treating most surface waters. Ferrous iron is reasonably well removed in concentrations up to 3 mg/L, along with the $\text{CaCO}_3(\text{s})$, if it is precipitated as $\text{FeCO}_3(\text{s})$. However, if dissolved oxygen is present, the iron may be oxidized and precipitated as poorly adhering $\text{Fe}(\text{OH})_3(\text{s})$, which may pass through to the filters (Graveland et al., 1983). The process may perform poorly for waters high in color or NOM, which can soften $\text{CaCO}_3(\text{s})$, but this problem can potentially be alleviated by using a preoxidation step. For the foregoing reasons, pellet reactors are well suited for treating only certain types of water supplies.

Advantages of pellet reactors include their short hydraulic retention time (small areal footprint), relatively low installation cost, and elimination of waste solids. The pellets are large, typically 0.8 to 1.0 mm in diameter, so they can be drained by gravity to 5 to 10 percent moisture, and in some cases as little as 1 to 2 percent. They are well suited for agricultural and other commercial uses (Graveland et al., 1983), so they can be sold as a product rather than disposed of as waste.

Despite the potential advantages of pellet reactors, they are still rarely used in North America. However, they are used by a number of utilities outside the United States, especially in the Netherlands. Operating data for 16 Dutch plants using pellet reactors were

FIGURE 13-6 A cylindrical pellet reactor (the Crystalactor[®]; drawing courtesy of DHV BV Water, The Netherlands.)

reported by van Dijk and Wilms (1991). Interestingly, 11 of them were using caustic soda instead of lime, which cuts solids production in half and conserves alkalinity in waters having CNH (see Softening with Sodium Hydroxide). Under some conditions, including water temperatures below 5°C (van der Veen and Graveland, 1988), use of NaOH in pellet reactors has been found to improve process performance. Use of NaOH is expected to produce higher levels of supersaturation, which could potentially result in the formation of fresh nuclei and solids carryover; but the choice between caustic soda and lime is usually based primarily on local chemical costs, residuals disposal costs, and chemical handling considerations.

Coagulation in Precipitative Softening Processes

Coagulation is an integral part of the precipitative softening process. The solids formed in the softening process must be flocculated and settled, except when using a pellet softener, to avoid overloading the filters. Solids that escape from the process must be properly coagulated so they can be effectively removed by filtration and the finished water turbidity goal can be met. Most precipitative softening plants employ a coagulant dose of about 5 to 15 mg/L of alum or ferric sulfate, 1 to 5 mg/L of polymer, or a proprietary blend of coagulants. Sodium aluminate, activated silica, and ferrous sulfate were commonly used in the past, but are now used infrequently. At most plants a small dose of coagulant (typically a polymer, but sometimes alum or a proprietary coagulant blend) is also added to the filter influent as a filter aid. When using a pellet reactor, a coagulant is typically added after softening, prior to filtration, since coagulants can interfere with crystallization or cause the pellets to be softer and more easily abraded.

Since $\text{Mg}(\text{OH})_2(\text{s})$ acts as a coagulant, an additional coagulant is normally not needed when a sufficient amount of magnesium hardness is being removed; but addition of alum or sodium aluminate has been reported to increase removal of magnesium and silica (Larson and Buswell, 1940; Larson, 1951; Tuepker and Hartung, 1960). Since aluminum hydroxide is relatively soluble at the pH values associated with precipitative softening, aluminum evidently forms other solids, such as aluminosilicates, in lime softening applications (e.g., Larson and Buswell, 1940). Thus, when treating waters low in silica, the potential exists for high residual aluminum concentrations and postprecipitation of aluminum hydroxide.

Alum and ferric sulfate are acidic (see Chap. 8), as is gaseous (elemental) chlorine, which may be used as a predisinfectant. When these chemicals are used, a slightly higher lime dose may be required to achieve a given degree of softening. Alternatively, to avoid adding an acid along with the lime (or other caustic chemical), sodium aluminate, which is alkaline rather than acidic, can be used in place of alum or ferric sulfate, and sodium hypochlorite can be used in place of chlorine gas.

Despite the importance of coagulation in precipitative softening, it is not understood nearly as well as it is in plants that coagulate but do not soften (Chap. 8). Surface water sources are often turbid and may contain pathogens, so at plants treating surface water, the coagulant is often added, sometimes with vigorous mixing, prior to or concurrently with the lime, in an effort to effectively coagulate particles present in the raw water. The basis for this practice, which some regulatory agencies may require, appears to be the assumption that coagulation proceeds in the same manner whether or not the water is softened. However, coagulation clearly differs in precipitative softening plants, since

1. At the pH values associated with precipitative softening, positively charged aluminum and iron hydrolysis products are not expected to form, and it is not clear what species actually do form.
2. The softening solids being coagulated are not present in the raw water but form during treatment, and it can take a significant amount of time for stable crystals to form if the softening solids are not recycled. In fact, it can take a significant amount of time for the lime to dissolve, and adding the coagulant prematurely may hinder crystal growth or cause inefficient use of the coagulant.
3. Particles present in the raw water may serve as nuclei for heterogeneous precipitation, as can also occur during coagulation, but a much greater amount of solids is typically precipitated, providing more opportunity for particles in the raw water to be flocculated and settled.

It may be advantageous in some cases to delay coagulant addition. At some plants, the coagulant is added after the lime, and both the lime and a coagulant are commonly added

directly into the mixing zone when using solids contact basins. Sometimes one order of addition or point of addition works better than another, but this must be determined empirically, since a theoretical basis for determining the optimum point of coagulant addition is lacking.

Process Monitoring and Control

Parameters typically monitored in the raw and finished water at precipitative softening plants include alkalinity, calcium hardness, total hardness, pH, and temperature. Raw water turbidity is normally monitored at plants treating surface water, and settled- and filtered-water turbidities are usually monitored regardless of the water source. Additional parameters commonly monitored for process control purposes include pH in the mixing zone or flocculation basin; pH, alkalinity, and hardness in the settled water; and pH following recarbonation. Samples are collected manually and analyzed in the plant laboratory at some plants, especially those treating groundwater and having a relatively simple control system. Online instrumentation is used at other plants, especially those with a supervisory control and data acquisition (SCADA) system. Many plants use a combination of online and laboratory methods.

The softening process itself is typically controlled using only a small subset of the parameters listed above, with the choice of parameters and their set points based on the specific process variation employed, treatment objectives, and local preferences that may be strongly influenced by past experience with control parameters and the methods and instrumentation used to monitor them. In developing a control strategy, there are many tools to choose from, but the most important consideration is the operator's need to understand the system and to have the proper tools to control it under changing conditions. The lime or soda ash dosage is usually controlled to maintain a particular value of pH, carbonate alkalinity, calcium hardness, magnesium hardness, or hydroxide alkalinity. At a straight lime or lime-soda softening plant or in the first stage of two-stage recarbonation, removal of calcium hardness may be maximized by maintaining an acidity of 0 mg/L as CaCO_3 or a phenolphthalein alkalinity that is half the value of the total alkalinity. The recarbonation process is typically controlled on the basis of measurement of pH or alkalinity following addition of CO_2 or mineral acid. The coagulant dosage is typically selected on the basis of observations of settled water turbidity and the floc characteristics in the mixing zone or flocculator, but it may also be based on jar test results.

Proper control of a precipitative softening process involves more than simply maintaining appropriate chemical dosages. When using quicklime, the slaking process must also be controlled. Incomplete slaking, which can be caused by temperamental lime slakers, poor quality lime, or low water temperatures, can cause degradation of effluent quality and inefficient use of lime. Plugging of chemical feed lines is a common problem when using lime. When using solids contact basins or recycling solids in a conventional system, the solids concentration must be monitored and properly maintained by blowing down excess solids. If the solids concentration is too low, the treated water will be poorly stabilized, settled water turbidity may rise to an unacceptable level, and chemical use may increase. An excessive solids concentration can cause clogging problems and can plug the draft tubes in solids contact basins, causing poor solids recirculation, degradation of effluent quality, and inefficient use of chemicals. Between these extremes, the solids concentration appears to make little difference (Hartung et al., 1951). Solids contact basins are commonly designed to maintain a solids concentration of at least 1 percent by weight in the mixing zone (Recommended Standards, 2007). They are commonly operated to maintain a given volumetric solids concentration in the mixing zone, for example, 10 percent by volume after 10 min of settling, and a higher volumetric concentration in the residuals stream bled to waste.

Settled water turbidity must also be controlled to limit the chemical costs associated with stabilization and to avoid overloading the filters. A high settled water turbidity may indicate that fresh nuclei are forming in the clarifier. This can occur when the softening reactions are not sufficiently complete, which can be caused by a low solids concentration in the mixing zone of a solids contact basin, clogging of a solids return line in a conventional system, or a very low water temperature. A high settled-water turbidity may also indicate that the coagulant dosage needs to be adjusted, but not necessarily that the dosage should be increased. An excessive polymer dosage, for example, can interfere with crystallization of $\text{CaCO}_3(\text{s})$, causing pin floc to form, in which case a further increase will only make matters worse. If the operator is in doubt as to whether to lower or raise the coagulant dosage, jar testing is recommended.

Filtration of Lime-Softened Water

Settled water turbidities at lime softening plants are typically higher than those experienced at coagulation plants. A typical settled water turbidity goal for a softening plant is 2 to 5 ntu, but some plants routinely experience values over 10 ntu. Thus, filters at softening plants may receive relatively high solids loadings. However, this generally does not appear to pose a problem, as the solids are typically small, crystalline, and noncompacting; hence, they are amenable to filtration and compatible with relatively high filtration rates. At plants visited by the author, filter run times of 3 to 4 days are common even when the settled water turbidity exceeds 10 ntu, and the run time is typically selected on the basis of a desire to keep the filters clean and not because they reach terminal head loss or breakthrough of turbidity. However, a filter aid must normally be used to achieve compliance with filtered water turbidity requirements.

A question that often arises regarding filtration of lime-softened water is whether the scale inhibitor, most commonly sodium hexametaphosphate, should be added before or after filtration. Filter encrustation is a common problem at lime softening plants, and adding a scale inhibitor prior to filtration helps to avoid this problem. However, scale inhibitors can also act as dispersing agents, stabilizing colloidal particles and causing an increase in filtered water turbidity. Indeed, at several plants that have experimented with the point of addition, a distinct increase in filtered water turbidity has been observed when adding polyphosphate prior to filtration. Perhaps an adjustment to the dosage of filter aid could counteract this effect. In any event, both approaches (pre- and postfilter addition) are currently practiced, and operators should be aware that when changing the point of addition they may be trading one problem for another.

Precipitative Softening Versus Ion-Exchange and Membrane Softening

Hardness can also be effectively removed by ion exchange and membrane softening. As described in Chap. 12, cation exchange resins in the sodium form are used to soften water, and water can also be demineralized using a combination of cation and anion exchange resins in the hydrogen and hydroxide forms, respectively. As described in Chap. 11, nanofiltration (NF) membranes can remove divalent cations, and are sometimes referred to as *softening membranes*, and reverse osmosis (RO) removes not only hardness but other ions as well. Factors influencing process selection include

- *Raw water hardness.* Chemical costs and residuals disposal costs for precipitative and ion exchange softening increase in direct proportion to the amount of hardness removed. For membrane softening, a higher influent hardness may require higher dosages of acid

or antiscalants to prevent precipitation of calcium and magnesium salts, and a higher pressure may be required, but recovery is likely to be governed by other factors, as is the cost of residuals disposal.

- *Noncarbonate hardness.* The cost of precipitative softening increases when noncarbonate hardness must be removed, since soda ash is more expensive than lime, but for ion exchange and membrane softening, it makes little or no difference whether carbonate or noncarbonate hardness is being removed.
- *Raw water turbidity.* Precipitative softening is compatible with relatively high levels of turbidity, though presedimentation is typically employed to pretreat highly turbid surface waters. Ion exchange and membrane softening require pretreatment to remove particles unless the source water is very low in turbidity, as is the case for most groundwater supplies, which may still require pretreatment with pressure filtration to remove corrosion products or aquifer materials that pass through well screens.
- *Raw water color and NOM.* Precipitative softening partially removes NOM, especially the fraction contributing to color, but high concentrations of NOM can interfere with the crystallization of $\text{CaCO}_3(\text{s})$. Ion-exchange softening resins (cation exchangers) are not adversely affected by color or NOM, but do not remove NOM. NOM tends to foul anion-exchange resins, as well as NF and RO membranes, so pretreatment to remove NOM may be needed when using these materials.
- *Raw water TDS concentration.* High TDS concentrations make calcium and magnesium slightly more soluble (less removable) in precipitative softening processes and can adversely impact ion-exchange softening, since resin selectivity for calcium and magnesium ions decreases as TDS increases. At very high TDS concentrations a cation-exchange resin may even prefer sodium over calcium or magnesium, a phenomenon referred to as *selectivity reversal*. If TDS removal is desired, lime softening can achieve a modest reduction in TDS, as is evident in the bar diagrams in Examples 13-3, 13-4, and 13-6, whereas ion exchange softening increases TDS (since two sodium ions weigh more than the calcium or magnesium ion they are exchanged for). Ion-exchange demineralization and RO can reduce TDS to any desired value.
- *Iron and manganese.* Lime softening effectively removes iron and manganese, but iron and manganese can foul both cation-exchange resins and NF and RO membranes unless pretreatment is provided to remove them.
- *Treatment objectives.* Precipitative, ion-exchange, and membrane softening can all meet typical treatment objectives for municipal water supplies, but only ion-exchange and membrane softening can completely remove hardness. Complete removal of hardness is desirable in certain industrial applications. Lime softening and membrane softening do not increase the sodium concentration, but using soda ash or caustic soda in precipitative softening will increase the sodium concentration, as will ion-exchange softening when using sodium chloride as the regenerant. Softening can influence the corrosivity or scaling potential of the treated water, but regardless of which process is used for softening, the finished water should be properly stabilized as described in Chap. 20.
- *Other constituents requiring treatment.* Precipitative, ion-exchange, and membrane softening are all generally effective in removing divalent cations, but they differ greatly in their ability to remove other contaminants, including silica, fluoride, sulfate, arsenic, chromium, DBP precursors, and other organic and inorganic contaminants. They also differ in their compatibility with other processes that may be needed to remove specific contaminants. See Chap. 5 for process recommendations for contaminant removal.
- *Flow rate and variations in flow rate.* For small systems (households, noncommunity water supplies, small industrial applications, and so forth), ion-exchange softening is the

usual method of choice, but NF and RO systems are often used when other contaminants must also be removed. For mid- to large-size water utilities, lime-softening was routinely selected in the past, but today it is common for utilities to also consider NF (or even RO, for high TDS waters) when building new facilities or rehabilitating existing facilities. Ion-exchange systems have little difficulty handling variable flows, up to their design flow, but both precipitative and membrane softening processes can be adversely affected or difficult to control when the flow rate is highly variable, so additional storage may be required if the demand is highly variable.

- *Process control and operational requirements.* For small systems, especially those that rely on groundwater, ion-exchange and membrane softening are more readily automated and require less operator attention than precipitative softening. For surface water supplies requiring pretreatment, all three options are broadly comparable with respect to process control. Operator training requirements do not vary greatly from one process to another, but different skills are required. A utility may be inclined to select a process that their operators or operators in the area are already familiar with.
- *Options for residuals disposal.* Lime softening produces residual solids, whereas ion-exchange and membrane softening produce residual brines. The cost of residuals disposal is influenced by the type and quantity of waste produced, hauling distances to potential disposal sites, and other factors, as described in Chap. 22. Some disposal options may not be environmentally or socially acceptable. Efforts to control salinity and encourage water reuse, especially in water-short areas, have recently led to limits on brine discharges and in some cases to bans on domestic ion-exchange softeners (e.g., Force, 2009). Efforts are underway to address these challenges.
- *Cost.* Both capital and O&M costs are strongly influenced by many of the factors mentioned here. Process selection is typically based on overall cost, taking non-economic environmental, and social concerns into consideration through public hearings and other appropriate means.

Since precipitative softening removes both particles and organic matter, it is suitable as a pretreatment process for ion-exchange demineralization and membrane processes. It is rarely used ahead of an ion-exchange softening process, except in certain industrial applications where the source water is turbid or colored and complete removal of hardness is desired or, as described by Pizzi (1995), when it is more economical to remove noncarbonate hardness using ion exchange rather than soda ash addition. Kweon and Lawler (2002) found that an increased degree of softening resulted in increased NOM removal and also increased flux (reduced fouling) through an ultrafiltration membrane. Similar results are expected for other types of membranes.

Removal of Organic Contaminants by Precipitative Softening Processes

Precipitative softening can also remove certain organic contaminants, including a fraction of the natural organic matter (NOM) present in every natural water supply. NOM removal is important because NOM reacts with chemical oxidants, exerting an oxidant demand and forming DBPs. Formation of one group of DBPs, the trihalomethanes (THMs), is of particular concern because THM formation is catalyzed by the high-pH environment associated with precipitative softening. NOM can also impart color to the water, transport metal ions, serve as a food source for bacteria, and foul anion-exchange resins and membranes. Additional information regarding regulation of DBPs and other contaminants, the health effects of regulated contaminants, and the characteristics of NOM can be found in Chaps. 1, 3, and 19.

Removal Mechanisms. Organic contaminants may be present in water in either a solid (particulate) or dissolved state. As described in Chap. 3, organic contaminants in water are collectively measured as total organic carbon (TOC), with the dissolved fraction measured as dissolved organic carbon (DOC). Particulate organic carbon (POC) is the difference between TOC and DOC.

In precipitative softening processes, particles (both organic and inorganic) are removed by coagulation, flocculation, and sedimentation, with a subsequent filtration process removing most of the particles that fail to settle. Coagulation is an essential part of precipitative softening, since the solids formed in the process (except in pellet reactors) must be coagulated so they can be effectively removed by sedimentation and filtration. The coagulation mechanisms involved are the same as those described in Chap. 8. For practical purposes, POC can be considered to be completely removed in treatment plants employing precipitative softening, since filtered-water turbidities are typically so low that the POC concentration is negligible. Even when coagulation is done poorly in the softening process itself, coagulant addition prior to filtration allows nearly all of the remaining solids to be captured on granular media filters.

Dissolved organic (and inorganic) contaminants can be removed by precipitative softening only if they are first converted into solid form. The major mechanisms for accomplishing this are precipitation and coprecipitation, which were described earlier in this chapter. Most if not all organic contaminants lack the size and other characteristics to be incorporated into, or dissolved into, the crystal structure of softening solids. Therefore, organic chemicals are expected to be coprecipitated only if they are able to adsorb onto the softening solids as they precipitate (occlusion) or after they precipitate (surface adsorption).

NOM and other organic contaminants can potentially be removed by precipitation (formation of insoluble calcium or magnesium salts), coprecipitation, or adsorption onto previously formed CaCO_3 or $\text{Mg}(\text{OH})_2(\text{s})$ (Liao and Randtke, 1985; 1986; Russell et al., 2009). Liao and Randtke (1985) argued that coprecipitation is expected to be the dominant mechanism in precipitative softening systems due to the large surface area of the softening solids during the initial moments following chemical addition. They observed that most of the removal of a fulvic acid occurred in less than 1 min and that the Ca^{2+} concentration dropped very rapidly during the initial moments of the reaction. Any organic molecules initially able to be precipitated would also be readily incorporated into the solids by coprecipitation under these conditions, and the opportunity for coprecipitation by adsorption and occlusion would be much greater in the initial moments of the softening reaction than it would be after the solids were fully formed.

Mechanisms that may influence the removal of a limited number of organic contaminants include polymerization and hydrolysis. Some organic chemicals, such as certain polyphenols, can potentially be removed by polymerizing them (chemically or enzymatically) into large insoluble molecules (Liao and Randtke, 1986), and some of the reactions involved may be promoted by a high-pH environment or by the presence of oxidants (e.g., Chrostowski et al., 1983). Similar reactions are involved in the formation of humic substances in the environment. Polymerization may play a role in the removal of organic chemicals from certain industrial wastes, but it is unlikely to be significant in the removal of DOC or trace contaminants from drinking water by precipitative-softening processes because the concentrations of chemicals able to react in this manner are expected to be negligible in drinking water supplies. A limited number of organic chemicals may hydrolyze in the high-pH environment associated with precipitative softening, and Johnson and Randtke (1983) demonstrated that this was the case for a fraction of the total organic halogen produced by prechlorination. This mechanism is expected, however, to play little or no role in the removal of DOC or most organic contaminants from drinking water by precipitative softening.

Factors Influencing TOC Removal. Removal of TOC depends on the fraction that is particulate (POC), since this fraction will be completely removed; on the removability of the dissolved fraction (DOC); and on treatment conditions. TOC removals of 50 percent

or more are commonly obtained when softening highly turbid surface waters, which may contain organic-laden clay particles or high concentrations of algal cells, or when softening highly colored waters. Lower TOC removals, in the range of 15 to 30 percent, are commonly observed when treating relatively clear waters containing little POC or color. The DOC in clear surface water supplies is generally less amenable to removal, perhaps due to the source of the DOC, to bleaching by sunlight (fragmentation by free radical reactions), or to microbial activity. DOC in groundwater supplies low in color tends to be poorly removed by precipitative softening processes.

The characteristics of DOC influencing its removal by lime softening are the same as those influencing its removal by coagulation (Chap. 8). Precipitative softening preferentially removes the fraction of DOC that is higher in molecular weight, more hydrophobic, higher in color and UV absorbance, and capable of binding Ca^{2+} ions more strongly (Liao and Randtke, 1985; Randtke, 1988; Thompson et al., 1997; Shorney et al., 1999; Randtke, 1999; Kalscheur et al., 2006; Russell et al., 2009). The ability to bind Ca^{2+} depends on the nature and density of the functional groups involved. Dissociated carboxylic acids (carboxylate ions) are known to have a relatively strong affinity for Ca^{2+} ions; but low-molecular-weight carboxylate ions tend to form relatively soluble complexes that are poorly removed by precipitative softening, as are relatively insoluble compounds that are unable to complex Ca^{2+} or CO_3^{2-} (Liao and Randtke, 1986).

Treatment-related factors influencing DOC removal (or, in some studies, TOC removal) by precipitative softening processes include

1. *Lime dose.* As the lime dose increases, more solids are formed, providing greater surface area for adsorption (coprecipitation) of DOC, so DOC removal typically increases with increasing lime dose, up to a maximum beyond which additional lime has little or no effect on removal. Typical results are shown in Fig. 13-7. As the lime dose increases,

FIGURE 13-7 Removal of TOC, calcium, and magnesium by lime softening. (Data-point labels are treated water pH values, the water source was the Missouri River at Kansas City, Missouri, and no supplemental coagulants were added.) (Source: Shorney et al., 1999.)

the solution pH increases, magnesium removal increases, the carbonate concentration decreases, and the calcium concentration eventually begins to increase as well (once most of the carbonate has been precipitated); and these water quality changes also contribute to increased DOC removal, as discussed below. Mustafa and Walker (2006) found that some grades of lime were more effective than others and suggested that this was related to the available Mg content of the lime.

2. *pH*. As pH increases, DOC removal tends to increase. This is attributable to increased dissociation of NOM, enabling it to bind more strongly to Ca^{2+} ions; to increased precipitation of $\text{Mg}(\text{OH})_2(\text{s})$ and a reduction in the carbonate concentration, both discussed below; and to an increase in Ca^{2+} ions in vicinity of the $\text{CaCO}_3(\text{s})$ surface, which helps to neutralize the surface charge of the solids (or makes them positively charged) and also helps to coprecipitate additional DOC (Liao and Randtke, 1985; Russell et al., 2009).
3. *Magnesium removal*. Many studies have shown that precipitation of $\text{Mg}(\text{OH})_2(\text{s})$ helps to remove organic matter (e.g., Liao and Randtke, 1985; Thompson et al., 1997; Shorney et al., 1999; Kweon and Lawler, 2002; Roalson et al., 2003). $\text{Mg}(\text{OH})_2(\text{s})$ is precipitated as a noncrystalline solid having a much greater surface area than an equivalent mass of $\text{CaCO}_3(\text{s})$, and it is also positively charged, facilitating adsorption of organic anions. (Most NOM is anionic, though individual molecules may be nonionic or cationic.) Incorporating Mg^{2+} into $\text{CaCO}_3(\text{s})$ crystals may also improve their ability to remove organic contaminants (Liao and Randtke, 1985; Russell et al., 2009). Russell et al. (2009) found that $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$ were capable of achieving the same maximum removal of NOM but that a much greater mass of $\text{CaCO}_3(\text{s})$ was needed to achieve the same degree of removal, and they also suggested that some plants might be able to increase NOM removal by adding magnesium.
4. *Carbonate removal*. As lime is added, CO_3^{2-} ions are formed, from the HCO_3^- ions (alkalinity) naturally present in the water, but they are also consumed as $\text{CaCO}_3(\text{s})$ precipitates. Eventually, a point is reached where the supply of carbonate is depleted and the Ca^{2+} concentration begins to increase. This promotes DOC removal because CO_3^{2-} competes with DOC for adsorption sites, while Ca^{2+} can help to remove DOC by both precipitation and coprecipitation (Liao and Randtke, 1985).
5. *Soda ash addition*. Adding soda ash can hinder DOC removal by increasing the carbonate concentration (Randtke et al., 1982; Liao and Randtke, 1985; Russell et al., 2009). Therefore, DOC removal in the primary softening basin can potentially be increased by eliminating use of soda ash (and accepting a higher finished water hardness), by delaying soda ash addition until the second stage of softening, or by substituting two-stage recarbonation for soda ash addition. However, for waters containing high concentrations of noncarbonate hardness, soda ash addition may increase DOC removal by precipitating additional solids and increasing the opportunity for DOC to be coprecipitated.
6. *Solids recirculation*. Solids recirculation should inhibit DOC removal, since it promotes crystal growth over nucleation, which is expected to inhibit both precipitation and coprecipitation of organic contaminants. The $\text{CaCO}_3(\text{s})$ lattice ions, Ca^{2+} and CO_3^{2-} , are small and will diffuse to the crystal surfaces more rapidly than the larger organic contaminant molecules; this results in purer crystals and reduced removal of contaminants. In fact, solids recirculation is used in industrial crystallization processes to help make purer crystals. Liao and Randtke (1985) found that that recirculating softening solids reduced DOC removal, and Roalson et al. (2003) found that it had no effect. Mustafa and Walker (2006) observed increased DOC removal as increasing amounts of softening sludge were added during jar testing, but magnesium removal also increased; thus, the increase in DOC removal was attributable to increased precipitation of $\text{Mg}(\text{OH})_2(\text{s})$ and it is not clear that the results are applicable to solids recirculation in a full-scale plant.

7. *Mixing.* Mixing intensity is expected to have little or no effect on DOC removal by precipitative softening processes, and Randtke et al. (1982) found this to be the case for removal of a fulvic acid. The reactions responsible for DOC removal occur at a molecular level and are not expected to be significantly influenced by agitation of the bulk solution. However, a minimal amount of mixing is helpful because the opportunity for contaminant molecules to be coprecipitated will be reduced if the contaminants are not present in the immediate vicinity of the softening solids as they are precipitated.
8. *Coagulant addition.* Coagulant addition can enhance DOC removal. However, as noted earlier in this chapter, coagulation is an integral part of precipitative softening, and softening solids must be coagulated to achieve satisfactory settled- and filtered-water turbidities. $Mg(OH)_2(s)$ is an effective coagulant, so it is not necessary to add an additional coagulant when practicing excess lime softening. At most lime-softening plants, alum, ferric sulfate, or a polymer is added as a coagulant. Increasing the coagulant dosage beyond that required to achieve a satisfactory filtered-water turbidity or changing from one coagulant to another is expected to have little or no effect on DOC removal. Shorney et al. (1999) found that a 10- to 15-mg/L dose of alum or ferric sulfate increased TOC removal by an average about 15 percent, relative to softening with no coagulant addition. These dosages are typical of those normally employed in practice. Taylor et al. (1984) found that adding 20 mg/L of alum increased TOC removal by approximately 10 percent when using the magnesium carbonate process, but further alum addition removed no more TOC and resulted in soluble aluminum in the finished water. Other investigators have reported that higher coagulant dosages increased DOC or TOC removal, but in some cases it is not clear that the results are applicable to full-scale systems. For example, Qasim et al. (1992) observed increasing TOC removal with an increasing dose of ferric sulfate, but the filtered-water turbidities were in excess of 2 ntu at all doses below the maximum dose tested, and relevant variables, such as lime dose and magnesium removal, were not reported. There are indications that the timing of coagulant addition influences TOC removal by softening (Randtke, 1999), but until more information is available, the recommended approach is to determine the optimum dose and order of addition empirically, that is, by conducting bench-, pilot-, or full-scale tests on the water being treated. In summary, increasing the coagulant dose or changing coagulants may slightly increase DOC or TOC removal. However, chemical costs, solids production, and possible effects of coagulant overdosing (such as clogging of filter underdrains, postprecipitation of aluminum hydroxide, and increased settled water turbidity) should also be considered.
9. *Preoxidation.* Oxidants such as chlorine, ozone, and chlorine dioxide can increase or decrease the removal of DOC by coagulation, depending on the oxidant dose, characteristics of the organic matter, and water quality (Randtke, 1988; Edwards and Benjamin, 1992; Edwards et al., 1994). Little is known about the effects of preoxidation on removal of DOC by precipitative softening processes, but Johnson and Randtke (1983) found that prechlorination reduced removal of TOC from three different water sources by an average of nearly 10 percent.

Several of these factors were experimentally examined by Liao and Randtke (1985), and the results of one set of experiments are presented in Table 13-6. TOC removal was found to increase with pH, a higher Ca^{2+} concentration, a delay in the addition of soda ash, and addition of magnesium or phosphate. TOC removal was lower in a carbonate-rich environment or when softening solids, produced in prior jars tests under the same conditions, were recycled.

Enhanced Softening. The Stage 1 Disinfection/Disinfectants By-Products Rule (Stage 1 D/DBP Rule) (Chap. 1) requires precipitative-softening plants that treat surface water

TABLE 13-6 Effects of Operational Changes on the Removal of Groundwater Fulvic Acid and Water Hardness by Lime Softening

Process variable	TOC removed, %	Residual hardness, mg/L as CaCO ₃
pH		
9	28	25

(or groundwater under the direct influence of surface water) to practice enhanced softening if they use conventional filtration (USEPA, 1998). This requirement can be met by achieving a specified TOC removal depending on raw water TOC and alkalinity (see Table 8-1) and/or by meeting one of the alternative performance criteria for coagulation, based on TOC or specific UV absorbance in the raw or finished water or on finished water DBP concentrations (Chap. 8; USEPA, 1998 and 1999; Pontius and Diamond, 1999); or by meeting one of the two additional alternative performance criteria established for lime softening: (1) softening that reduces the treated water alkalinity to less than 60 mg/L as CaCO₃ or (2) softening that achieves a magnesium hardness removal of at least 10 mg/L as CaCO₃. For precipitative softening, there is no Step 2 procedure (a jar test procedure for determining the point of diminishing returns in TOC removal as the dosage increases) as there is for coagulation. The rule does not require plants practicing conventional lime softening to change to lime-soda softening or excess lime softening to attempt to remove more TOC, as this would require a plant to operate under conditions for which it was not designed.

If the enhanced softening requirements of the Stage 1 D/DBP Rule are not being met, relatively simple options to change the process to meet them include increasing the lime dose, reducing or eliminating soda ash addition, and changing the coagulant type, dosage, or point of addition. Increasing the lime dose can increase TOC removal in several ways, and, in many cases, a relatively modest increase in the lime dose will result in compliance with one or more of the alternative performance criteria. Reducing or eliminating soda ash addition or changing the coagulation process may result in only a slight increase in TOC removal, but that may be all that is needed. These and other relatively simple options can be evaluated using bench-scale tests, following protocols such as those for enhanced softening described by the USEPA (1999). Shorney et al. (1999) found that, for both softening and coagulation, TOC removals observed in bench-scale tests agreed well with those measured

in full-scale plants; and Liao and Randtke (1985) found the bench- and full-scale results for the one softening plant they studied to agree to within 1 percent.

Shorney et al. (1996) found that excess lime softening removed, on average, 18 percent (or 0.5 mg/L) more TOC than conventional lime softening, on the basis of bench-scale testing of five source waters. However, this required an increase in the average lime dose from 88 mg/L as CaO for conventional lime softening to 175 mg/L as CaO for excess lime softening. Most treatment plants are not equipped to handle such a large increase in lime dose or to handle all the additional solids that excess lime softening would produce. Before making such a drastic change, a utility might wish to consider other options, such as changing the raw water source or replacing both precipitative softening and conventional rapid sand filtration with a membrane softening system, especially if these options also offer other site-specific advantages. It is generally best to evaluate the simplest and least expensive options first and to evaluate expensive and more complicated options as part of a utility's long-term planning process.

Softening Versus Coagulation. Softening and coagulation remove similar types of organic contaminants, and when using the chemical dosages typically employed in practice, they generally remove similar amounts of TOC from a given source water. However, coagulation with high dosages of metal salt coagulants has generally been found to remove more TOC than high-pH lime softening (e.g., Taylor et al., 1986; Semmens and Staples, 1986; Shorney, 1998; Shorney et al., 1999), as illustrated in Fig. 13-8. Thus, in plants employing separate coagulation and softening processes, coagulation may be able to remove a small fraction of TOC not removable by precipitative softening. In plants employing both processes, the coagulation process should be placed ahead of the softening process, as this will reduce THM formation (which is base catalyzed) and improve the performance of the

FIGURE 13-8 TOC removal by lime softening and by coagulation with alum and ferric sulfate. (Data-point labels are treated water pH values; the water, drawn from Clinton Lake, Kansas, had an initial alkalinity of 112 mg/L as CaCO_3 , $\text{Ca}^{2+} = 100$ mg/L as CaCO_3 , and $\text{Mg}^{2+} = 29$ mg/L as CaCO_3 .) (Prepared using data from Shorney, 1998.)

softening process by removing NOM. NOM inhibits softening by complexing Ca^{2+} and Mg^{2+} and interfering with the formation of $\text{CaCO}_3(\text{s})$ crystals (Randtke et al., 1982; Liao and Randtke, 1985; Lin et al., 2005; Hsu and Singer, 2009).

Removal of Organic Chemical Contaminants. Precipitative softening processes have the potential to remove organic chemicals able to adsorb onto $\text{CaCO}_3(\text{s})$ or $\text{Mg}(\text{OH})_2(\text{s})$. Liao and Randtke (1986) found that softening was generally effective in removing compounds that formed relatively insoluble complexes with Ca^{2+} and higher-molecular-weight or polymeric compounds having acidic oxygen-containing functional groups able to facilitate their adsorption onto $\text{CaCO}_3(\text{s})$. Most regulated organic contaminants, as well as most other organic chemicals of concern to the drinking water community, adsorb onto $\text{CaCO}_3(\text{s})$ poorly or not at all, and those able to interact with Ca^{2+} or CO_3^{2-} ions tend to form soluble complexes that are poorly adsorbed.

Organic chemicals can usually be better removed by adsorption on powdered activated carbon (PAC) than by precipitative softening. PAC is compatible with the softening process, but its performance may be influenced by the point of addition. In general, it is better to add the PAC well before or after adding the lime. If lime and PAC are added simultaneously, $\text{CaCO}_3(\text{s})$ crystals will form on the surface of the PAC and may slow diffusion of the contaminants to the PAC surface. Randtke et al. (2004) found greater removal of atrazine when the PAC was added some time after the lime, presumably because lime softening removed a fraction of the TOC that was competing with atrazine for adsorption sites. On the other hand, Pan et al. (2002) found that the timing of PAC and lime addition had no significant effect on removal of geosmin and 2-methylisoborneol. The optimum point of addition for a given application is best determined by bench-, pilot-, or full-scale testing of the water to be treated, taking into consideration possible chemical addition points and the availability of mixing adequate to keep the PAC in suspension.

Residuals

Precipitative softening processes typically produce residuals composed primarily of $\text{CaCO}_3(\text{s})$ and, if Mg is removed, $\text{Mg}(\text{OH})_2(\text{s})$. Residuals composed mostly of $\text{CaCO}_3(\text{s})$ are dense, stable, and relatively easy to thicken and dewater; but $\text{Mg}(\text{OH})_2(\text{s})$, coagulants, and organic matter make softening residuals more difficult to thicken and dewater. Stoichiometric estimates of solids production (see Example 13-4) have been found to be reasonably accurate when one accounts for significant contributions of coagulants, suspended solids, organic matter, and PAC. See Chap. 22 and AWWA and ASCE (2005) for additional information regarding the quantities, characteristics, handling properties, and disposal of precipitative softening residuals, as well as those produced by ion-exchange and membrane softening.

OTHER APPLICATIONS

Precipitative softening can remove other contaminants besides calcium, magnesium, and NOM. A variety of trace contaminants can be removed by other precipitative processes, including those coprecipitated with metal hydroxides formed by metal salt coagulation (Chap. 8) or by oxidation of iron and manganese (Chap. 7). Removal of NOM by coagulation is addressed in Chap. 8. Inorganic contaminants that can be removed by precipitative processes include

- *Regulated inorganic chemicals (IOCs)*. Coagulation and lime softening can, under certain conditions, effectively remove a number of IOCs from drinking water, including

arsenic, barium, cadmium, chromium, lead, mercury, and selenium (Sorg, 1977; Sorg and Logsdon, 1980; AWWA, 1988), and these processes are designated as best available technologies (BATs) for several IOCs. Table 13-7 summarizes IOC removals achieved by coagulation and lime softening, under selected conditions, based on reports by Sorg (1977) and Sorg and Logsdon (1980). Additional information regarding IOCs and their removal can be found in several other chapters in this handbook.

- *Metal ions.* Many metal ions, including those regulated as IOCs, can be effectively removed by precipitation or coprecipitation. The ligands most commonly utilized to precipitate metal ions are hydroxide, carbonate, silicate, and sulfide. Each of these ligands increases in concentration as pH increases, so adding a caustic chemical (usually lime) to increase pH is the most common way to promote precipitation of metal ions. However, due to complex formation, some metal ions become more soluble as pH increases beyond a certain point, as discussed previously. Therefore, an optimum pH for precipitation may exist. Also, some metal ions form insoluble phases with other ligands. For example,

TABLE 13-7 Effectiveness of Chemical Coagulation and Lime Softening for Inorganic Contaminant Removal

Contaminant	Process	Approximate removal, %
Arsenic		
As ³⁺	Oxidation to As ⁵⁺ required for effective removal	—
As ⁵⁺	Ferric sulfate coagulation, pH 6–8	>90
	Alum coagulation, pH 6–7	>90
	Lime softening, pH > 10.8	>95
	Lime softening, pH < 10.8	30–95
Barium	Lime softening, pH > 10–11	>90
Cadmium	Ferric sulfate coagulation, pH > 8	>90
	Lime softening, pH 8.5–11.3	>95
Chromium [†]		
Cr ³⁺	Ferric sulfate coagulation, pH 6.5–9.3	>98
	Alum coagulation, pH 6.7–8.5	>90
	Lime softening, pH 10.6–11.3	>98
	Lime softening, pH < 10.6	70–95
Cr ⁶⁺	<i>Ferrous</i> sulfate coagulation, pH 6.5–9.3 (pH may have to be adjusted after coagulant addition to promote reduction to Cr ³⁺)	>98
Lead	Ferric sulfate coagulation, pH 6–9	>97
	Alum coagulation, pH 6–9	80–90
	Lime softening, pH 8.5–11.3	>98
Mercury, Hg ²⁺	Ferric sulfate coagulation, pH 7–8	66–97
	Alum coagulation, pH 7–8	38–47
	Lime softening, pH 10.7–11.4	60–80
Selenium, Se ⁴⁺	Ferric sulfate coagulation, pH 6–7	60–80
	Lime softening, pH 9.5–11.3	20–40
Silver	Ferric sulfate coagulation, pH 7–9	70–80
	Alum coagulation, pH 6–8	70–80
	Lime softening	80–90

Note: Approximate removals are based on a limited number of laboratory experiments and/or pilot-plant or full-scale data. Removal is expected to vary with water quality, pH, contaminant concentration, chemical dosages, temperature, and other treatment conditions.

[†]Oxidation of Cr³⁺ to Cr⁶⁺, e.g., by chlorination, will impair removal.

Source: Based on Sorg (1977) and Sorg and Logsdon (1980).

barium can be readily precipitated using a small amount of sulfate, and phosphate is commonly removed from lake water and wastewater effluents by precipitating aluminum phosphate. Sulfide imparts an offensive odor, exerts a strong oxidant demand, and is more complicated and expensive to use than other alternatives for removing trace metals from drinking water supplies, so its use is normally limited to industrial applications. However, sulfide often limits metal solubility under anaerobic conditions, such as those sometimes found in a groundwater supply or in the hypolimnion of a eutrophic lake.

Most metal ions in drinking water supplies are present only in trace concentrations. Sometimes they must be removed by coprecipitation because precipitation is either not possible or not practical. However, they can often be conveniently removed by a process already being used for another purpose, such as coagulation, precipitative softening, or oxidation of iron and manganese. In some cases, the required degree of removal can be accomplished at no additional cost, although in other cases increased chemical dosages or pH adjustments may be necessary to meet treatment objectives. In addition to the IOCs shown in Table 13-7, other metal ions that can be removed by coprecipitation include beryllium, cobalt, copper, iron, manganese, nickel, zinc, and perhaps antimony and thallium (Jenne, 1968; AWWA, 1988; Faust and Aly, 1998).

- *Radionuclides.* Radium, strontium, and uranium can be removed by coprecipitation. Logsdon (1977) reported that lime softening can remove 80 to 90 percent of radium. Brinck et al. (1978) and Sorg and Logsdon (1980) reported 75 to 96 percent removal of radium by lime softening in pilot- and full-scale systems. Radium removal usually exceeds total hardness removal (Figure 13-9). Brinck et al. noted a positive correlation between radium removal and softening pH, but this may have been due, at least in part, to increased hardness removal at higher pH values. Logsdon (1977), citing Straub (1964), reported that softening followed by filtration achieved 87 to 96 percent removal of strontium. Radium and strontium are well removed by lime softening because they are chemically similar to calcium and magnesium, but radium is poorly removed (less than 25 percent) by coagulation (Logsdon, 1977). Lime softening is generally not economically feasible for removing radionuclides from soft waters, but radium can be removed from soft water by coprecipitating it with barium sulfate.

Lee and Bondietti (1983) and Sorg (1988) reported that lime dosages of 100 mg/L or greater, when accompanied by magnesium carbonate addition and resulting in a pH of 10.6 or higher, removed 89 to 99 percent of the uranium spiked into pond water. They also reported that coagulation with ferric sulfate or alum at pH 6 or 10 effectively removes uranium, whereas removal is poor at pH 4 or 8. Uranium speciation is strongly influenced by pH, and the data presented by these authors nicely illustrate how greatly this can impact contaminant removal by coprecipitation.

- *Silica.* Silica is not a regulated contaminant. Some water utilities choose to remove silica for the benefit of their industrial customers, since it interferes with a number of industrial water uses. Other utilities remove silica to reduce or eliminate silicate scaling in domestic water heaters. Silica can be removed by excess lime softening, which can precipitate silica as magnesium silicate or coprecipitate it with magnesium hydroxide, and by adsorption (coprecipitation) on freshly precipitated aluminum or iron hydroxide (Powell, 1954; Iler, 1979; NALCO Water Handbook, 1979; Pizzi, 1995). Since silica removal by lime softening is related to the amount of magnesium removed (Fig. 13-10), additional magnesium may need to be added to meet the treatment objective. The effectiveness of silica removal by excess lime softening increases with temperature, so hot-process lime softening is commonly employed for industrial applications. Silica adsorbs more strongly to aluminum and iron hydroxides at lower temperatures and higher pH values, but the pH is usually limited to about 8.5 for aluminum hydroxide and 10 for iron hydroxide to avoid solubilizing aluminum and iron, respectively.

FIGURE 13-9 Radium removal versus total hardness removal. (Adapted from Logsdon, 1977.)

FIGURE 13-10 Silica removal at 70°F as a function of initial silica concentration and the concentration of magnesium hardness removed. (Courtesy of Sheppard T. Powell Associates, LLC.)

- *Fluoride*. Fluoride can be coprecipitated with magnesium hydroxide or aluminum hydroxide (Sorg, 1977 and 1978; Sollo et al., 1978). However, these processes remove fluoride inefficiently, so their use is limited to situations where little removal is required or other alternatives are not available. When fluoride must be removed from a public water supply, adsorption on activated alumina (Chap. 12) is often the preferred method.
- *Phosphate*. Phosphate can be removed from the water column of a lake or reservoir using alum, ferric sulfate, or lime. Alum is the preferred chemical because under the anaerobic and slightly acidic conditions normally encountered at the bottom of a eutrophic water body, phosphate is more likely to be released back into the water column if precipitated as iron or calcium phosphate. These same chemicals are commonly used to remove phosphate from municipal and industrial wastewater effluents, and magnesium ammonium phosphate (struvite) precipitates out of anaerobic digester supernatants if the pH is raised slightly, for example, due to off-gassing of CO₂ or if lime is added.
- *Halides*. Chloride, bromide, and iodide can be precipitated with silver, but due to the high cost of silver, this application is currently limited to laboratory applications, including titrimetric analysis of chloride, microcoulometric analysis of total organic halogens, and eliminating chloride interferences in ion chromatography.

ACKNOWLEDGMENTS

The chapters on chemical precipitation and lime softening in the third and fifth editions of this handbook served as helpful starting points for this chapter. The author is grateful to Jim Edzwald for his guidance, patience, and understanding during the preparation of this chapter; to Doug Elder and Mike Horsley for sharing their knowledge of the design and operation of lime-softening systems; to the reviewers (Doug Elder and Nick Dugan) for their many insightful comments and excellent suggestions; and to the many individuals, too numerous to mention individually (though works by many of them are cited herein), who contributed to his understanding of the topics addressed in this chapter.

NOTATION FOR EQUATIONS

<i>A</i>	constant (in the Davies equation)
<i>b</i>	empirically derived constant (used to calculate activity of uncharged molecules)

$C_{T,C}$	concentration of the sum of the carbonate species in solution
CCH	calcium carbonate hardness
CNH	calcium noncarbonate hardness
I	ionic strength
K	equilibrium constant
k	rate constant
K_{sc}	solubility product constant for calcite
K_{sa}	solubility product constant for aragonite
K_{sv}	solubility product constant for vaterite
K_1	first acid dissociation constant
K_2	second acid dissociation constant
K_{s0}	solubility product constant
${}^cK_{s0}$	concentration-based solubility product constant
MCH	magnesium carbonate hardness
Mg_r	magnesium hardness in the raw (unsoftened) water
Mg_1	magnesium hardness leaving the first-stage softening unit
Mg_f	magnesium hardness in the finished water
MI	magnesium index
MNH	magnesium noncarbonate hardness
Q	ion product or reaction quotient for a chemical reaction
R	universal gas constant (8.314 J/mole-K).
S	available surface area
SI	saturation index
SR	saturation ratio
T	absolute temperature in degrees kelvin (K) ($0^\circ\text{C} = 273.15\text{ K}$)
t	temperature in $^\circ\text{C}$ or $^\circ\text{F}$ (as indicated)
x	fraction of water bypassing the first stage
z	ionic charge
α	fraction of a chemical species in a given form
γ_d	activity coefficient for divalent ions
γ_m	activity coefficient for monovalent ions
γ_z	activity coefficient for ions having an ionic charge of z
γ_0	activity coefficient for uncharged species in solution
ΔG_{rxn}^0	free energy of reaction
ϵ	dielectric constant of water
{ }	activity
[]	molar concentration

ADSORPTION OVERVIEW

Adsorption of a substance involves its accumulation at the interface between two phases, such as a gas and a solid or, more germane to this chapter, a liquid and a solid. The molecule that accumulates, or *adsorbs*, at the interface is called the *adsorbate*, and the solid on which adsorption occurs is the *adsorbent*. Adsorbents of interest in water treatment include activated carbon; synthetic and carbonaceous adsorbent resins; ion exchange resins; metal oxides, hydroxides, and carbonates; activated alumina; zeolites; clays; and other solids that are suspended in or in contact with water. Adsorbates of interest in water treatment include both organic and inorganic compounds of natural and anthropogenic origins. The focus of this chapter is the adsorption of organic compounds by activated carbon.

Dissolved organic matter (DOM) in drinking water sources can be divided into several categories. For purposes of this chapter, we will use the categories shown in Fig. 14-1. DOM contains specific organic compounds of both natural and synthetic origin. When these compounds become of health or aesthetic concern to utilities and their consumers, they can be referred to as *micropollutants*. Naturally occurring micropollutants include microbial metabolites that cause taste and odor (e.g., geosmin) or are toxic (e.g., microcystins). There are also anthropogenic micropollutants, which are termed *synthetic organic compounds* (SOCs) for this chapter. SOCs include pesticides, solvents, and pharmaceuticals and personal-care

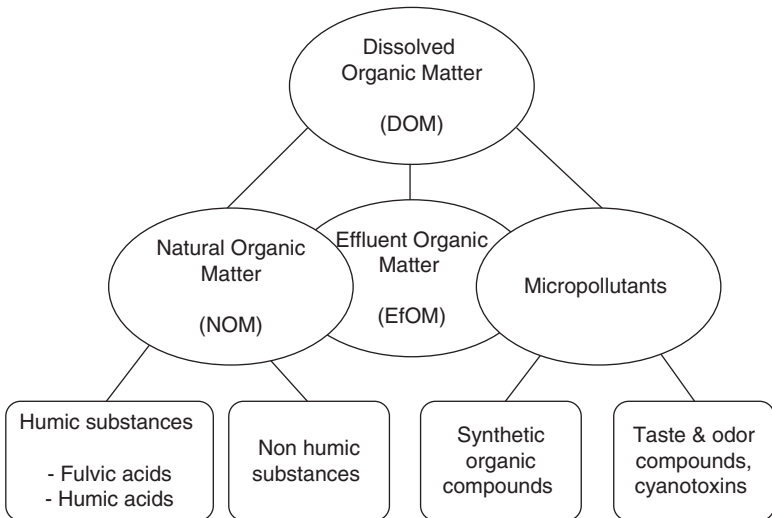

FIGURE 14-1 Categories of dissolved organic matter (DOM).

products (PPCPs). Two other components of DOM are natural organic matter (NOM) and wastewater treatment plant effluent organic matter (EfOM). NOM is a complex mixture of ill-defined organic compounds, such as fulvic and humic acids, hydrophilic acids, and specific compounds such as carbohydrates and proteins, all of natural origin (see Chap. 3 for coverage of NOM). EfOM includes background NOM, compounds from human activity, and metabolites from biological wastewater treatment.

Adsorption plays an important role in the improvement of water quality. Activated carbon, for example, is used most often to adsorb specific organic compounds that cause taste and odor or are of health concern, as well as NOM, which can cause color and can react with chlorine to form disinfection by-products (DBPs). Apart from activated carbon adsorption, a number of other adsorption processes are important in water treatment. The aluminum and ferric hydroxide solids that form during coagulation and the calcium carbonate and magnesium hydroxide solids that form in the lime softening process also adsorb NOM. Pesticides adsorbed on clay particles can be removed by coagulation and filtration. Ion exchange (IX) resins and synthetic and carbonaceous adsorbent resins are available that can be used for efficient removal of selected organic and inorganic compounds, as well as NOM. Removal of NOM by the coagulation process (see Chap. 8) and of organic and inorganic ions by IX resins and activated alumina (see Chap. 12) are also discussed in this book.

Activated carbon can be used as powdered activated carbon (PAC), which is added directly to the water to be treated, typically as a slurry at the rapid mixer, or as granular activated carbon (GAC), which is used in fixed-bed contactors. Historically, PAC has been favored for use with seasonal taste and odor problems because of its low capital cost and flexibility. However, when high PAC doses are required for long periods of time, GAC is an economical alternative to PAC. GAC is used in rapid media filters (filter adsorbers), where both adsorption and particle filtration can occur, in stand-alone units after filtration (postfilter adsorbers), or for groundwater treatment. The use of fixed GAC beds permits higher adsorptive capacities to be achieved and easier process control than is possible with PAC. The higher capital cost for GAC often can be offset by better efficiency, especially when the targeted adsorbate(s) must be removed on a continuous basis. GAC should be seriously considered for water supplies when odorous compounds or organic chemicals of health concern frequently are present, when a barrier is needed against organic compounds from accidental (or deliberate) spills, or in some situations that require DBP precursor removal. While GAC has excellent adsorption capacity for many undesirable substances, it must be removed periodically from the adsorber bed and replaced with fresh or reactivated GAC.

A 1977 study conducted by two committees of the American Water Works Association (AWWA) showed that approximately 25 percent of 645 U.S. utilities, including the 500 largest, added PAC (AWWA Committee Report, 1977). In 1984, 29 percent of the 600 largest utilities reported using PAC (AWWA, 1986), predominantly for odor control. According to the AWWA Water Stats 1996 database, PAC was available for use by 48 percent of the 543 responding surface water systems (AWWA, 1996). The U.S. Environmental Protection Agency (USEPA) Community Water System Survey 2000 (USEPA, 2002) surveyed 1246 community water systems, and PAC was used in 7.6 percent of the 620 surveyed surface water systems. Among surface water utilities serving more than 10,000 customers, more than 17 percent of the responding utilities used PAC (USEPA, 2002).

The number of drinking water plants using GAC increased from 65 in 1977 (AWWA Committee Report, 1977), principally for odor control, to 135 in 1986 (Snoeyink, 1990); in 1996, there were approximately 300 plants treating surface water and several hundred more treating contaminated groundwater (Snoeyink and Summers, 1999). Based on the AWWA Water Stats 1996 database, GAC was being used by 12 percent of the 543 responding surface water systems, with another 4 percent listing it in the planned stage, and 5.3 percent of the 493 responding groundwater systems used GAC (AWWA, 1996).

In the USEPA Community Water System Survey 2000, approximately 14 percent of surface water systems serving more than 3300 people used GAC. Among groundwater systems, 8.6 percent of surveyed utilities serving between 100,000 and 500,000 people employed GAC, but GAC use was less than 2 percent for groundwater systems in other population categories (USEPA, 2002).

ADSORBENT CHARACTERISTICS

Activated Carbon

Production. A wide variety of raw materials can be used to make activated carbon (Hassler, 1974), both PAC and GAC, and the substances used for drinking water treatment carbons predominantly are subbituminous coal, lignite, coconut, and wood. Both the physical and chemical manufacturing processes involve carbonization, or conversion of the raw material to a char, and activation or oxidation to develop the internal pore structure. With physical activation, carbonization or pyrolysis is usually done in the absence of air at temperatures less than 700°C, whereas activation is carried out with oxidizing gases such as steam and carbon dioxide (CO₂) at temperatures of 800 to 900°C. Chemical activation combines carbonization and activation steps by mixing a chemical activating agent, such as phosphoric acid, with the base material and heating the mixture in the absence of oxygen. Patents describing carbonization and activation procedures are discussed by Yehaskel (1978). Both the base material and manufacturing process affect activated carbon characteristics and performance.

Activated carbons are manufactured by either direct activation or a reagglomeration process. Direct activation means that the raw material (e.g., coal) is fed to the furnace as mined, with only some crushing and screening prior to the activation process. The reagglomeration process calls for crushing the raw material, adding some volatile material (such as coal tar pitch), reagglomerating the mixture under high pressure (typically in a pocket briquettor), crushing the material once again, and then activating it.

Physical Characteristics. Activated carbon is a highly porous material with an internal surface area that typically ranges from about 800 to 1500 m²/g (Bansal et al., 1988). Typically, the manufacturer provides data that include the *BET surface area*. This parameter is determined by measuring the adsorption isotherm for nitrogen (N₂) gas molecules and then analyzing the data using the Brunauer-Emmett-Teller (BET) isotherm equation (Adamson and Gast, 1997) to determine the amount of N₂ to form a complete monolayer of N₂ molecules on the carbon surface. Multiplying the surface area occupied per N₂ molecule (0.162 nm² per molecule of N₂) by the number of molecules in the monolayer yields the BET surface area. Not all the BET surface area is accessible to aqueous adsorbates; because N₂ is a small molecule, it can enter pores that are unavailable to larger adsorbates.

The pores that give rise to this large surface area can be envisioned as spaces between irregularly arranged graphite-like platelets (Leon y Leon et al., 1992) or condensed polycyclic aromatic sheets (Bansal et al., 1988) that are the building blocks of activated carbon. To classify pores according to size, the International Union of Pure and Applied Chemistry (IUPAC) differentiates between (1) micropores (<2 nm width), (2) mesopores (2–50 nm width), and (3) macropores (>50 nm width) (Sing et al., 1985). PAC and GAC for water treatment typically exhibit a heterogeneous pore structure, in which micropores, mesopores, and macropores are all present. Activated carbon pore size distributions in the micropores and mesopores are calculated using gas adsorption data, whereas mercury porosimetry data are used to calculate pore size distributions in the macropores.

TABLE 14-1 Physical Characteristics of Representative Activated Carbons and a Carbonaceous Resin

Adsorbent	BET surface area (m ² /g)	Micropore volume ^a (cm ³ /g)	Mesopore volume ^b (cm ³ /g)
F400 (bituminous coal based)	940	0.340	0.160
HD4000 (lignite based)	525	0.148	0.430
CC-602 (coconut shell based)	1160	0.437	0.060
Picazine (wood based)	1680	0.496	0.655
Ambersorb 563 (carbonaceous resin)	550	0.201	0.318

^aMicropore volume calculated by density functional theory (DFT) for pores with widths less than 2 nm.

^bMesopore volume calculated by Barrett, Joyner, and Halenda (BJH) method for pores with widths ranging from 2 to 50 nm.

Sources: Data from Knappe et al. (2007) and Mezzari (2006).

BET surface areas, micropore volumes, and mesopore volumes for representative activated carbons are shown in Table 14-1. For reference, data for a carbonaceous resin are also shown.

The particle shape of crushed GAC is irregular, but extruded GACs have a smooth, cylindrical shape. Particle shape affects the filtration and backwash properties of GAC beds. Particle size is an important parameter because of its effect on adsorption kinetics and breakthrough, as well as filtration performance. *Particle size distribution* refers to the relative amounts of different-sized particles that are part of a given sample, or lot, of carbon. Commonly used GAC sizes include 12 × 40 and 8 × 30 U.S. Standard Mesh, which range in apparent diameter from 1.68 to 0.42 mm and 2.38 to 0.59 mm, respectively, and have average diameters of about 1.0 and 1.5 mm, respectively. Customized particle size distributions are available to meet site-specific needs. The uniformity coefficient (see Chap. 10) is often quite large, typically on the order of 1.9, to promote stratification during backwashing. Usually, commercially available activated carbons have a small percentage of material smaller than the smallest sieve and larger than the largest sieve, which significantly affects the uniformity coefficient. Extruded carbon particles all have the same diameter, but they vary in length.

The *apparent density*^{*} is the mass of nonstratified dry activated carbon per unit volume of activated carbon, including the volume of voids between grains. Typical values for GACs manufactured from bituminous coal, lignite, and coconut shells are 350 to 650 kg/m³ (22–41 lb/ft³), whereas typical values for wood based GAC are in the range of 225 to 300 kg/m³ (14–19 lb/ft³). Distinguishing between the apparent density and the *bed density*, *backwashed and drained* (i.e., stratified, free of water) is important for GAC. The former is a characteristic of GAC as shipped. The latter is a characteristic of the GAC as placed in a bed and is about 10 percent less than the apparent density. The bed density is typical of GAC during normal operation unless the GAC becomes destratified during backwashing. The bed density determines how much GAC must be purchased to fill a contactor of a given size and therefore is an important GAC characteristic.

The *particle density wetted in water* is the mass of solid activated carbon plus the mass of water required to fill the internal pores per unit volume of particle. Its value for GAC typically ranges from 1300 to 1500 kg/m³ (81–94 lb/ft³), and it determines the extent of fluidization and expansion of a given size particle during backwash.

^{*}This definition is based on ASTM Standard D2854-09 (ASTM, 2009). It conflicts with ASTM Standard C128-07a for apparent specific gravity, as used in Chap. 10, which does not include the volume of interparticle voids.

Particle hardness is important because it affects the amount of attrition during backwash, transport, and reactivation. In general, the harder the activated carbon is, the less is the attrition for a given amount of friction or impact between particles. Activated carbon hardness generally is characterized by an experimentally determined hardness or abrasion number using a test such as the American Society for Testing and Materials (ASTM) ball pan hardness test (ASTM Standard D3802), which measures the resistance to particle degradation on agitating a mixture of activated carbon and steel balls (ASTM, 2009). The relationship between the amount of attrition that can be expected when activated carbon is handled in a certain way and the hardness number has not been studied extensively, however. Comparing wood based GAC with an abrasion number of 47 and bituminous coal based GAC with an abrasion number of 75, Grens and Werth (2001) showed that filter performance and changes in GAC bed height were similar during 500 air-water backwash cycles.

The primary difference between PAC and GAC is particle size. As specified by AWWA Standard B600-05 (AWWA, 2005a), not less than 90 percent by mass of PAC shall pass a 44- μm (325 U.S. Standard Mesh) sieve unless the activated carbon is wood based. For wood based PACs, not less than 60 percent by mass shall pass a 44- μm sieve. The particle size distribution is important because the smaller PAC particles adsorb organic compounds more rapidly than large PAC particles (Najm et al., 1990; Adham et al., 1991). The apparent density of PAC ranges from 200 to 750 kg/m^3 (12–47 lb/ft^3) and depends on the base material and the manufacturing process.

Chemical Characteristics. At the edges of the condensed polyaromatic sheets that constitute the building blocks of activated carbons, heteroatoms (i.e., atoms other than carbon) are encountered that define the chemical characteristics of activated carbon surfaces. A typical elemental composition of activated carbon is approximately 88 percent C, 6 to 7 percent O, 1 percent S, 0.5 percent N, and 0.5 percent H, with the remainder being mineral matter (i.e., ash) (Bansal et al., 1988). However, the elemental composition of activated carbons can vary substantially from these average values; for example, the oxygen content can range from as low as 1 percent to as high as 25 percent (Bansal et al., 1988), and the ash content can range from 1 to 20 percent (Jankowska et al., 1991).

Because of its abundance and profound effects on activated carbon hydrophilicity and surface charge, oxygen is generally the most important heteroatom from a standpoint of activated carbon surface chemistry. Oxygen commonly occurs in the form of carboxylic acid groups ($-\text{COOH}$), phenolic hydroxyl groups ($-\text{OH}$), and quinone carbonyl groups ($>\text{C}=\text{O}$) (Boehm et al., 1964; Puri, 1970; Mattson and Mark, 1971; Snoeyink and Weber, 1972; Leon y Leon and Radovic, 1992; Boehm, 1994). Activated carbons assume an acidic character when exposed to oxygen at between 200°C and 700°C or to oxidants such as hydrogen peroxide (e.g., Puri, 1970, 1983). The activated carbon acidity is explained primarily by the formation of carboxylic acid and phenolic hydroxyl groups (Leon y Leon and Radovic, 1992). Oxidation of activated carbon surfaces also occurs during the exposure of activated carbon to common oxidants used in water treatment, such as chlorine, permanganate, and ozone.

Adsorption Properties. Both physical and chemical characteristics of activated carbon affect its performance. Pore size distribution is one important characteristic of an activated carbon. The size of adsorbent pores affects the adsorption of organic contaminants in two important ways. First, size exclusion limits the adsorption of contaminants of a given size and shape if pores are too small. Second, the strength of adsorbate-adsorbent interactions increases with decreasing pore size because adsorption potentials between opposing pore walls begin to overlap once the micropore width is less than twice the adsorbate diameter (e.g., Dubinin, 1960; Sing, 1995). Therefore, adsorption of micropollutants preferentially takes place in the smallest pores that are accessible to a given pollutant. As outlined in

more detail below, the adsorption of micropollutants and NOM occurs primarily in pores with dimensions that match those of the targeted adsorbate. Thus many micropollutants adsorb in small micropores (<1 nm), whereas the largest percentage of NOM preferentially adsorbs in mesopores and large micropores (>1 nm)

With respect to surface chemistry, hydrophobic adsorbents (i.e., activated carbons with low oxygen content) exhibit larger adsorption capacities for organic micropollutants than hydrophilic adsorbents (i.e., activated carbons with high oxygen content) with similar physical characteristics (Knappe et al., 2003). This trend is principally attributable to enhanced water adsorption on hydrophilic activated carbons (e.g., Kaneko et al., 1989, Li et al., 2002, Quinlivan et al., 2005). More detailed information about surface chemistry effects on the adsorption of micropollutants can be found in Knappe (2006).

A number of surrogate parameters are used to describe the adsorption capacity of activated carbon (Sontheimer et al., 1988). The *iodine number* (ASTM Standard D4607-94; ASTM, 2009) measures the amount of iodine that will adsorb under a specified set of conditions, and it generally correlates well with the surface area available for small molecules. The *molasses number* or *decolorizing index* is related to the ability of activated carbon to adsorb large-molecular-weight color bodies from molasses solution and generally correlates well with the ability of the activated carbon to adsorb other large adsorbates. Other surrogate parameters include the *carbon tetrachloride activity*, the *methylene blue number*, the *acetoxime number*, the *tannin value*, and the *phenol adsorption value*.

Surrogate parameters give some insight into the possible performance of activated carbons in drinking water treatment. BET surface area and iodine number tend to correlate well with adsorption capacity when high solid-phase concentrations can be reached, such as in the treatment of highly contaminated waters or in solvent recovery operations (e.g., Manes, 1998). For the removal of micropollutants from drinking water sources; however, activated carbon performance generally does not correlate well with BET surface area or iodine number (e.g., Quinlivan et al., 2005). In all cases, data from bench- or pilot-scale tests (e.g., isotherm tests, jar tests to evaluate PAC performance, and column tests to evaluate GAC performance) conducted with the specific compound(s) and water of interest are much better indicators of field performance.

Other Adsorbents

Apart from PAC and GAC, a wide range of alternative adsorbents has been tested for their effectiveness to remove organic compounds from water. Among the more frequently studied alternative adsorbents are synthetic adsorbent resins, carbonaceous resins, activated carbon fibers, and hydrophobic zeolites.

Synthetic Adsorbent Resins. Synthetic adsorbent resins are polymeric beads with a large internal surface area that is created during the polymerization process (Neely and Isacoff, 1982). Synthetic adsorbent resins, such as the styrene-divinylbenzene (SDVB) copolymer resin and the phenol-formaldehyde (PF) resin, differ from IX resins because they lack charged or ionizable functional groups. (See Chap. 12 for a discussion of the removal of inorganic substances and NOM by IX resins.) In synthetic adsorbent resins, the degree of cross-linking between the polymers that constitute the matrix can be varied, and thus resins with different pore size distributions can be prepared. In theory, pore size distributions can be tailored to a specific target compound that needs to be removed from water.

Carbonaceous Resins. Carbonaceous resins are prepared by heating macroporous polymer beads in an inert atmosphere. This heat treatment, or pyrolysis, step creates micropores while largely maintaining the macroporous structure of the starting polymer (Neely and Isacoff, 1982).

Thus the pore structure of carbonaceous resins can be tailored in a manner similar to that of synthetic adsorbent resins. Furthermore, pyrolysis conditions can be chosen such that the carbonaceous adsorbents have molecular sieve properties (Neely and Isacoff, 1982). One commonly studied carbonaceous resin is prepared from macroporous SDVB beads, and properties of a representative member (Ambersorb 563) are summarized in Table 14-1.

Activated Carbon Fibers. Activated carbon fibers (ACFs) are manufactured from woven and nonwoven materials such as cross-linked phenolic fibers, polyacrylonitrile, and cellulose (Economy and Lin, 1976; Bahl et al., 1998). ACFs are commonly prepared by pyrolysis and steam activation, and preparation conditions can be controlled such that uniform pore size distributions are obtained (Kasaoka et al., 1989a; Daley et al., 1996). Examination of ACFs by scanning tunneling microscopy showed that both mesopores and micropores are present at the ACF surface; the mesopores were oriented parallel to the fiber axis and did not penetrate the bulk fiber to a depth greater than about 60 nm. Because of their narrower pore size distribution, ACFs are particularly suitable to elucidate pore size effects on organic compound adsorption from aqueous solution (Kasaoka et al., 1989b; Pelekani and Snoeyink, 1999, 2000, 2001; Li et al., 2002; Karanfil et al., 2006).

Zeolites. In water treatment, hydrophilic low-silica zeolites are well known as cation exchangers. These zeolites are aluminosilicates with relatively low $\text{SiO}_2/\text{Al}_2\text{O}_3$ ratios that give rise to negative charges in the zeolite framework (Dyer, 1984; Townsend, 1984). In contrast, hydrophobic zeolites with high $\text{SiO}_2/\text{Al}_2\text{O}_3$ ratios show promise for the removal of organic compounds from aqueous solution (e.g., Ellis and Korth, 1993; Kawai et al., 1994; Rossner and Knappe, 2008). Because of their highly ordered lattice structure, zeolites are adsorbents with well-defined pore sizes. For example, ZSM-5 zeolites have straight, elliptical channels with minor and major axis dimensions of 0.53×0.56 nm. The straight channels intersect perpendicularly with sinusoidal, elliptical channels with minor and major axis dimensions of 0.51×0.55 nm. From a drinking water treatment perspective, high-silica zeolites are attractive because pore sizes can be selected that permit the targeted adsorption of smaller organic contaminants while preventing the adsorption of competing substances with larger molecular sizes. High-silica zeolites are marketed in the form of powders and extrudates.

ADSORPTION THEORY

Adsorption Equilibrium

Adsorption of molecules can be represented as a chemical reaction:

where A is the adsorbate, B the adsorbent, and A:B the adsorbed compound. Adsorbates are held on the surface by intermolecular forces such as van der Waal's forces, dipole-dipole interactions, and hydrogen bonds. If the reaction is reversible, as it is for many compounds adsorbed to activated carbon, molecules continue to accumulate on the surface until the rate of the forward reaction (adsorption) equals that of the reverse reaction (desorption). When this condition exists, equilibrium has been reached, and no further accumulation will occur.

Isotherm Equations. One of the most important characteristics of an adsorbent is the quantity of adsorbate that it can accumulate. The constant-temperature equilibrium

relationship between the quantity of adsorbate per unit of adsorbent q and its equilibrium aqueous-phase concentration C is called the *adsorption isotherm*. Several equations or models are available that describe this relationship (Sontheimer et al., 1988), but only the commonly used Freundlich model is presented here.

The empirical Freundlich model is useful because it effectively describes adsorption isotherm data for many organic contaminants. The Freundlich isotherm equation has the form

$$q = KC^{1/n} \tag{14-2}$$

and can be linearized as follows:

$$\log q = \log K + \frac{1}{n} \log C \tag{14-3}$$

The parameters q (with units of mass adsorbate/mass adsorbent or mole adsorbate/mass adsorbent) and C (with units of mass/volume or moles/volume) are the equilibrium surface and solution concentrations, respectively. The terms K and $1/n$ are constants for a given system; $1/n$ is unitless, and the units of K are determined by the units of q and C . Although the Freundlich equation was developed to empirically fit adsorption data, the Freundlich equation also can be developed from adsorption theory (e.g., Halsey and Taylor, 1947; Weber and DiGiano, 1996).

The parameter K in the Freundlich equation is related primarily to the adsorption capacity of the adsorbent for the adsorbate, and $1/n$ is a function of the adsorbent heterogeneity. A $1/n$ value of 1 is obtained for homogeneous adsorbents (i.e., adsorbents with a uniform pore size and surface chemistry); $1/n$ values typically are less than 1 for activated carbons, which exhibit a broad distribution of adsorption site energies; much of the heterogeneity results from the variety in pore sizes and shapes in activated carbons. For fixed values of C and $1/n$, the larger the value of K , the larger is the adsorption capacity q . Figure 14-2 depicts an example isotherm; note that both the x - and y -axis scales are logarithmic, in which case

FIGURE 14-2 Example isotherm data and Freundlich isotherm model fit.

the Freundlich model yields a straight line. In Fig. 14-2, equilibrium solid-phase concentrations are presented in units of milligrams of adsorbed compound per gram of activated carbon (mg/g) and equilibrium aqueous-phase concentrations in units of micrograms per liter ($\mu\text{g/L}$). In this case, the parameter K represents the adsorption capacity (in mg/g) at an equilibrium liquid-phase concentration of $1 \mu\text{g/L}$. The parameter $1/n$ represents the slope of the line; for the example isotherm in Fig. 14-2, $\log q$ increases by 0.549 for each unit increase in $\log C$.

The Freundlich equation cannot apply to all values of C , however. As C increases, for example, q increases (in accordance with Eq. 14-2) only until all adsorbent pore surfaces are occupied. At saturation, q is a constant, independent of further increases in C , and the Freundlich equation no longer applies. Also, no assurance exists that adsorption data will conform to the Freundlich equation over all concentrations less than saturation, so care must be exercised in extending the equation to concentration ranges that have not been tested.

Tabulations of single-solute isotherm constants are useful when only rough estimates of adsorption capacity are needed to determine whether a more intensive analysis of the adsorption process is warranted. The Freundlich isotherm constants of Speth and Miltner (1990, 1998) are reproduced in Table 14-2 for this purpose. Freundlich isotherm

contants for 2-methylisoborneol (MIB), a taste and odor compound, and sulfamethoxazole and trimethoprim, two antimicrobial compounds, are also shown in Table 14-2. The adsorption isotherm parameters in Table 14-2 were derived from adsorption isotherm experiments conducted with coal based activated carbons with BET surface areas of approximately 1000 m²/g. Furthermore, adsorbent-adsorbate contact times in these studies were sufficient to reach adsorption equilibrium (5 days for MIB, ≥3 weeks for all other compounds), and the tested aqueous-phase concentrations in were most cases environmentally relevant. Additional isotherm parameters can be found in Sontheimer and colleagues (1988). The parameters in Table 14-2 can be used to judge relative adsorption efficiency. The K values of isotherms that have nearly the same values of $1/n$ show the relative capacity of adsorption. For example, if a GAC column is satisfactorily removing benzene [$K = 1.26(\text{mg/g})(\text{L}/\mu\text{g})^{1/n}$ and $1/n = 0.533$], the removal of compounds with larger values of K and approximately the same concentration likely will be better. (An exception might occur if the organic compounds adsorb to particles that pass through the adsorber.) If the $1/n$ values are much different, however, the capacity of activated carbon for each compound of interest should be calculated at the equilibrium concentration of interest using Eq. 14-2 because the relative adsorbability will depend on the equilibrium concentration.

Adsorption isotherms for representative micropollutants are shown in Fig. 14-3. Among the depicted contaminants, the herbicides metolachlor and atrazine exhibit the largest adsorption capacities, while MTBE exhibits the lowest. At an equilibrium concentration of 1 μg/L, adsorption capacities for MIB and TCE are similar; however, at concentrations that are relevant for MIB (tens of ng/L), the adsorption capacity of activated carbon is considerably lower. The use of isotherm values to estimate GAC adsorber life and PAC usage rate is discussed in the sections “GAC Performance Estimation” and “PAC Adsorption,” respectively.

FIGURE 14-3 Adsorption isotherms for representative trace organic contaminants.

Factors Affecting Adsorption Equilibria. Important adsorbent characteristics that affect adsorption uptake at equilibrium include surface area, pore size distribution, and surface chemistry. The maximum amount of adsorption is proportional to the amount of surface area within pores that are accessible to the adsorbate. However, in drinking water treatment applications, organic contaminants typically are present at trace levels well below their aqueous solubility limit, at which the maximum amount of adsorption is observed. At trace levels, adsorption occurs primarily at sites associated with high adsorption energies, that is, in pores whose dimensions closely match those of the targeted micropollutant. Therefore, adsorption uptake by a given activated carbon at a given aqueous-phase micropollutant concentration is related to the volume of pores in a size range that closely matches the size of the targeted adsorbate (e.g., Li et al., 2002; Karanfil and Dastgheib, 2004). Because many micropollutants are small [i.e., total surface areas of about 1–3 nm² (Okouchi et al., 1992), which corresponds to spherical diameters of about 0.55–1.0 nm], the presence of small micropores is important for their removal from aqueous solution. For example, the results of Karanfil and Dastgheib (2004) suggest that the adsorption capacity of trichloroethene (TCE) is proportional to the volume of micropores with widths of about 0.5 to 0.8 nm, dimensions that are very close to those of the adsorbate. For emerging contaminants such as pharmaceuticals, endocrine-disrupting chemicals, personal-care products, and flame retardants, Rossner and colleagues (2009) showed that a large micropore volume in the width range of 0.6 to 0.9 nm is important for their effective removal. To achieve effective NOM removal, a large volume of mesopores and micropores larger than 1 nm is required (Ebie et al., 1995; Newcombe et al., 1997; Pelekani and Snoeyink, 1999; Cheng et al., 2005).

The surface chemistry of activated carbon and adsorbate properties also can affect adsorption (e.g., Snoeyink and Weber, 1972; Coughlin and Ezra, 1968; Snoeyink et al., 1974; Pendleton et al., 1997; Karanfil and Kilduff, 1999; Franz et al., 2000; Li et al., 2002, 2005; Quinlivan et al., 2005; Knappe, 2006). These researchers demonstrated that extensive oxidation of carbon surfaces led to large decreases in the amounts of phenol, nitrobenzene, benzene, benzoic acid, benzenesulfonate, 1,2,4-trichlorobenzene, TCE, and MTBE that could be adsorbed. Oxidation of the activated carbon surface with aqueous free and combined chlorine also was found to oxidize the carbon surface and correspondingly to decrease the adsorption capacity for phenol (Snoeyink et al., 1974), MIB (Gilligly et al., 1998a; Lalezary-Craig et al., 1988), and geosmin (Lalezary-Craig et al., 1988). If possible, contact between activated carbon and oxidants such as potassium permanganate and chlorine should be avoided during the treatment of drinking water because the resulting oxygenation of the activated carbon surface decreases micropollutant uptake. In addition, reactions between activated carbon and the oxidizing chemical decrease the oxidant concentration or lead to complete elimination of the oxidant such that the intended oxidation and/or disinfection process is adversely affected. The reaction between activated carbon and ozone produces hydroxyl radicals (Jans and Hoigne, 1998); in the process, the activated carbon surface is oxidized, and ozone decomposition is enhanced. Additional research is needed to better understand micropollutant fate when activated carbon and ozone come into contact at conditions that can be considered typical for drinking water treatment.

The tendency of a molecule to adsorb is a function of its affinity for water compared with its affinity for the adsorbent. Generally, the more hydrophobic the pollutant (or the lower its aqueous solubility), the greater is its tendency to escape from aqueous solution and adsorb on the activated carbon surface, and this tendency is known as *solvent-motivated adsorption* (Weber and DiGiano, 1996). As a molecule becomes larger through the addition of hydrophobic groups such as $-\text{CH}_2-$, its solubility decreases, and its extent of adsorption increases as long as the molecule can gain entrance to the pores. When an increase in size causes the molecule to be excluded from some pores, however, adsorption capacity may decrease as solubility decreases. Also, as molecular size increases, the rate of diffusion within the activated carbon particle decreases, especially as molecular size approaches the size of the adsorbent pore.

FIGURE 14-4 Effect of solution pH on MCPB adsorbability. (Source: J. Y. Hu et al. (1998), *Adsorptive characteristics of ionogenic aromatic pesticides in water on powdered activated carbon*. *Water Research* 32(9), 2593-2600. Copyright © 1998, with permission from Elsevier.)

The affinity of weak organic acids or bases for activated carbon is an important function of pH. When the pH is in a range where the molecule is in the neutral form, adsorption capacity is relatively high. When the pH is in a range where the species is ionized, however, the affinity for water (or aqueous solubility) increases, and activated carbon capacity decreases accordingly. Phenol that has been adsorbed on activated carbon at a pH below 8, where phenol is neutral, can be desorbed if the pH is increased to 10 or above, where phenol is anionic (Fox et al., 1973). For the acidic pesticide MCPB ($pK_a = 4.8$), Hu and colleagues (1998) illustrated that adsorption capacity decreases with increasing solution pH (Fig. 14-4). As MCPB changes from the neutral to the anionic form, its hydrophobicity (as measured by the octanol-water partition coefficient) decreases, and so does its adsorbability. Similar results have been obtained for other acidic pesticides (Hu et al., 1998), as well as for the acidic antibiotic sulfamethoxazole ($pK_a = 5.6$) (Knappe et al., 2007). For basic compounds that transition from the cationic to the neutral form as pH increases, the reverse trend is observed; that is, for the basic pesticide imazalil ($pK_b = 7.5$), adsorption capacity increased with increasing solution pH (Hu et al., 1998). A similar trend was observed by Knappe and colleagues (2007) for the basic antimicrobial compound trimethoprim ($pK_b = 7$).

Competitive Adsorption in Multisolute Systems of Known Composition. Competitive adsorption is important in drinking water treatment because most compounds to be adsorbed exist in solution with other adsorbable compounds. The quantity of activated carbon or other adsorbent required to remove a certain amount of a compound of interest from a mixture of adsorbable compounds is greater than if adsorption occurs without competition because part of the adsorbent's surface is used by the competing substances.

The extent of competition on activated carbon depends on the strength of adsorption of the competing molecules, the concentrations of these molecules, and the type of activated carbon. To illustrate the effect of competition among adsorbates in multisolute systems,

Crittenden and colleagues (1985a) compared single-solute and multisolute adsorption isotherm data. For example, for a trisolute system containing initial bromoform, chloroform, and TCE concentrations in the range of 30 to 40 μM , the bromoform adsorption capacity at an equilibrium concentration of 0.6 μM was approximately 38 percent of the single-solute adsorption capacity. For the more strongly adsorbing TCE, the adsorption capacity in the trisolute system at an equilibrium concentration of 0.6 μM was approximately 80 percent of the single-solute adsorption capacity.

Displacement of previously adsorbed compounds by competition can result in a column effluent concentration of a compound that is greater than the influent concentration, as shown in Fig. 14-5. A dimethylphenol (DMP) concentration about 50 percent greater than the influent resulted when dichlorophenol (DCP) was introduced to the influent of a column saturated with DMP (Thacker et al., 1984). Similar occurrences have been observed in full-scale GAC systems. Effluent concentrations in excess of influent concentrations can be prevented through careful operation and monitoring. Crittenden and colleagues (1980) showed that the magnitude of the displacement decreased when the value of $C_{\text{eff}}/C_{\text{inf}}$ was lowered at the time the second compound was introduced. Thus a reasonable strategy to prevent the occurrence of an undesirable compound at a concentration greater than the influent is (1) to monitor the column for that compound and (2) to replace the activated carbon before complete saturation at the influent concentration occurs (i.e., before $C_{\text{eff}} = C_{\text{inf}}$).

FIGURE 14-5 Breakthrough curves for sequential feed of DMP and DCP to a GAC adsorber ($C_{01} = 0.990 \text{ mmol/L}$, $C_{02} = 1.02 \text{ mmol/L}$, EBCT = 25.4 seconds). (Source: W. E. Thacker, J. C. Crittenden, and V. L. Snoeyink, *Modeling of adsorber performance: Variable influent concentration and comparison of adsorbents*. *Journal Water Pollution Control Federation* 56:243, with permission. Copyright © 1984, Water Environment Federation, www.wef.org.)

A number of models have been used to describe competitive adsorption equilibria (e.g., Butler and Ockrent, 1930; Jain and Snoeyink, 1973; Sheindorf et al., 1981). A common model for describing adsorption equilibrium in multiadsorbate systems is the *ideal adsorbed solution theory* (IAST) of Radke and Prausnitz (1972), which has proven to be applicable to a large number of situations. The following two equations, based on the IAST as developed by Radke and Prausnitz (1972) and modified by Crittenden and colleagues (1985a) to include the Freundlich equilibrium expression, describe equilibrium in a two-solute system:

$$C_{2,0} - q_2 C_c - \frac{q_2}{q_1 + q_2} \left(\frac{n_1 q_1 + n_2 q_2}{n_2 K_2} \right)^{n_2} = 0 \quad (14-4)$$

$$C_{1,0} - q_1 C_c - \frac{q_1}{q_1 + q_2} \left(\frac{n_1 q_1 + n_2 q_2}{n_1 K_1} \right)^{n_1} = 0 \quad (14-5)$$

where q_1 and q_2 are the equilibrium solid-phase concentrations of compounds 1 and 2, $q_1 = (C_{1,0} - C_{1,e})/C_c$ and $q_2 = (C_{2,0} - C_{2,e})/C_c$, $C_{1,0}$ and $C_{2,0}$ are the initial aqueous-phase concentrations of compounds 1 and 2, $C_{1,e}$ and $C_{2,e}$ are the equilibrium concentrations of compounds 1 and 2, and K_1 and K_2 are single-solute Freundlich parameters for compounds 1 and 2, $1/n_1$ and $1/n_2$ are single-solute Freundlich exponents for compounds 1 and 2, and C_c is the activated carbon dose.

These equations show the relationship between the initial concentration of each adsorbate, the amount of adsorbed compound per unit mass of activated carbon, and the activated carbon dose. The Freundlich parameters are derived from single-solute tests in organic free water. Extending Eqs. 14-4 and 14-5 to N components yields

$$C_{i,0} - C_c q_i - \left(\frac{q_i}{\sum_{j=1}^N q_j} \right) \left(\frac{\sum_{j=1}^N n_j q_j}{n_i K_i} \right)^{n_i} = 0 \quad (14-6)$$

where N is the number of components in the solution, $C_{i,0}$ is the initial aqueous-phase concentration of compound i , C_c is the carbon dose, q_i is the equilibrium solid-phase concentration of compound i , and n_i and K_i are the single-solute Freundlich parameters for compound i .

The system of IAST equations can be solved simultaneously to determine the concentrations for each component present in solution. The following example illustrates a spreadsheet solution for a bisolute system in which the single-solute isotherms of two competing adsorbates follow the Freundlich isotherm model. Benjamin (2009) presented a more comprehensive spreadsheet model that solves the IAST equations for up to eight competing adsorbates whose single-solute adsorption isotherms follow either the Freundlich or Langmuir model.

Example 14-1 Adsorption Equilibrium in Multisolute Systems (IAST)

Apply the IAST to predict the adsorption isotherms for trichloroethene (TCE) and bromoform in a system containing 100 $\mu\text{g/L}$ of each compound in ultrapure water. Perform the calculations for activated carbon doses of 10 to 100 mg/L using 10 mg/L dose increments. Plot the resulting isotherms ($\log q$ versus $\log C$), and compare them with the respective single-solute isotherms. The single-solute Freundlich isotherm constants

for TCE and bromoform are

$$K_{\text{TCE}} = 1245 \text{ (}\mu\text{g/g)(L/}\mu\text{g)}^{1/n} \text{ and } 1/n_{\text{TCE}} = 0.4696$$

$$K_{\text{bromoform}} = 436.6 \text{ (}\mu\text{g/g)(L/}\mu\text{g)}^{1/n} \text{ and } 1/n_{\text{bromoform}} = 0.6889$$

Provided that the initial TCE concentration is kept at 100 $\mu\text{g/L}$, calculate the bromoform equilibrium liquid-phase and solid-phase concentrations for initial bromoform concentrations of 10 and 1 $\mu\text{g/L}$. Use the same carbon doses as in part a. On a log-log plot, show the single-solute bromoform isotherm and the isotherms obtained at 100, 10, and 1 $\mu\text{g/L}$. What do you observe?

Solution

a. Convert initial concentrations to micromolar units:

$$C_{0,\text{TCE}} = 100 \text{ }\mu\text{g/L} \times 1 \text{ }\mu\text{mol}/131.4 \text{ }\mu\text{g} = 0.761 \text{ }\mu\text{mol/L}$$

$$C_{0,\text{bromoform}} = 100 \text{ }\mu\text{g/L} \times 1 \text{ }\mu\text{mol}/252.7 \text{ }\mu\text{g} = 0.396 \text{ }\mu\text{mol/L}$$

Convert Freundlich K values to micromolar units:

$$K_{\text{TCE}} = 1245 \text{ (}\mu\text{g/g)(L/}\mu\text{g)}^{1/n} \times 1 \text{ }\mu\text{mol}/131.4 \text{ }\mu\text{g} \times (131.4 \text{ }\mu\text{g}/\mu\text{mol})^{0.4696} \\ = 93.64 \text{ (}\mu\text{mol/g)(L/}\mu\text{mol)}^{1/n}$$

$$K_{\text{bromoform}} = 436.6 \text{ (}\mu\text{g/g)(L/}\mu\text{g)}^{1/n} \times 1 \text{ }\mu\text{mol}/252.7 \text{ }\mu\text{g} \times (252.7 \text{ }\mu\text{g}/\mu\text{mol})^{0.6889} \\ = 78.10 \text{ (}\mu\text{mol/g)(L/}\mu\text{mol)}^{1/n}$$

For each carbon dose (10–100 mg/L), set up mass balance Eqs. 14-4 and 14-5; for example, for a carbon dose of 10 mg/L , the following equations result for TCE and bromoform:

$$0.761 \text{ }\mu\text{mol/L} - q_1 \times 0.010 \text{ g/L} - \frac{q_1}{q_1 + q_2} \left[\frac{(1/0.4696) \times q_1 + (1/0.6889) \times q_2}{(1/0.4696) \times 93.64 \text{ (}\mu\text{mol/g)(L/}\mu\text{mol)}^{0.4696}} \right]^{1/0.4696} = 0$$

$$0.396 \text{ }\mu\text{mol/L} - q_2 \times 0.010 \text{ g/L} - \frac{q_2}{q_1 + q_2} \left[\frac{(1/0.4696) \times q_1 + (1/0.6889) \times q_2}{(1/0.6889) \times 78.10 \text{ (}\mu\text{mol/g)(L/}\mu\text{mol)}^{0.6889}} \right]^{1/0.6889} = 0$$

Using a nonlinear optimization tool (e.g., Solver in Microsoft Excel), vary q_1 (TCE solid-phase concentration) and q_2 (bromoform solid-phase concentration) such that the two equations are satisfied for each carbon dose. A solution can be efficiently obtained by varying q_1 and q_2 for each carbon dose such that the sum of squares of all 20 equations that result for the 10 carbon doses is minimized. The results in Table 14-3 are obtained for a system with initial bromoform and TCE concentrations of 100 $\mu\text{g/L}$ each.

Furthermore, the equilibrium aqueous-phase concentrations of TCE and bromoform can be computed from $C = C_0 - q \times C_c$ (e.g., at a carbon dose of 10 mg/L , the aqueous-phase TCE concentration is $100 \text{ }\mu\text{g/L} - 6.35 \text{ }\mu\text{g/mg} \times 10 \text{ mg/L} = 36.5 \text{ }\mu\text{g/L}$). Aqueous-phase concentration results are included in Table 14-3.

Plotting q as a function of C yields the adsorption isotherms shown in Fig. 14-6. This figure illustrates that the presence of the more weakly adsorbing bromoform has only a small effect on TCE adsorption; that is, the predicted TCE adsorption isotherm for the two-solute system is very similar to the single-solute TCE adsorption isotherm. In contrast, the presence of the more strongly adsorbing TCE has a more pronounced effect on the bromoform adsorption isotherm. For example, at an equilibrium aqueous-phase bromoform concentration of 10 $\mu\text{g/L}$, the adsorption capacity in the two-solute system is only 53 percent of that in the single-solute system (1.14 versus 2.13 mg/g).

100	7.56	0.37	0.99	0.093	0.63	0.72

For an initial bromoform concentration of 10 $\mu\text{g/L}$ in the presence of 100 $\mu\text{g/L}$ TCE, the results in Table 14-4 are obtained (using the same solution approach as in part a).

Similarly, for an initial bromoform concentration of 1 $\mu\text{g/L}$ in the presence of 100 $\mu\text{g/L}$ TCE, the results in Table 14-5 are obtained.

Using the results shown in Tables 14-3 to 14-5, bromoform isotherms for different initial bromoform concentrations in the two-solute system are compared with the single-solute bromoform isotherm in Fig. 14-7. Fig. 14-7 illustrates that the effect of the competing adsorbate TCE on bromoform uptake becomes more pronounced as the initial bromoform concentration decreases. ▲

NOM Adsorption. Adsorption equilibrium assessments can be made for heterogeneous mixtures of compounds such as NOM. Typically, group parameters such as total organic carbon (TOC), dissolved organic carbon (DOC), and ultraviolet (UV) absorbance at a wavelength of 254 nm (UVA) are used as a measure of the total concentration of substances present. For mixtures such as NOM that have compounds with a wide range of affinities

FIGURE 14-7 Comparison of single-solute and two-solute bromoform adsorption isotherms. Two-solute isotherms are in the presence of 100 µg/L trichloroethene.

for an adsorbent, the shape of the isotherm depends on the relative amounts of compounds in the mixture. For example, the isotherms for an isolated groundwater NOM shown in Fig. 14-8a display the expected characteristics of a nonadsorbable fraction, about 10 percent of the initial concentration, as well as components with a range of adsorbabilities (Hong, 1996). The strongly adsorbable compounds can be removed with small doses

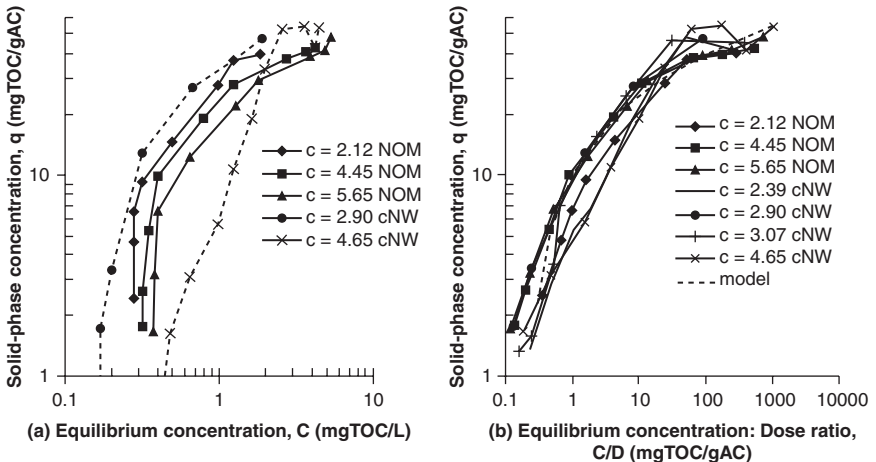

FIGURE 14-8 Equilibrium adsorption isotherms for isolated groundwater NOM and coagulated natural waters from a range of sources using a bituminous-based ground GAC. (Source: Adapted with permission from Hong, 1996.)

of adsorbent and yield large values of q . In contrast, the weakly adsorbable compounds can be removed only with large adsorbent doses that yield relatively low values of q . The nonadsorbable compounds produce a vertical isotherm at low C values. This behavior also results in different isotherms at different initial concentrations of the same heterogeneous mixture (Fig. 14-8a), in contrast to single-solute isotherms. The IAST model predicts the increase in adsorbability q as a function of decreasing initial concentration. Also shown in Fig. 14-8a are isotherms from two coagulated natural waters (cNWs) with initial TOC concentrations of 2.90 and 4.65 mg/L that also display this behavior.

To account for preferential adsorption of the strongly adsorbing compounds in a mixture that causes the impact of initial concentration on equilibrium data, Summers and Roberts (1988a) used an isotherm model that related the solid-phase concentration q to the ratio C/D , where C is the of the equilibrium liquid-phase concentration and D is the adsorbent dose. For isolated humic and fulvic acid fractions of NOM, this approach yielded a good fit between a modified Freundlich model with parameters K_{HS} and $1/n_{HS}$ and the data.

$$q = K_{HS}(C/D)^{1/n_{HS}} \quad (14-7)$$

Using Eq. 14-7, the data in Fig. 14-8a were replotted in Fig. 14-8b, and the impact of initial TOC concentration was mitigated. In addition, data from four cNW isotherms with a range of sources, geographic locations, and initial concentrations (Hong, 1996) are also plotted and show that this approach normalizes the cNW equilibrium data. The modified Freundlich model used by Summers and Roberts (1988a) for isolated NOM fractions does not fit the natural water data in Fig. 14-8b because the natural waters have a wider range of adsorbability, including a nonadsorbable fraction. However, a seminatural log equation does fit the data, $q_e = 6.43 \ln(C_e/D) + 9.94$ ($r^2 = 0.91$), as shown in Fig. 14-8b. This model also was applied to the isotherm data from four ozonated natural waters (Hong, 1996), resulting in a slope that was 10 percent lower than that of the nonozonated waters ($r^2 = 0.90$). As will be shown later in this chapter, the relative adsorbability of compounds within a mixture has an important effect on adsorption column performance. The nonadsorbable fraction cannot be removed regardless of the column design, whereas the strongly adsorbable fraction may cause the effluent concentration to slowly approach the influent concentration.

The adsorption of organic acids and bases by GAC can be affected by solution pH (see Fig. 14-4). At environmental pH values, the carboxylic acid and phenolic functional groups in NOM humic substances yield a negative charge that dominates the NOM characteristics. Several researchers have shown the impact of influent pH on the adsorption of NOM. Unfortunately, some of the work has been done with different initial TOC concentrations, and the increased performance attributed to low pH may be because of the lower initial TOC concentrations (Fig. 14-8). A relationship between the relative adsorption capacity for TOC and pH was developed from batch isotherm data at different doses for 10 different source waters and a bituminous coal based GAC and is shown in Fig. 14-9 (Hooper et al., 1996a). Within the pH range shown, a decrease in the pH of 1 unit yielded a 6 percent increase in adsorption capacity.

The inorganic composition of water also can have an important effect on the extent of NOM adsorption. Divalent cations such as calcium can interact with the NOM, increasing its adsorption capacity through the formation of complexes (Randtke and Jepsen, 1982). Increases in ionic strength have been shown to decrease the size of NOM (Cornel et al., 1986), thus allowing access to more surface area and, in turn, increasing the adsorption (Summers and Roberts, 1988b).

Competitive Adsorption in Natural Waters. Adsorption of organic compounds at trace concentrations from natural waters is an important problem in water purification. Essentially all synthetic organic chemicals that must be removed in water treatment by adsorption must compete with natural or background organic matter for adsorption sites.

FIGURE 14-9 Impact of pH on percent DOC adsorbed at equilibrium for 10 waters. (Source: Hooper et al., 1996a.)

The heterogeneous mixture of compounds in natural waters adsorbs on activated carbon and reduces the number of sites available for the micropollutants either by direct competition for adsorption sites or by pore blockage (Carter et al., 1992; Pelekani and Snoeyink, 1999; Li et al., 2003a). The amount of competition and the adsorption capacity for the micropollutant depend on the nature of the background DOM and its concentration, as well as the characteristics of the activated carbon (Li et al., 2003b). Also important is the concentration of the micropollutant because this concentration affects how much of the compound can adsorb on the carbon. For example, Fig. 14-10 shows that the adsorption capacity of MIB, an important earthy/musty odor compound, has a capacity in natural water that is lower than in distilled water and that this capacity is reduced further as initial concentration decreases (Gilligly et al., 1998b).

FIGURE 14-10 Effect of initial concentration on MIB adsorption capacity in Lake Michigan water. (Source: Gilligly et al., 1998b.)

A procedure is needed to predict adsorption capacity as a function of initial target compound concentration because the adsorption capacity of activated carbon depends in such an important way on initial concentration and because the concentrations of micropollutants vary widely in drinking water sources. The IAST can be used for this purpose, but approaches are needed to represent the competing background organic matter.

In natural waters, the competing organic matter is a complex mixture of many different compounds. Representing each of them, even if they could be identified, would be computationally prohibitive. Several researchers have modeled NOM adsorption by defining several fictive components that represent groups of compounds with similar adsorption characteristics, as expressed by Freundlich K and n values (Sontheimer et al., 1988). Crittenden and colleagues (1985b) used this fictive-component approach to describe the adsorption of a target compound in the presence of NOM. With a single-solute isotherm of the target compound and experimental results from target-compound isotherms in the natural water, parameters for each of the fictive components were found through a best-fit search procedure. These results then were applied to describe the adsorption of other compounds in that water.

The IAST was applied to the problem of micropollutant adsorption in natural waters by Najm and colleagues (1991a) using a procedure that was modified subsequently by Qi and colleagues (1994) and Knappe and colleagues (1998). These researchers assumed that the background organic matter that competed with the micropollutant could be represented as a single compound, called the *equivalent background compound* (EBC). Their approach involved determination of the single-solute isotherm for the micropollutant and an isotherm in natural water for the micropollutant at two different initial concentrations. A search routine was used to find the Freundlich parameters K and $1/n$ and the initial concentration C_0 for the EBC that gave the observed amount of competition. For example, Fig. 14-11

FIGURE 14-11 EBC model results for atrazine isotherms in Illinois groundwater. (Source: Reprinted with permission from D. R. U. Knappe et al. (1998), Predicting the capacity of powdered activated carbon for trace organic compounds in natural waters. Environmental Science & Technology 32, 1694–1698. Copyright © 1998, American Chemical Society.)

shows isotherms determined for atrazine in organic-free water and in Illinois groundwater at initial concentrations of 176 and 36 $\mu\text{g/L}$ (Knappe et al., 1998). These data were used to determine the EBC parameters, which are specific for the type of carbon, the type and concentration of the competing background organic matter, and the type of micropollutant. The EBC parameters (K_{EBC} , $1/n_{\text{EBC}}$, $C_{0,\text{EBC}}$) were used in Eqs. 14-4 and 14-5 together with the initial concentration of the micropollutant and its single-solute Freundlich parameters to calculate the surface coverage of micropollutant as a function of carbon dose C . Given the surface coverage q , the initial concentration C_0 , and the carbon dose C_c , the equilibrium concentration of the micropollutant can be calculated from the equation $q = (C_0 - C)/C_c$. This approach was used to determine the predicted isotherm for atrazine at an initial concentration of 8.3 $\mu\text{g/L}$ shown in Fig. 14-11, which compares well with the measured data. At an equilibrium concentration of 1 $\mu\text{g/L}$, there is a 63 percent reduction in capacity for atrazine as the initial concentration is reduced from 176 to 8.3 $\mu\text{g/L}$.

An important modification of the EBC model was developed by Knappe and colleagues (1998), who showed that the amount of adsorption on a unit mass of activated carbon was directly proportional to the initial concentration of that micropollutant in an adsorption test if (1) the Freundlich exponents for the micropollutant ($1/n_1$) and the EBC ($1/n_2$) both fall between 0.1 and 1, as is generally the case and (2) the solid-phase concentration of the background organic matter is much greater than that of the micropollutant ($q_2 \gg q_1$), which also is often true. When these two approximations hold, the IAST model (Eq. 14-5) simplifies to

$$q_1 = C_{1,0} \left[C_c + \frac{1}{q_2} \left(\frac{n_2 q_2}{n_1 K_1} \right)^{n_1} \right]^{-1} \quad (14-8)$$

Equation 14-8 shows that the surface loading of micropollutant q_1 is directly proportional to its initial concentration. This equation also can be manipulated to show that the percent removal, or percent remaining, of a compound for any carbon dose, when the preceding two assumptions are valid, is a constant (e.g., Matsui et al., 2002; Qi et al., 2007). The implication of this result is that for low concentrations of micropollutant in a natural water, only one isotherm needs to be determined. This isotherm can be plotted as percent remaining versus carbon dose, as shown in Figs. 14-12 and 14-13 for the same data shown in Figs. 14-10 and 14-11, respectively. In Fig. 14-13, the atrazine data for $C_0 \leq 36 \mu\text{g/L}$ plot on 1 percent remaining versus carbon dose line, and the $C_0 = 176 \mu\text{g/L}$ line is only slightly above. All the MIB data in Fig. 14-12 plot on one line.

Graham and colleagues (2000) independently derived a different form of Eq. 14-8 and applied it using the EBC approach to the adsorption of MIB and geosmin from four natural waters. For a lignite based PAC, the same EBC isotherm parameters [$K = 1.35 (\mu\text{g/mg}) (\text{L}/\mu\text{g})^{1/n}$ and $1/n = 0.20$] were found to be applicable to both MIB and geosmin and, at different initial concentrations (15–51 $\mu\text{g/L}$), for all four natural waters. For three of the four natural waters, the EBC initial concentration was about 0.45 percent of the TOC initial concentration. Cho and Summers (2007a) extended this approach to six additional waters with the same PAC (lignite based) as Graham and colleagues (2000) and successfully used the same EBC isotherm parameters (K , $1/n$) and EBC concentration function for the lignite based PAC. In addition, they developed EBC parameters for wood- and bituminous-based PACs.

These results allow the following general procedure to be used to determine adsorption capacity for a micropollutant in natural water: (1) determine one adsorption isotherm for the micropollutant in natural water at a sufficiently low initial concentration, (2) plot the data on a log-log plot of percent remaining versus carbon dose, and (3) use this isotherm

FIGURE 14-12 Percent MIB remaining as a function of PAC dose. (Source: Gillogly et al., 1998b.)

plot to determine the carbon dose required for any desired percent removal for any initial concentration that satisfies the assumptions. The validity of this simplified approach depends on the micropollutant concentration being low relative to that of the competing EBC. Research to date has shown that MIB (Gilligly et al., 1998b) and geosmin (Graham et al., 2000) concentrations of less than 1000 ng/L and atrazine concentrations of less than about 50 µg/L (Knappe et al., 1998) will give a satisfactory plot. For emerging contaminants, satisfactory plots were obtained for the antibiotic sulfamethoxazole at concentrations less than 100 µg/L (Rossner et al., 2009) and for the hormone estradiol at concentrations less than 1000 ng/L (Westerhoff et al., 2005). This database needs to be expanded to include other micropollutants.

Preloading in Natural Waters (GAC Fouling). Because water treatment plants typically operate GAC adsorbers on a continuous basis, NOM adsorbs on GAC even during periods when targeted micropollutants are absent in the source water. As a result, the GAC becomes preloaded with or fouled by humic substances (Summers and Roberts, 1988a). As explained in more detail below, both the GAC adsorption capacity for a micropollutant and the rate of micropollutant adsorption are adversely affected by preadsorbed NOM.

Figure 14-14 illustrates the preloading phenomenon by showing typical aqueous-phase concentration profiles of a micropollutant and two fractions of NOM: a small, strongly adsorbing fraction that competes directly for preferred micropollutant adsorption sites and a larger, weakly adsorbing fraction that constricts adsorbent pores and slows adsorption kinetics. The figure shows that only the upper reaches of the GAC bed are exposed to the micropollutant early in an adsorber run, but the entire bed is exposed to the larger, weakly adsorbing NOM compounds. The concentration profile of smaller, strongly adsorbing NOM is similar to the micropollutant but typically proceeds slightly ahead of the micropollutant because of the higher initial concentration of the strongly competing compound (Schideman et al., 2007).

FIGURE 14-14 Conceptual illustration of NOM preloading along length of GAC bed. (Source: L. Schideman et al. (2007), *Application of a three-component competitive adsorption model to evaluate and optimize granular activated carbon systems*. *Water Research* 41(15), 3289–3298. FIGURE 14-15 Effect of NOM preloading time (or GAC service time) on remaining GAC adsorption capacity for TCE in four drinking water sources. (Source: M. E. Jarvie et al. (2005), *Simulating the performance of fixed-bed granular activated carbon adsorbers: Removal of synthetic organic chemicals in the presence of background organic matter. Water Research, 39, 2407–2421. Copyright © 2005, with permission from Elsevier.*)

Two general trends have been observed when studying the effects of NOM preloading on the remaining adsorption capacity for micropollutants: (1) Adsorption capacity, as measured by the Freundlich K value, decreased rapidly during the initial weeks of preloading and more gradually thereafter (Fig. 14-15), and (2) differences in adsorption capacity as a function of bed depth diminished as preloading time increased (e.g., Summers et al., 1989; Knappe et al., 1999; Jarvie et al., 2005). With respect to the first observation, the decrease in the adsorption capacity for micropollutants is initially a result of the continuing adsorption of NOM. GAC fouling will continue beyond the point at which the GAC is saturated with NOM, however, because reorientation of preloaded NOM and/or chemical reactions involving preloaded NOM can take place on the GAC surface (Summers et al., 1989, 1990). For example, oxidative polymerization of preloaded NOM may proceed in the presence of dissolved oxygen (Vidic and Suidan, 1991). Regarding the second observation, the remaining adsorption capacity for micropollutants typically varies with GAC bed depth when a GAC bed has been in service for a relatively short time because the adsorbed NOM concentration is highest near the influent end of the GAC bed and lowest near the effluent end. Over time, GAC becomes uniformly saturated with NOM such that the remaining adsorption capacity for micropollutants is similar throughout the entire GAC bed. Because adsorption of humic substances on GAC is governed primarily by size-exclusion effects, and because the largest percentage of adsorption sites is contained in micropores (<2 nm diameter), preferential adsorption of humic substances with lower molecular weights occurs on GAC (McCreary and Snoeyink, 1980; Summers and Roberts, 1988b; Kilduff et al., 1996). Consequently, preloading experiments with different humic acid size fractions showed that the lowest-molecular-weight fraction had the greatest adverse effect on the remaining micropollutant adsorption capacity (Kilduff et al., 1998).

Adsorption Kinetics

Removal of organic compounds by physical adsorption on porous adsorbents involves a number of steps, each of which can affect the overall adsorption kinetics:

1. *Bulk solution transport.* Adsorbates must be transported from bulk solution to the boundary layer of water surrounding the adsorbent particle. Bulk transport to the boundary layer is affected by diffusion, dominant under low levels of mixing, and by turbulence, dominant under high levels of mixing. The latter conditions may be encountered during turbulent flow through a packed bed of GAC or when PAC is being mixed in a rapid-mix unit or flocculator.
2. *External (film) resistance to transport.* Adsorbates must be transported by molecular diffusion through the stationary layer of water (hydrodynamic boundary layer) that surrounds adsorbent particles when water is flowing past them. The distance of transport and thus the time for this step are determined by the bulk flow past the particle. The higher the flow rate, the shorter are the transport distance and time.
3. *Internal (intraparticle) transport.* After passing through the hydrodynamic boundary layer, adsorbates must be transported through the adsorbent's pores to available adsorption sites distributed throughout the particle. Intraparticle transport may occur by molecular diffusion through the solution in the pores (pore diffusion) and by diffusion along the adsorbent surface (surface diffusion) after adsorption takes place.
4. *Adsorption.* After transport to an available site, an adsorption bond is formed between the adsorbate and adsorbent. This step is rapid for physical adsorption (Adamson and Gast, 1997). As a result, one of the preceding diffusion steps will control the rate at which molecules are removed from solution. If adsorption is accompanied by a chemical reaction that changes the nature of the molecule, the chemical reaction may be slower than the diffusion step and thereby control the rate of compound removal.

The transport steps occur in series, so the slowest step, called the *rate-limiting step*, will control the rate of removal. In packed bed GAC adsorbents used for potable water treatment, a combination of film diffusion and intraparticle diffusion typically controls the rate of compound removal. Film diffusion may control initially, and after some adsorbate accumulates within the GAC particle, internal transport may control (Weber and Liu, 1980; Knappe et al., 1999). The mathematical models of the adsorption process therefore usually include both mass transfer steps. In contrast to GAC adsorption systems, film mass transfer typically is rapid in many PAC applications and, therefore, can be neglected (e.g., Najm, 1996)

Both adsorbate molecular size and adsorbent particle size have important effects on the overall adsorption kinetics. Diffusion coefficients are inversely proportional to the molecular size to about the one-third power. Thus humic substances with higher molecular weights diffuse more slowly into activated carbon particles than micropollutants with lower molecular weights. To reach an adsorption site, larger molecules tend to travel a shorter distance into the activated carbon particle because size-exclusion effects limit their access to smaller pores. Thus, despite the smaller diffusion coefficient, large molecules may equilibrate faster than small molecules that must travel farther into the activated carbon particle. Adsorbent particle size is even more important because it determines diffusion path length and thus the time required for transport within the particle to available adsorption sites. If the rate of adsorbate uptake is controlled by intraparticle diffusion, and the effective diffusion coefficient is constant, the time to reach adsorption equilibrium is directly proportional to the diameter of the particle squared. Calculations by Randtke and Snoeyink (1983) for activated carbon illustrate these points. For dimethylphenol (molecular weight 122 g/mol), nearly 8 days are estimated for near-equilibrium

($C_{\text{final}} = 1.01C_{\text{equilibrium}}$) of 2.4 mm diameter activated carbon, but only about 25 minutes would be required for 44 μm diameter activated carbon. For humic acid with a molecular weight of approximately 50,000 g/mol, the 2.4 mm diameter particle is expected to take much longer than a year to equilibrate, but only 2 days are required for the 44 μm diameter particle (assuming the same travel distance as for dimethylphenol). Calculations for fulvic acid with a molecular weight of 10,000 g/mol showed only about 25 percent saturation of 2.4 mm diameter particles after 40 days of contact. Thus the smaller the particle, the faster equilibrium is achieved in both column and complete-mix adsorption systems.

Some conclusions that can be drawn from these observations are that (1) the adsorption capacity of PAC can be used more quickly relative to GAC because of its smaller size, (2) the smallest-size GAC, consistent with other process constraints such as head loss and loss during reactivation, should be chosen for the fastest kinetics, and (3) depending on the compound, all the capacity of large GAC particles in a column may not be used because the time interval between GAC replacements is not sufficient for equilibrium to be achieved.

Estimation of Adsorption Kinetic Parameters. To determine adsorption kinetic parameters for PAC adsorption processes, batch experiments are conducted that measure the time rate of change of the adsorbate concentration in solution (e.g., Qi et al., 1994). For GAC beds, kinetic parameters typically are determined in (1) differential column batch reactors (DCBRs) (Hand et al., 1983) that permit the estimation of intraparticle diffusion coefficients or (2) short-bed adsorber (SBA) tests (Weber and Liu, 1980; Liang and Weber, 1985) that permit the estimation of both film mass transfer and intraparticle diffusion coefficients. A common model that is used to describe adsorption kinetic data is the homogeneous surface diffusion model (HSDM). Spreadsheet solutions of the HSDM for PAC adsorption systems are available (e.g., Hand et al., 1983; Najm, 1996; Zhang et al., 2009), and an example of such a solution is presented below. Numerical solutions to the HSDM, the pore diffusion model, and the pore-surface diffusion model typically are required to mathematically describe the evolution of the adsorbate concentration in the effluent of a GAC adsorber as a function of service time. Models for GAC adsorption systems have been described in detail by Sontheimer and colleagues (1988). Simplified models for fixed-bed adsorption systems have been described by Hand and colleagues (1984).

In the absence of film mass transfer, which typically is not rate limiting in PAC applications, the following equation has been developed as an approximate solution to the HSDM (Najm, 1996):

$$C_0 - C - 3C_c K C^{1/n} \left\{ \begin{array}{l} 0.33334 - 0.04903 \exp\left(-142.634 \frac{tD_s}{R^2}\right) \\ -0.05399 \exp\left(-39.996 \frac{tD_s}{R^2}\right) \\ -0.20240 \exp\left(-9.88686 \frac{tD_s}{R^2}\right) \end{array} \right\} = 0 \quad (14-9)$$

This equation illustrates that knowledge of the Freundlich isotherm parameters (K , $1/n$), the surface diffusion coefficient (D_s), the PAC particle radius (R), and the initial target compound concentration (C_0) is required to predict what contaminant concentration remains in solution for a given PAC dose (C_c) and contact time (t). Results obtained with Eq. 14-9 are in good agreement with those of a finite-element model when $tD_s/R^2 > 0.001$. For systems involving the adsorption of micropollutants from waters containing NOM, a pseudo-single-solute approach can be employed (Qi et al., 1994). In this approach, the Freundlich K value is calculated from isotherm data for the target contaminant in the water of interest, whereas

the $1/n$ value is taken from the single-solute isotherm. The D_s value then is estimated directly from batch kinetic data obtained in the water of interest. The following example illustrates the application of the HSDM for estimating D_s with the pseudo-single-solute approach.

Example 14-2 Homogeneous Surface Diffusion Model (HSDM): Atrazine Adsorption on PAC

A batch kinetic test was conducted with PAC to measure the rate of atrazine adsorption from a drinking water source. Determine the surface diffusion coefficient for the following data set:

$$C_0 = 179 \mu\text{g/L} \quad R = 6.7 \mu\text{m} \quad C_c = 2.6 \text{ mg/L}$$

Time, min	C/C_0
4.50	0.906
7.17	0.884
10.5	0.864
17.0	0.811
30.0	0.784
50.0	0.729
75.0	0.688
107	0.634
135	0.617
165	0.586
210	0.562
240	0.542
270	0.526
300	0.509
330	0.501
402	0.474
467	0.462

To be able to apply Eq. 14-9 for the determination of D_s , the Freundlich isotherm parameters K and $1/n$ need to be known. From isotherm experiments conducted with the same PAC in the same water, the relationship between the remaining atrazine percentage in solution as a function of PAC dose was determined (Fig. 14-16). This relationship permits calculation of the K value that applies to the kinetic test. The Freundlich $1/n$ value is 0.443.

Solution Using the isotherm data for an initial atrazine concentration of 179 $\mu\text{g/L}$, the Freundlich K value can be calculated from a point on the line, for which PAC dose and percent atrazine remaining in solution can be easily read from the graph. For example, for a PAC dose of 4 mg/L , Fig. 14-16 shows that approximately 8 percent atrazine remains in solution at equilibrium. The equilibrium solid-phase concentration q for this PAC dose and the Freundlich K value can be calculated from

$$q = \frac{C_0 - C}{m/V} = \frac{C_0 - 0.16 \times C_0}{2.6 \text{ mg/L}} = \frac{(179 - 28.64) \mu\text{g/L}}{2.6 \text{ mg/L}} = 57.2 \mu\text{g/mg} = 57.2 \text{ mg/g}$$

$$q = K \times C^{1/n} \quad \text{or} \quad K = \frac{q}{C^{1/n}} = \frac{57.2 \text{ mg/g}}{(28.64 \mu\text{g/L})^{0.443}} = 12.9 \text{ (mg/g)(L/\mu g)}^{1/n}$$

FIGURE 14-16 Atrazine adsorption isotherms in a drinking water source at three initial concentrations.

Approach for Determining D_s from Eq. 14-9

Using a spreadsheet, calculate the result of Eq. 14-9 for each data point by assuming a value for D_s and by using the given/calculated values for C_0 , C_e , R , K , $1/n$, and t . Add a column that contains the square or absolute value of the result of Eq. 14-9 for each data point. At the bottom of that column, determine the sum of the squares or absolute values. Then use a nonlinear optimization tool (e.g., Solver in Microsoft Excel) to minimize the value of the sum of squares or absolute values by varying D_s —or better, the log of D_s because D_s is on the order of 10^{-13} cm^2/s . This procedure yields a D_s value of 3.6×10^{-13} cm^2/s as the best estimate for the preceding data set. The resulting D_s value can be used to predict PAC performance in different reactor configurations (i.e., plug flow, completely mixed). ▲

Breakthrough Curves for Packed Bed GAC Reactors. The region of a GAC column in which adsorption is taking place, the *mass transfer zone* (MTZ), is shown in Fig. 14-17a. The activated carbon behind the MTZ has reached the adsorption capacity for the given influent concentration C_0 , and the solid-phase concentration per unit mass of GAC is q_0 . The activated carbon in front of the MTZ has not been exposed to the adsorbate, so both the aqueous- and solid-phase concentrations are zero. Within the MTZ, the solid-phase concentration varies from q_0 to zero. The length of the MTZ L_{MTZ} depends on the rate of internal and external mass transfer and the adsorption capacity. Anything that causes a higher rate of mass transfer, such as a smaller carbon particle size, higher temperature, larger diffusion coefficient of adsorbate, greater strength of adsorption of adsorbate, and larger adsorption capacity (i.e., a larger Freundlich K value), will decrease the length of the MTZ.

In some circumstances, for example, small, strongly adsorbing compounds in long GAC columns, L_{MTZ} will be reduced sufficiently relative to bed length so that it can be assumed to be zero, yielding the ideal plug-flow behavior, as shown in Fig. 14-17b. If L_{MTZ} is negligible, analysis of the adsorption process is greatly simplified.

The breakthrough curve is a plot of the column effluent concentration as a function of either the volume treated, the time of treatment, or the throughput in terms of number of bed volumes (BVs) treated (BV = volume of water treated/GAC volume V). The number

FIGURE 14-17 Adsorption column (a) with MTZ and (b) without MTZ.

of BVs is a particularly useful parameter because the data from columns of different sizes and with different flow rates are normalized. A breakthrough curve for a single, adsorbable compound is shown in Fig. 14-18. The *breakthrough concentration* C_B for a column is defined as the maximum acceptable effluent concentration. When the effluent concentration reaches this value, the GAC must be replaced. V_B is the volume treated to breakthrough. The shape of the curve is affected by the same factors that affect the length of the MTZ and in the same way. Anything that causes the rate of adsorption to increase will increase the sharpness of the curve. The breakthrough curve will be vertical if $L_{MTZ} = 0$, as was shown in Fig. 14-17b. *Breakthrough capacity* is defined as the mass of adsorbate removed by the adsorber at the maximum acceptable effluent concentration or at breakthrough, $C_{eff} = C_B$, as illustrated in Fig. 14-18. The degree of column utilization is defined as the ratio of the mass adsorbed at breakthrough relative to the mass adsorbed at complete breakthrough, where $C_{eff} = C_0$. Values of both parameters increase as the rate of adsorption increases.

The breakthrough curve can be used to determine the activated carbon usage rate (CUR) at breakthrough. The CUR is the mass of activated carbon used per unit volume of water treated:

$$CUR \left(\frac{\text{mass}}{\text{volume}} \right) = \frac{\text{mass of GAC in column}}{\text{volume treated to breakthrough } V_B} = \text{GAC bed density } \rho / BV_B \quad (14-10)$$

where BV_B is the number of bed volumes treated at breakthrough V/V_B .

FIGURE 14-18 Adsorption column breakthrough curve.

Breakthrough curves of single compounds are affected by the relationship between the L_{MTZ} and the GAC bed depth. Immediate breakthrough of adsorbable compounds occurs if the L_{MTZ} is greater than the GAC bed depth (compare curves A and B in Fig. 14-19).

For heterogeneous mixtures such as NOM, breakthrough can be strongly affected by the presence of nonadsorbable compounds, biodegradable compounds, and the slow

FIGURE 14-19 Effect of biodegradation and the presence of nonadsorbable compounds on the shapes of breakthrough curves.

FIGURE 14-20 Schematic of NOM breakthrough.

adsorption of large NOM molecules. Nonadsorbable compounds appear immediately in the column effluent, even when the GAC bed depth is greater than the L_{MTZ} of specific components of the NOM (compare curves *B* and *C* in Fig. 14-19). Removal of adsorbable biodegradable compounds by microbiological degradation in a column results in continual removal, even after the carbon normally would be saturated with adsorbable compounds (see curve *D* in Fig. 14-19). Breakthrough curves shown in Fig. 14-20 also illustrate some of these effects.

Figure 14-20 shows breakthrough of NOM and its different components as measured by DOC. In this case, the MTZ is contained in the bed depth, and zone 1 shows the immediate breakthrough of nonadsorbable compounds. Note that UVA (UV absorbance) does not detect these compounds because most nonadsorbable compounds do not absorb light at the wavelength used. In zone 2, weakly adsorbable compounds break through, and strongly adsorbable compounds are removed until zone 3. A small level of removal continues by slow adsorption of large NOM constituents into small GAC pores in zone 4, as shown by the UVA. Zone 5 shows the long-term biodegradation as measured by the DOC, and zone 6 shows the desorbable fraction, which will be discussed later.

NOM Preloading Effect on Adsorption Kinetic Parameters. For fixed-bed GAC adsorption processes, NOM preloading lowers not only the adsorption capacity of GAC (see above) but also the rate of target contaminant adsorption. Both external film mass transfer and intraparticle diffusion coefficients decrease.

Several studies have shown that the film mass transfer coefficient k_f decreases as preloading (or GAC service) time (e.g., Speth, 1991; Carter and Weber, 1994; Knappe et al., 1999) or NOM surface loading (Schideman et al., 2006a) increases. For TCE adsorption from Huron River water, the k_f value for GAC that was preloaded for 4 weeks was approximately 30 percent of that for fresh GAC (Carter and Weber, 1994), whereas the k_f value

describing atrazine adsorption from Seine River water was approximately 50 percent of that obtained with fresh GAC after preloading times of 5 and 20 months (Knappe et al., 1999). A reduction in k_f with increasing preloading time or NOM surface loading may appear surprising given that the k_f value for a given adsorbate should depend only on the adsorbent geometry and the interstitial water velocity in an aqueous system. However, NOM may accumulate near the outer surface of the adsorbent particles as a result of slow adsorption kinetics (Matsui et al., 1994). Consequently, the local water viscosity at the external GAC surface may increase and/or the effective surface area for mass transfer may decrease, which would explain lower k_f values in the presence of preloaded NOM (Carter and Weber, 1994). For the herbicide atrazine, Fig. 14-21 shows the dependence of the external film mass transfer coefficient on NOM surface loading. The effect of NOM preloading on k_f can be important for short GAC beds (e.g., Schideman et al., 2006b) or treatment systems involving the application of PAC in conjunction with membrane filtration processes (e.g., Ding et al., 2006). Breakthrough curve predictions for typical GAC adsorber designs are relatively insensitive to k_f , however (e.g., Knappe et al., 1999).

FIGURE 14-21 Dependence of the external film mass transfer coefficient on NOM surface loading. (Source: Reprinted with permission from L. Schideman et al. (2006a), *Three-component competitive adsorption model for fixed-bed and moving-bed granular activated carbon adsorbers: I. Model development*. *Environmental Science & Technology* 40(21), 6805–6811. Copyright © 2006, American Chemical Society.)

Several researchers have studied the effect of preloaded NOM on internal mass transfer (Zimmer et al., 1987; Hand et al., 1989; Speth, 1991; Carter and Weber, 1994; Li et al., 2003a, 2003b). Internal mass transfer can take place by both surface and pore diffusion. Because the two intraparticle diffusion processes occur in parallel, the faster of the two is rate determining. For TCE adsorption from natural waters, a reduction in the effective surface diffusion coefficient D_s of approximately one order of magnitude was observed after a preloading time of 5 weeks (Zimmer et al., 1987; Hand et al., 1989). The decrease in D_s

FIGURE 14-22 Effect of NOM surface loading on the magnitude of the surface diffusion coefficient D_s . (Source: Q. Li et al. (2003b), Pore blockage effect of NOM on atrazine adsorption kinetics of PAC: The roles of PAC pore size distribution and NOM molecular weight. *Water Research* 37, 4863–4872. Copyright © 2003, with permission from Elsevier.)

was such that pore diffusion became rate determining, and a pore diffusion model was used to describe the removal rate of TCE (Hand et al., 1989; Weber and Carter, 1994). Relating changes in D_s to NOM surface loading, Li and colleagues (2003b) showed that NOM surface loadings in excess of 100 mg/g can lower D_s for the herbicide atrazine by more than two orders of magnitude relative to the value obtained with fresh GAC (Fig. 14-22). Both activated carbon and NOM characteristics affect the manner in which D_s decreases with NOM surface loading (Li et al., 2003b).

Desorption and Attenuation

Adsorption of many compounds is reversible, which means that they can desorb. Desorption may be caused by displacement by other compounds, as discussed earlier, or by a decrease in influent concentration. An analysis of specific compound desorption at high concentration ranges (>1 mg/L) by Thacker and colleagues (1983) showed that the quantity of adsorbate that can desorb in response to a decrease in influent concentration increased as (1) the diffusion coefficient of the adsorbate increased, (2) the amount of compound adsorbed increased, (3) the strength of adsorption decreased (e.g., as the Freundlich $1/n$ value increased), and (4) the activated carbon particle size decreased. Volatile organic compounds (VOCs) are especially susceptible to displacement because they are weakly adsorbed and diffuse rapidly.

Summers and Roberts (1988a, 1988b) have shown that NOM only partially desorbs, and for the desorbing fraction, the desorption diffusivity is lower than that during adsorption. Corwin and colleagues (2008) found that desorption occurred much more slowly than predicted by the pore-surface diffusion model for target organic compounds at very low concentrations (<1 $\mu\text{g}/\text{L}$) in waters containing adsorbable NOM. To model the results, Freundlich K values of desorption were reduced by 10 to 50 percent compared with the

adsorption K values, with more strongly adsorbing compounds showing the largest differences. Longer-term desorption tests indicated a relatively fast decrease in effluent concentration that approached a steady desorption phase that lasted for over 50,000 BVs at about 10 percent of the previously applied influent concentration.

Periodic episodes such as spills and seasonal taste and odor events can occur in surface waters. In these events, the influent concentration increases for a relatively short period, hours to weeks, and then decreases to a baseline concentration that may be very small. A low influent concentration after the episode causes a reversal of the concentration gradient, and desorption occurs. The attenuation of pulses can be an effective way of dampening the exposure to high concentrations, but the total mass passing through the system theoretically should be the same as that in the influent. The peak concentration of the effluent is a function of the factors listed above (Thacker et al., 1983), as well the service life and amount of DOM adsorbed prior to the episode (Matsui et al., 1994; Gilligly et al., 1999, 2006). Hindered desorption has implications in the modeling the micropollutant attenuation by GAC. The actual concentrations are lower initially than those predicted by standard models.

GAC ADSORPTION SYSTEMS

GAC contactors can be classified by the following characteristics: (1) driving force: gravity versus pressure, (2) flow direction: downflow versus upflow, (3) configuration: parallel versus series, and (4) position: filter adsorber versus postfilter adsorber. GAC may be used in pressure or gravity contactors. Pressure filters enclose the GAC and can be operated over a wide range of flow rates because of the wide variations in pressure drop that can be used. In many groundwater systems, pressure filters can take advantage of existing pressure in the system to avoid repumping and the associated costs. Another advantage of these filters is that they can be prefabricated, shipped to the site, and installed quickly. A disadvantage is that the GAC cannot be observed visually or sampled with ease. Gravity contactors are better suited to systems in which wide variations in flow rate are not desirable because of the need to remove turbidity, large pressure drops are undesirable because of their impact on operational costs, there is available hydraulic head in the plant, and visual observation is needed to monitor the condition of the GAC. For many systems, the decision between pressure or gravity contactors is made on the basis of cost. Medium- and large-sized systems normally use gravity contactors, and groundwater systems typically use pressure filters because the flows from a well normally are low.

Water may be applied to GAC either downflow or upflow, and upflow columns may be either packed bed or expanded bed. Downflow columns are the most common and seem best suited for drinking water treatment. McCarty and colleagues (1979) found that carbon fines were produced during packed bed upflow operation and were not produced during downflow operation. The pulsed bed contactor also can be used to decrease carbon usage rate from that of a single contactor. The flow is applied upward through the column; the spent GAC, a fraction of the total amount present, is removed periodically from the bottom of the column, and an equal amount of fresh GAC is applied to the top. Upflow pulsed bed operation followed by membrane filtration can be used to eliminate the problem of fines production (Schideman et al., 2006a, 2006b).

Single-stage contactors are used often for small groundwater systems, but if more than one contactor is required, lower activated carbon usage rates can be achieved by arranging them either in series or in parallel, as shown in Fig. 14-23, possibly yielding a lower-cost system. GAC in a single-stage contactor must be removed about the time the MTZ begins to exit the column. At this point, only a portion of the activated carbon is saturated at the influent concentration, so the activated carbon usage rate may be relatively

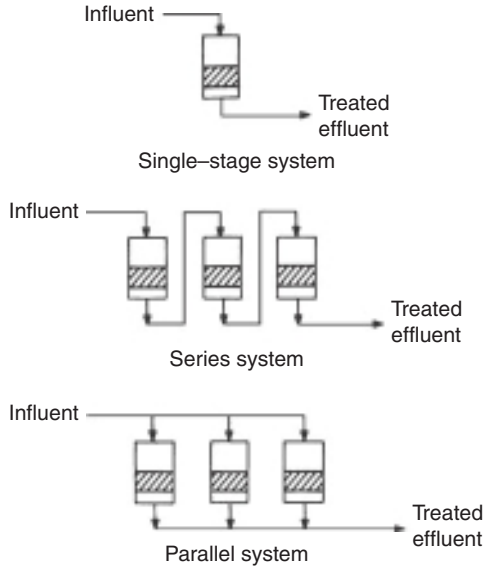

FIGURE 14-23 GAC adsorber systems.

high (see Fig. 14-18). Alternatively, columns may be arranged in series so that the MTZ is contained entirely within the downstream columns after the lead column has been saturated with the influent concentration. When the activated carbon is replaced in the lead column, the flow is redirected so that it goes through the freshest activated carbon last. Thus the activated carbon “moves” countercurrent to the flow of water, and lower activated carbon usage rates are achieved than with single-stage contactors. Series configuration is best used when the effluent criterion is very low compared with the influent concentration (Wiesner et al., 1987). However, for many SOCs at low concentrations, the adsorption capacity is decreased when the GAC is exposed to the background NOM for prolonged times; thus the capacity in the second column in series may be lower than that of the first. The increased cost of plumbing also counters the cost benefit of reduced activated carbon usage rate, especially when more than two columns must be used in series.

When parallel-flow adsorbers are operated in staggered mode, they also can be used to decrease the activated carbon usage rate from that which is possible with a single-stage contactor (Westrick and Cohen, 1976; Roberts and Summers, 1982). Because the effluent from each unit is blended, an individual unit can be operated to effluent concentrations higher than the treated water goal because it is blended with water from another unit that has an effluent below the treatment goal. Only the composite flow must meet the effluent quality goal. Dvorak and Maher (1999) showed that the GAC use rate for NOM removal decreased asymptotically with increasing number of adsorbers in parallel, with the largest decrease occurring when moving from a single adsorber to two adsorbers in parallel.

Denning and Dvorak (2009) used the pore-surface diffusion model to extensively evaluate the performance of lead-lag series operation, blended parallel operation, and bypass operation, which is similar to parallel operation with a column at exhaustion. They found that when high levels of removal were required, $C/C_0 = 0.05$, the lead-lag system was most efficient. For a less stringent criterion, $C/C_0 = 0.25$, the lead-lag series and blended parallel operation yielded similar results. Bypassing was found to be an effective approach in reducing costs.

Other flow arrangements can be used to produce lower activated carbon usage rates. Sontheimer and Hubele (1987) reported the use of pressure filters with two layers of GAC at Pforzheim, Germany. Each of the two layers could be backwashed and replaced independently, and the order of flow through these layers could be reversed. For removing halogenated hydrocarbons from groundwater, a 35 percent lower carbon usage rate (CUR) was reported for this system compared with a single-stage system.

In water treatment plants where filtration is required, for example, surface water treatment, GAC contactors also can be classified by their position in the process train. The filter adsorber employs GAC to remove particles as well as dissolved organic compounds. These contactors may be constructed simply by removing all or a portion of the granular medium from a rapid filter and replacing it with GAC. Alternatively, a new filter box and underdrain system for the GAC may be designed and constructed. Graese and colleagues (1987a) discuss these types of filters in detail. The postfilter adsorber is preceded by a granular media filter and thus has as its only objective the removal of dissolved organic compounds. Backwashing of these adsorbers is unnecessary for particle removal, but if immediately preceded by ozonation and in the presence of extensive biological growth, they may require regular backwashing. In groundwater treatment systems in which precipitates are not formed, filtration typically is not required, and the GAC adsorbers are more like postfilter adsorbers with respect to design and nonbackwashing operation.

PERFORMANCE OF GAC SYSTEMS

Factors Affecting Removal Efficiency

Adsorbate and GAC properties both have important effects on adsorption that have been discussed in earlier sections. Additional factors that must be considered in the design of full-scale systems are presented here.

GAC Particle Size. The effect of particle size on the rate of approach to equilibrium, discussed previously, has a similar effect on rate of adsorption in columns if the rate of adsorption is controlled by intraparticle diffusion. Decreasing particle size will decrease the time required to achieve equilibrium and will decrease the length of the MTZ in a column, with all other factors constant. This is not an important factor if only 50 percent removal is needed, but it becomes important if high levels of removal, for example, greater than 90 percent, are needed. Thus, under high removal requirements, the particle size selected for a contactor should be as small as possible, which will improve fixed-bed adsorption efficiency and minimize the GAC bed size required. For filter adsorbers, the rate of head loss buildup caused by particle removal may limit the GAC particle size that can be used. Small GAC particle sizes lead to a higher initial head loss and rate of head loss buildup. Thus cost of energy and availability of head have an important influence on the GAC size selected for a filter adsorber design. Additionally, if a filter adsorber is constructed by replacing media in an existing rapid filter, turbidity removal efficiency generally increase as the GAC size decreases. If the GAC size is too small, the rate of head loss buildup because of particle accumulation becomes excessive, causing frequent backwashing, low net water production, and uneconomical operation.

The commercial sizes of GAC typically are characterized by a relatively large uniformity coefficient of up to 1.9. This large coefficient causes the bed to re-stratify more easily after backwashing. Large uniformity coefficients also require greater percentage bed expansion during backwash in order to expand and clean the bottom media (Graese et al., 1987a). Some GAC filters use GAC with a small uniformity coefficient (~1.3) in deep beds to improve depth removal of turbidity and to increase net water production

(Graese et al., 1987b). Mixing of the media in these filters undoubtedly is more than in filters with large uniformity coefficients, so they should not be used in applications where desorption from the mixed GAC will require early GAC replacement.

Filter adsorbers that are used to remove turbidity commonly employ 8×30 U.S. Standard Mesh (2.38×0.60 mm) or larger activated carbon to promote longer filter runs. Common practice is to use 12×40 U.S. Standard Mesh (1.68×0.42 mm) or similar activated carbon in postfilter adsorbers. The small particle sizes decrease the L_{MTZ} , and regular backwashing for accumulated particle removal is not required. The option of using custom-sized GAC to obtain a better media design for a particular application also is available.

Contact Time, Bed Depth, Hydraulic Loading Rate. An important GAC adsorber design parameter that affects performance is the contact time, most commonly described by the *empty bed contact time* (EBCT). For a given situation, a critical depth of GAC and a corresponding minimum EBCT exist that must be exceeded to contain the MTZ and minimize or eliminate immediate breakthrough. As the EBCT increases, the run time to a given effluent concentration typically will increase. However, in most cases, the relationship is not linear. Pilot data that show the effect of increasing EBCT on bed life for VOCs have been given by Love and Eilers (1982). In general, they showed that the CUR for *cis*-1,2-dichloroethylene, 1,1,1-trichloroethane, and carbon tetrachloride decreased substantially as the EBCT was increased from 6 to 12 minutes, but little change was noted when the EBCT was increased to 18 minutes. For micropollutants in the presence of background NOM, the CUR of GAC beds with long EBCTs can become larger than that of GAC beds with shorter EBCTs, however. This trend is related to the poorer adsorbability of NOM relative to the micropollutant. NOM will penetrate deeper into the bed and will foul the GAC in the bottom of the adsorber. As a result, the adsorption capacity and adsorption rate of micropollutants are reduced, as discussed earlier in this chapter.

For adsorption of NOM, longer EBCTs have been found to be more efficient in many cases, that is, lower CURs and higher throughput than for shorter EBCTs in the range of 5 to 20 minutes. Summers and colleagues (1997) reported that for three of the four waters examined for TOC and DBP precursor control, no significant change in the BVs treated or CUR occurred when the EBCT was increased from 10 to 15 to 20 minutes. Analysis of the Information Collection Rule (ICR) data by Zachman and Summers (2010) has shown that increasing the EBCT from 10 to 20 minutes increased BVs treated to a given effluent concentration by 10 percent and resulted in a lower CUR. This will be discussed in more detail later in this chapter.

The impact of EBCT on the breakthrough of NOM (measured by UVA) and bisphenol A (BPA) is shown in Fig. 14-24. The mass transfer zones of both the NOM, as measured by UVA, and BPA are contained by the 5.0 minute EBCT. For the first 5000 BVs, the longer EBCTs show better performance for both compounds. This trend continues for the NOM breakthrough; however, the EBCT trend reverses for BPA, reflecting the “fouling” of adsorption sites deeper in the bed with time (Corwin, 2010). Collecting pilot-plant data for a range of EBCT values is important if the lowest activated carbon cost for a given application is to be determined.

Increasing EBCT by increasing the bed depth at a constant hydraulic application rate increases the capital cost of the GAC system (Wiesner et al., 1987; Kornegay, 1979; Lee et al., 1983). Operating costs decrease because of decreasing GAC replacement frequency. Thus the optimal depth, or EBCT, can be calculated by the intersection of the capital and operation and maintenance (O&M) cost curves.

While hydraulic loading rates affect external mass transfer, under normal operating conditions, intraparticle mass transfers controls, rendering hydraulic loading rate impacts negligible (Sontheimer et al., 1988). Cover and Pieroni (1969) review data that show adsorbers with the same EBCT but with different hydraulic loading rates give essentially the same

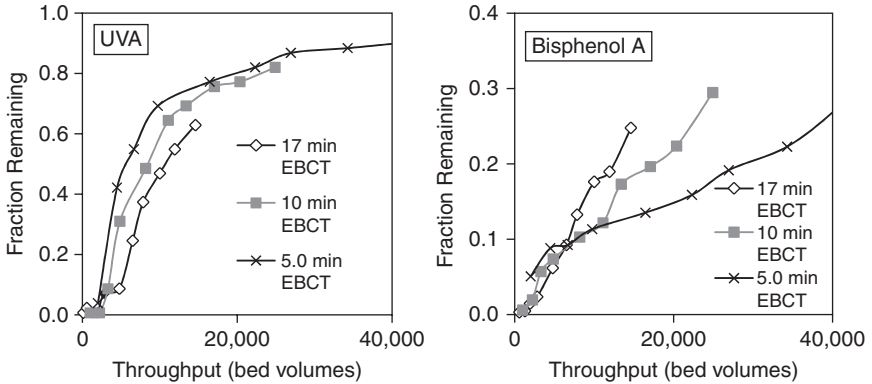

FIGURE 14-24 Impact of EBCT on NOM and bisphenol A breakthrough. (Source: Adapted with permission from Corwin, 2010.)

performance in terms of number of BVs processed to breakthrough, provided that the depth is considerably greater than the critical depth L_{MTZ} .

The EBCTs in use range from a few minutes for some filter adsorbers (Graese et al., 1987a) to more than 4 hours for the removal of high concentrations of certain specific contaminants (Snoeyink, 1983). Typical values for filter adsorbers are in the 5 to 10 minute range and for postfilter adsorbers in the range of 15 to 25 minutes. Hydraulic application rates vary from 1 to 30 m/h (0.4–12 gpm/ft²), with a typical value being 7 to 10 m/h (3–4 gpm/ft²). For filter adsorbers, selection of hydraulic loading rate and bed depth needs to also include considerations for optimal filtration performance (see Chap. 10).

Backwashing. Backwashing of GAC filter adsorbers is essential to remove trapped particles and maintain the desired hydraulic properties of the bed. Regular backwashing of postfilter adsorbers is not normally required, although some may be needed to control biological growth and head loss. Backwashing should be minimized, however, because of its possible effect on adsorption efficiency. Mixing of the bed may take place during backwashing, and if so, GAC with adsorbed molecules near the top of the bed may move deeper into the bed, where desorption is possible. Molecules with low K values, such as carbon tetrachloride and other VOCs, may be partially desorbed in this new position, leading to a spreading out of the MTZ and to early breakthrough (Wiesner et al., 1987). Desorption will not occur if the molecules are irreversibly adsorbed or if they are removed by a destructive mechanism such as biodegradation instead of adsorption. The large uniformity coefficient of most commercial activated carbons promotes restratification after backwash. If the underdrain system does not distribute the wash water properly, or if the backwash is not carried out in a manner that aids restratification, substantial mixing of the activated carbon can occur with each backwash (Graese et al., 1987a). Hong and Summers (1994) have shown that backwashing had little impact on the time to 50 percent breakthrough for the TOC and trihalomethane (THM) precursors of four waters. For two of the waters, some increase in TOC after backwashing was detected, but the maximum amount was only 0.2 mg/L, consistent with the TOC being essentially irreversibly adsorbed. Hong and Summers (2006) used models to predict significantly earlier breakthrough of organic contaminants based on complete mixing; however, Corwin and colleagues (2008) did not find a significant impact of mixing using small columns. This discrepancy is likely due to the model assumption of Freundlich and diffusion parameters being constant for adsorption and desorption.

Biological Activity. In a filter or packed column, indigenous microorganisms will accumulate on the surface of the medium, such as sand or GAC, as long as a disinfectant residual is not present in the effluent and if a biodegradable substrate, organic or inorganic, is available. This process is often termed *biofiltration*, and when GAC is the filter medium, the term *biological activated carbon* (BAC) has been used. Chlorine reacts strongly with GAC such that under normal operating conditions, chlorine is not present in the column effluent. Thus all applications of GAC in water treatment have biomass growth and a biological removal component. In the last 10 years, several reviews of biofiltration as used in drinking water treatment have been published (Ufer et al., 1997; Servais et al., 2005; Evans et al., 2010). One review, that by Chowdhury and colleagues (2010), specifically focused on BAC in filter adsorbers with nonozonated influent, the most common use of BAC in the United States. The reviews by Chowdhury and colleagues (2010) and Evans and colleagues (2010) also include utility surveys.

Based on these reviews, some generalizations can be made. GAC seems to provide slightly better biological removal performance than sand or anthracite and adds the potential to attenuate pulses of influent adsorbable compounds. However, there are more similarities than differences between biologically active GAC and inert media with respect to design, operation, and performance. For all biological filters (except in some cases slow sand filters), the following generalizations hold true: Specific organic compounds that are biodegradable, as well as a biodegradable fraction of NOM, can be removed. Increasing EBCT can increase the removal. Lower temperatures can decrease the removal. Preozonation can increase the biodegradable fraction of the NOM. Bioacclimation time can take from days for easily assimilated compounds to months for more resistant compounds, especially at low (submicrogram per liter) concentrations. For GAC, biodegradable compounds may be removed by microbes, without prior adsorption to the GAC, if a microbial community structure capable of degrading such compounds is present. Adsorbable biodegradable compounds may be adsorbed first if the microbial community structure is not developed when the compounds enter the column and then desorbed and degraded as the microbial community structure develops.

Biological oxidation has been shown to be responsible for the removal of specific compounds such as phenol (Chudyk and Snoeyink, 1984), the odor-causing compounds geosmin and MIB (Ho et al., 2007; Chae et al., 2006; Namkung and Rittman, 1987; Silvey and Roach, 1964), the cyanotoxin microcystin-LR (Wang et al., 2007), *p*-nitrophenol and salicylic acid (DeLaat et al., 1985), ammonia (Bablon et al., 1988), trichlorobenzene (Summers et al., 1989), bromate (Kirisits and Snoeyink, 1999; Kirisits et al., 2001), perchlorate (Brown et al., 2002, 2003, 2005), and specific ozonation by-products (Servais et al., 2005). The performance of biofilters for these compounds varies and is a function of influent water quality and filter conditions. Longer EBCTs normally will lead to better removal.

Some portion of the NOM in natural waters can be oxidized biologically by biological filters, as shown in Fig. 14-25 for an anthracite-sand filter and a GAC filter for nonozonated water. The anthracite-sand filter took a few weeks to acclimate but then achieved removals ranging from 5 to 20 percent depending on the time of year. The GAC filter adsorber displayed both adsorption and bioremoval over the first 9 months; thereafter, removal was by slow adsorption and biodegradation. For coagulated waters without preozonation, the biodegradable NOM fraction is about 10 to 15 percent, of which 50 to 75 percent can be removed in biological filters. This would yield a steady state TOC removal of 5 to 10 percent, which is similar to that shown in Fig. 14-25. For ozonated waters, the biodegradable NOM fraction increases to about 20 to 40 percent, of which 50 to 75 percent can be removed in biological filters. This would yield a steady state TOC removal of 10 to 30 percent, as reported in Table 14-6 for biofiltration of ozonated and settled Ohio River water.

Under conditions of drinking water treatment, the concentration of biodegradable NOM (0.1–1.0 mg/L) is orders of magnitude greater than that of the specific biodegradable organic compounds ($<<0.1$ mg/L). Thus most of the biomass accumulation is associated with biodegradable NOM. The dependency of the bioremoval of specific compounds on that of NOM

FIGURE 14-25 Normalized effluent TOC from a GAC filter-adsorber (D1) and an anthracite-sand filter (P6) treating nonozonated water at the City of Birmingham’s demonstration and pilot-plant facility. (Source: Chowdhury et al., 2010.)

and the associated biomass is not understood. The biodegradation of NOM increases with increasing EBCT. This EBCT dependency yields a similar distribution of biomass on the filter beds, high at the top and asymptotically decreasing with depth (Wang et al., 1995; Servais et al., 2005). Under normal operating conditions, the easily degraded NOM fraction, about 50 percent of the total degradable fraction, can be removed in the first 5 minutes of EBCT, with some additional removal occurring in EBCTs up to 30 minutes (Servais et al., 2005; Wang and Summers, 1995). Complete removal of the biodegradable NOM fraction is not possible with the range of EBCTs used in practice (5–30 minutes). Thus, increasing the EBCTs beyond that of a filter adsorber (5–10 minutes) may not yield significant additional removal.

Since the kinetics are that lower at low temperatures, longer EBCTs are need at low temperature to achieve the same results, biological oxidation may vary significantly throughout the year if low temperatures are expected (Servais et al., 2005). TOC removal by biologically

TABLE 14-6 Impact of Media Type on Performance—Ozonated/Settled Ohio River Water

Parameter	Removal (%)				
	Anthracite-sand	Sand	GAC-microporous	GAC-mesoporous	GAC-macroporous
TOC	16	20	29	27	21
AOC-NOX	39	43	51	47	42
THMFP	23	23	40	34	27
TOXFP	28	25	52	44	31

Source: Wang et al. (1995).

active GAC systems seems to be a conservative indicator for DBP precursor removal (Miltner et al., 1996; Wang et al., 1995). Table 14-6 shows the removal of TOC, DBP precursors (as measured by the formation potential for THMs and total organic halide (TOX), and assimilable organic carbon (AOC), a measure of the biodegradable fraction of NOM, by biofiltration of ozonated and settled Ohio River water. All filters had a total depth of 0.76 m (30 in), including a bottom layer of 0.20 m (8 in) of sand, yielding an overall EBCT of 9.2 minutes. The steady state removals reported in the table were taken between 5 and 11 months of operation. The GAC columns outperformed the inert media columns, and the micro- and mesoporous GACs seem to perform best in the biological mode.

Several studies have shown that bacterial counts in the effluent of a biofilter are most often higher than in the influent (Servais et al., 2005). A thorough analysis of this is given by Symons and colleagues (1981). They report data from Beaver Falls, PA, that show that both coliform and standard plate counts were higher in GAC effluent than influent when the water temperature was greater than about 10°C, even though 1 to 2 mg/L of chlorine residual was present in the influent to the bed. Apparently, the GAC reduced the chlorine and allowed the bacteria to regrow. When the water temperature was below about 10°C, no regrowth was noticed. Other data from Philadelphia showed that coliform organisms such as *Citrobacter freundii*, *Enterobacter cloacae*, and *Klebsiella pneumoniae* were found in the GAC filters. In all cases, postdisinfection produced water meeting USEPA regulations.

Another problem may occur if activated carbon particles penetrate the underdrain and provide a habitat for microbes that protects them from being killed by disinfectants (LeChevallier et al., 1984; Servais et al., 2005). These problems can be minimized through proper underdrain design and installation, placement and backwashing of new charges of GAC, and backwashing of beds during operation (Servais et al., 2005).

Macroorganisms can grow in GAC filters if the filters are biologically active. Organisms such as protozoa, rotifers, and nematodes have been reported in biofilters and their effluent, especially at warmer temperatures (Servais et al., 2005). Optimized backwashing conditions have been shown to be effective in controlling this problem.

BAC must be controlled to avoid undesirable effects. Anaerobic conditions may develop, with attendant odor problems, if the system is not kept aerobic. This may happen if large concentrations of ammonia enter the filter (each milligram per liter of NH_3 requires about 3.8 mg/L of dissolved oxygen if it is converted to NO_3^-), if insufficient dissolved oxygen is in the water, or if the bed is allowed to stand idle for a period of time.

Application of chlorine to GAC adsorbers does not prevent biological growth and increases the concentration of adsorbed chlorinated organic compounds. The potential exists for chlorine to make the activated carbon become more friable and break up more easily, especially during backwash, because chlorine destroys some of the activated carbon when it is reduced (Snoeyink and Suidan, 1975). Also, the potential exists for formation of unique organic compounds through the catalytic action of the activated carbon surface, as shown later. Thus application of chlorine to GAC filters is not recommended.

Pretreatment for GAC Systems. Pretreatment can have a significant impact on the performance of GAC systems. The influent concentration of target and competing organic compounds may be lowered, thus increasing the run time to a given target concentration. The species of compounds or NOM composition may be changed, thus changing adsorbability and biodegradability. NOM removal by conventional surface water treatment and by biofiltration is important for specific organic compound adsorption because it reduces the fouling or preloading of GAC. It also decreases the NOM load on the GAC, thus increasing the run time to a target TOC level. In both cases, the CUR and cost of GAC operation are lowered (see Chap. 8 for a discussion of organic compound removal by coagulation).

Kim and colleagues (2007) and Kim (2006) explored the impact of background NOM concentration, methylisoborneol (MIB) concentration, and EBCT on the breakthrough of MIB at the bench scale. Figure 14-26 shows that decreasing background TOC yielded longer

FIGURE 14-26 Impact of background TOC on MIB breakthrough in RSSCTs; MIB $C_0 = 100$ ng/L, EBCT = 10 minutes, bituminous 12 × 40 mesh GAC. (Source: Adapted with permission from Kim, 2006.)

run times to a given effluent MIB concentration. For an influent MIB concentration of 50 ng/L and an EBCT of 15 minutes, the adsorber would last for 6 months to greater than 20 months for this range of influent TOC concentrations and an effluent target of 10 ng/L. These authors also demonstrated that the fractional breakthrough C/C_0 was not affected by the initial concentration when C_0 was at or below 200 ng/L. Similar results have been reported for atrazine (Matsui et al., 2002). After analyzing the TOC and MIB breakthrough results of 35 rapid small-scale column test (RSSCT) runs, Kim and colleagues (2007) found a direct relationship between the throughput in BVs to 70 percent TOC breakthrough and BVs to 10 percent MIB breakthrough for EBCTs of 5, 10, 15, and 20 minutes, influent MIB concentrations ranging from 50 to 200 ng/L, and influent TOC concentrations ranging from 1.3 to 3.8 mg/L.

Summers and colleagues (1994), Hooper and colleagues (1996b), Bond and DiGiano (2004), and Zachman and Summers (2010) have shown that the run time in BVs to a target effluent TOC concentrations is inversely proportional to the influent TOC concentration. They developed models that are discussed later in this chapter.

Bond and DiGiano (2004) and Zachman and Summers (2010) have shown that the run time in BVs to a target effluent TOC concentrations is inversely proportional to the influent pH. The impact of pH on equilibrium capacities was shown in Fig. 14-4 for a specific organic compound and Fig. 14-9 for NOM. These impacts also translate to breakthrough curves; lower pH values yield longer run times for acidic compounds such as humic and fulvic acids that dominate NOM. Several investigators have reported better GAC performance for TOC control after coagulation or after increasing the coagulant dose to achieve enhanced coagulation. Hooper and colleagues (1996a, 1996b, 1996c) have shown that the increase in GAC run time after enhanced coagulation can be attributed to the lower pH and lower initial TOC concentration associated with the coagulated water.

Reactions of ozone with NOM (see Chap. 7) can alter the adsorption performance. For example, ozone can react with humic substances to produce more polar intermediates that are less adsorbable on GAC (Chen et al., 1987) but usually more biodegradable (Sontheimer and Hubele, 1987). If TOC is more biodegradable, increased removals by microbiological activity in a GAC contactor are expected. However, if biological treatment is not effective, then the weakly adsorbing compounds created by ozonation can have a negative impact on the overall GAC performance. Solarik and colleagues (1996) systematically evaluated the impact of ozonation and biotreatment on subsequent GAC performance for five waters. They showed that ozonation and biotreatment decreased the humic and intermediate-molecular-size DOM

fractions, which are the most strongly adsorbing fractions. They found that the early part of the breakthrough was dominated by a relative increase in the weakly adsorbing fraction, which in some cases led to earlier breakthrough, whereas the overall lower influent TOC concentration dominated the latter portion of the breakthrough curve and in some cases led to longer run times.

Chlorine-containing disinfectants (HOCl, ClO₂, or NH₂Cl) may react with both activated carbon and adsorbed compounds. Unusual products not characteristic of solution reactions may be formed when activated carbon is present. For example, the HOCl reaction with adsorbed 2,4-dichlorophenol (2,4-DCP) resulted in a series of hydroxylated polychlorinated biphenyls (PCBs) at HOCl concentrations normally encountered in drinking water treatment practice. A similar product mixture also was obtained when the GAC was first treated with HOCl and then 2,4-DCP was adsorbed. Furthermore, some of these products may desorb from the activated carbon column. Additional data are given on this effect by Voudrias and colleagues (1985). The reaction products that have been found to date have been measured only in laboratory systems. Further research is needed to show whether they also will form in field installations in the presence of humic substances. Because such compounds might form, and because their health effects are unknown, the application of chlorine-containing disinfectants to GAC adsorbers needs to be eliminated, where possible.

Pretreatment to prevent fouling of GAC is also important. Application of water that is supersaturated with salts such as calcium carbonate will lead to blockage of the activated carbon pores and possibly to complete coverage of the particle. Iron and manganese precipitates also may interfere with adsorption.

Adsorption Efficiency of Field-Scale Systems

In this section the performance of field-scale and both pilot- and full-scale GAC adsorbers is discussed for a range of adsorbates. Relationships are evolving that correlate the impact of background DOM on adsorption of micropollutants. However, the results are not yet definitive, and pilot-scale or, at a minimum, bench-scale testing should be carried out with the water in question prior to full-scale design.

TOC and DBP Precursors. Summers and colleagues (1994) and Hooper and colleagues (1996b), as shown in Fig. 14-27, developed a relationship that summarized the impact of the initial TOC concentration TOC_0 on the run time to a 50 percent TOC breakthrough, measured as bed volumes BV_{50} . The relationship can be expressed as

$$BV_{50} = \frac{18,000}{TOC_0} \quad (14-11)$$

Twenty-eight case studies of GAC bench-, pilot-, and full-scale contactors from 21 different source waters were evaluated. All systems used bituminous coal based GAC, and the influent pH was between 7 and 8 for the river, lake, and groundwaters examined. The relationship was verified by five GAC runs of the same isolated NOM, diluted to different concentrations (hollow symbols in Fig. 14-27). Part of the variability of the data around the regression line is likely due to differences in the adsorbability of the NOM caused by pretreatment and differences between sources. The type and adsorbability of NOM in source waters may vary widely from location to location; however, after coagulation, most waters have similar specific ultraviolet absorbance (SUVA) values, approximately 2.0 to 2.5 L/mg/m (see Chap. 3 for a discussion of SUVA), such that the influent TOC concentration and pH are the variables that control TOC breakthrough (Zachman et al., 2007a). Figure 14-27 can be used to provide estimates of the range of adsorbability for conventionally treated waters and one specific GAC type. In a later section, models to predict TOC breakthrough are presented.

FIGURE 14-27 Correlation between influent TOC concentration and bed volumes to 50 percent TOC breakthrough for 21 source waters and runs with five dilutions of an extracted NOM from a groundwater (FuNOM). (Source: Hooper et al., 1996b.)

Roberts and Summers (1982) presented a summary of full-scale plant performance for TOC removal. They evaluated removals from 47 different plants, including some wastewater reclamation plants. The ranges of design conditions are given in Table 14-7. The breakthrough curves reach an effluent concentration plateau about 10 to 25 percent below the influent concentration, indicating biodegradation and that the time to reach this plateau increased as the EBCT increased. These authors found that immediate breakthrough (TOC fraction in the effluent immediately after startup) decreased as the EBCT increased to about 10 minutes, indicating that the MTZ was contained in the bed at this point.

TABLE 14-7 Design Conditions for GAC Adsorbers

Parameter	Median	Range	Typical range
EBCT, minutes	10	3–34	5–24
Depth of bed, m	1	0.2–8	0.5–4
Hydraulic loading, m/h	6	1.9–20	2.6–17
Influent TOC, mg/L	3.5	1–16	2–6

Note: Data from 47 plants were analyzed. Also, $m/h \times 0.41 = gpm/ft^2$.
 Source: Roberts and Summers (1982).

Graese and colleagues (1987a) summarized TOC-removal data for a criterion of 50 percent removal and showed that adsorbers with EBCT values of less than 10 minutes had a life of less than 30 days and that service time increased as EBCT increased. To obtain the lowest-cost adsorption system for TOC removal, EBCTs in the range of 10 to 20 minutes should be closely examined.

The performance for GAC removal of DBP precursors usually parallels that for the removal of TOC (Hooper et al., 1996b; Lykins et al., 1988a). Symons and colleagues (1981) have summarized much of the research prior to 1981. Hooper and colleagues (1996b), Solarik and colleagues (1995a,b), and Summers and colleagues (1994) assessed the use of TOC and UVA as indicators of DBP precursor breakthrough for seven source waters and the following DBPs: THMs, haloacetic acids (HAAs), TOX, and chloral hydrate (CH). The precursors were assessed using the uniform formation conditions (UFC) test (Hooper et al., 1996b) (see Chap. 19). In all but one water, TOC was a good, conservative surrogate in that it broke through prior to the DPB precursors. In one case, THM precursors broke through a filter adsorber with an EBCT of 6.3 minutes prior to TOC. Organics measured by UVA tended to break through after the DBP precursors. TOC removal can vary seasonally because the adsorbability and initial concentration may change with season (Solarik et al., 1995b).

The bromide concentration of the water has an important bearing on the use of GAC for DBP control. Symons and colleagues (1981) observed that brominated THMs dominated in GAC adsorber product water. Graveland and colleagues (1981) made a similar observation and noted a shift to the formation of more highly brominated forms of THMs in GAC effluent. The requirement of a chlorine residual forces the DBP formation reactions to be precursor limited. When precursor concentration is low during the first part of the breakthrough curve, the more rapidly forming bromine-substituted THMs dominate relative to chloroform formation (Summers et al., 1993).

An example of field-scale application of GAC that illustrates the advantages of a pilot study over bench-scale studies has been presented by Snoeyink and Knappe (1994). In that study, the authors evaluated the removal of NOM and the control of DBPs by GAC and BAC at EBCTs of 5, 10, 15, and 19 minutes after conventional treatment at Newport News, VA. In addition, the influent to the BAC column was ozonated. The TOC concentration of the influent was 3 mg/L, which gave a distribution system THM of 60 µg/L before ozonation. The duration of the study was 107 days for the GAC columns and 83 days for the BAC columns. Figure 14-28 depicts the trihalomethane formation potential (THMFP) breakthrough curves at different EBCTs. In both cases, EBCT had little impact on the breakthrough curves, with the exception of the GAC breakthrough curve for an EBCT of 5 minutes. (The 5-minute curve was considered unreliable because of the difficulty in maintaining a constant depth of GAC above the first sampling port.) A comparison of GAC and BAC curves in Fig. 14-28 shows that both the GAC and the BAC treatment trains resulted in breakthrough curves that were beginning to plateau at a dimensionless THMFP concentration of about 0.7, an indication that biological removal of organic carbon occurred for both the ozonated and the nonozonated influent. Additional run time is needed to fully establish the effect of ozone on the plateau.

These results highlight some important issues that must be considered when dealing with biologically active filters. It must be determined whether the plateau region meets the treatment objective and whether the plateau region is a function of the ozone dose that was applied to the filter influent and EBCT. If the plateau region meets the treatment objective, long run times can be achieved with BAC filters. Long pilot-test runs are required to establish the plateau value. The life of the filter as a function of ozone dose and EBCT also needs to be examined if the treatment objective is exceeded before the plateau is reached. This long-term treatability data are not available from bench-scale tests.

Taste and Odor. Many types of taste and odor problems are encountered in drinking water, and some of the most frequently occurring ones are attributed to microbial metabolites, for example, MIB and gesomin, for which activated carbon has an excellent history of success. Taste and odor sensitivity to many microbial metabolites can be very low (parts per trillion, i.e., ng/L), which makes them difficult and expensive to quantify directly. In

(a) GAC Pilot Columns

(b) BAC Pilot Columns

FIGURE 14-28 Distribution system THMFP breakthrough curves: (a) GAC pilot columns; (b) BAC pilot columns. (Source: Snoeyink and Knappe, 1994.)

addition, the specific compound responsible for a given taste and/or odor many not be identified. Thus there are two methods of quantification: human sensory analysis, for example, *threshold odor number* (TON) and flavor profile analysis or direct measurement of the compound, for example, MIB and gesomin.

GAC filter adsorber systems are reported to remove odor effectively from source water. Bed life can range from 1 to 5 years (Graese et al., 1987b) but can be significantly shorter in some situations (Gilligly et al., 1999). The bed life depends on the type, concentration, and frequency of taste and odor compounds; the presence of organics that compete for adsorption sites; and the target effluent concentration, that is, the acceptable level in the treated water. Case-history information is difficult to apply at different utilities because the compounds responsible for the taste and odor are often not known, and the acceptable level

of taste and odor varies from community to community. Using pilot-plant data, Gilgoly and colleagues (1999) showed that the residual MIB adsorption capacity was a function of EBCT and GAC service time. Also, the MIB-removal percentage was not a function of the influent MIB concentration.

GAC performance at Regina, Saskatchewan, is an interesting example of high-intensity tastes and odors (Gammie and Giesbrecht, 1986; Snoeyink and Knappe, 1994). The water treatment plant has postfilter adsorbers with a bed depth of 3 m (10 ft), which yields an EBCT of 15 minutes. The influent water had a DOC concentration of 2 to 3 mg/L and typical TON values of 5 to 15 with spikes of 40 to 60. The effluent goal was a TON value of 1 with the GAC reactivated once per year. Figure 14-29a depicts TON breakthrough curves

(a) TON Breakthrough Curves

(b) TON Mass Transfer Zone

FIGURE 14-29 TON adsorption at Regina: (a) TON breakthrough curves; (b) TON mass transfer zone. (Source: Snoeyink and Knappe, 1994.)

curves at different depths within the GAC adsorber on a throughput basis (the number of BVs treated). The figure shows that the optimal filter depth was 1.5 m (5 ft), and increasing the bed depth to 8 and 10 ft (2.4–3.0 m) reduced the BVs treated before breakthrough, which is indicative of NOM preloading (which reduces the accessible adsorption sites for taste- and odor-causing substances). Decreasing the bed depth to 0.91 m (3 ft) also yielded earlier breakthrough. Figure 14-29*b* shows the progression of the TON mass transfer zone through the GAC bed. The TON value of 3 was reached after 18 days of operation at a GAC depth of 0.3 m (1 ft) (17,000 BVs), after 60 days at a bed depth of 0.91 m (3 ft) (19,000 BVs), and after 130 days at a bed depth of 2.4 m (8 ft) (16,000 BVs). After 130 days of operation (13,000 BVs), the entire GAC bed [3.0 m (10 ft)] had become ineffective for reaching the effluent TON goal.

Some useful observations have been made using data from full-scale GAC systems. Background organic matter, for example, usually breaks through much earlier than the taste- and odor-causing compounds (Love et al., 1973; Robeck, 1975), as was observed in Fig. 14-29*a*. This is also supported by bench-scale work (see Fig. 14-26).

In addition to adsorption, biodegradation has been shown to be responsible for the removal of MIB and geosmin (Silvey and Roach, 1964; Namkung and Rittmann, 1987; Meyer et al., 2005; Summers et al., 2006; Chae et al., 2006). However, Meyer and colleagues (2005) showed that it takes several months for the microorganisms to acclimate to the MIB at environmental concentrations (<500 ng/L). Chae and colleagues (2006) showed that the biodegradation capacity in filters with inert media is reduced after 2 months without MIB and geosmin in the influent. One hypothesis for an MIB- and geosmin-removal mechanism is that adsorption capacity is needed to prevent these molecules from passing through the GAC adsorber. After the initial accumulation on the GAC, a biofilm develops that is capable of degrading these compounds, and they desorb and diffuse to the biofilm, where they are biologically oxidized. The ability of GAC to remove odor decreases over time because adsorption sites are gradually taken up by NOM and thus are not available for MIB and geosmin. GAC replacement may be required when adsorption capacity has been depleted by these competitors.

Synthetic Organic Compounds. Synthetic organic compounds (SOCs) comprise a range of potentially adsorbable compounds that includes (1) volatile organic chemicals (VOCs), (2) pesticides, and (3) pharmaceutical and personal care products (PPCPs). Many VOCs are associated with solvent contamination of groundwaters and are regulated at about 5 µg/L. Pesticides appear in surface waters affected by runoff from agricultural land and domestic and commercial lawns. There is a wide range of regulated levels. PPCPs are found in surface waters affected by wastewater discharges, and many of them are not regulated. Pesticides and PPCPs often occur at very low concentrations (low µg/L to sub-µg/L and low ppb to ppt levels). In this chapter, these compounds at low concentrations are referred to as *micropollutants*.

VOCs include compounds such as tetrachloroethylene and trichloroethylene that are adsorbed relatively strongly and 1,1,1-trichloroethane, 1,2-dichloroethane, and chloroform that are adsorbed relatively weakly. The isotherm data in Table 14-2 show the relative adsorbability of these compounds. GAC adsorbers can be used to remove VOCs directly from contaminated water (Hess, 1981; Love and Eilers, 1982; Snoeyink, 1983) or from the off-gases from air-stripping towers (Crittenden et al., 1988). The best type of system will depend on the type of VOC to be removed and air emission standards that are in effect.

VOCs are found commonly in contaminated groundwaters, and although this type of water generally is low in TOC (Solarik et al., 1995a; Zimmer et al., 1989), large competitive effects are still noted. For example, Zimmer and colleagues (1989) studied the adsorption of three VOCs, tetrachloroethylene, trichloroethylene, and 1,1,1-trichloroethane, from distilled water and from groundwater in field installations. The full-scale field installations had

TABLE 14-8 GAC Bed Life with and Without Competition from Natural Organic Matter

Compound	Single-solute isotherm constants		Bed volumes to saturation, without competition, $C_0 = 50 \mu\text{g/L}^b$	Observed capacity of full-scale adsorbers in practice ^a		
	K	$1/n$		K'	$1/n'$	Bed volumes to breakthrough, $C_0 = \sim 50 \mu\text{g/L}$, $C_{\text{breakthrough}} = \sim 5 \mu\text{g/L}$
Tetrachloroethene	219	0.42	620,000	20.4	0.46	51,000
Trichloroethene	78	0.46	197,000	27.4	0.61	44,000
1,1,1-Trichloroethane	23	0.60	38,000	62	1.4	9400

^aAn adsorber isotherm of the form $q = K' C_0^{1/n'}$, where C_0 is the adsorber influent concentration, K' and $1/n'$ are constants, and q is the amount adsorbed in mg/g at the time of adsorber breakthrough, was used to describe the data. These data are based on the performance of several full-scale plants in Germany (Zimmer et al., 1989).

^bUnits on K and K' are $(\text{mg/g})(\text{L/mg})^{1/n}$. This number is calculated using the assumption that all influent compound is adsorbed until saturation is reached. Thus 52,500 BVs can be processed in 1 year if the EBCT is 10 minutes.

EBCTs ranging from 12 to 15 minutes. The groundwater contained 0.4 to 2 mg/L of DOC and was applied at a rate of 10 to 15 m/h (4–6 gpm/ft²). As the data in Table 14-8 show, the amount of water containing 50 $\mu\text{g/L}$ of tetrachloroethylene that could be processed in the field was about 8 percent of the distilled water value. The capacity for trichloroethylene and 1,1,1-trichloroethane was reduced to 22 and 24 percent, respectively, of the distilled water value. Even low levels of NOM “fouled,” or blocked, significant portions of the GAC surface.

Hess (1981) used pilot-plant data (Love and Eilers, 1982) to predict the effect of influent concentration and type of VOC on GAC life (Fig. 14-30). The figure shows that GAC adsorber life decreases as influent concentration increases. Each water that is treated will

FIGURE 14-30 Effect of contaminant type and influent concentration on carbon life. (Note: 100 days = 14,400 BVs if EBCT = 10 minutes). (Source: Hess, 1981.)

have different background organic matter, and thus Fig. 14-30 should be taken only as providing estimates of performance. Other data for Mississippi River water at Jefferson Parish, LA, at low VOC concentrations show that a bed life of approximately 200 days (30,000 BVs) can be achieved for trichloroethylene at an influent concentration of 14 $\mu\text{g/L}$ and an effluent concentration of 7 $\mu\text{g/L}$. Also, 400 days of life (60,000 BVs) can be achieved for tetrachloroethylene for an influent concentration of 22 $\mu\text{g/L}$ and an effluent concentration of 11 $\mu\text{g/L}$. In each case, the EBCT was 10 minutes (Qi et al., 1992; Snoeyink and Knappe, 1994).

Arbuckle (1980) observed that GAC at the end of an adsorber train adsorbed less SOCs per unit mass than GAC at the front of the adsorber train. Similar effects were observed for VOC adsorption from groundwater (Baldauf and Zimmer, 1986; Zimmer et al., 1989) and for adsorption of chlorinated organic compounds from Rhine River water (Summers et al., 1989). The explanation given for this phenomenon was that large molecules of background organics adsorbed first in the lower reaches of the adsorber and either blocked pores or occupied adsorption sites so that adsorption of micropollutants was decreased. The effect was called the *premature exhaustion or preloading effect*, and it results in higher activated carbon usage rates as EBCT is increased beyond a certain value.

Crittenden and colleagues (1988) developed mass transfer models to predict the removal of VOCs in air stripper off-gas by GAC and investigated the regeneration of this GAC with steam. They found that adsorption efficiency decreased as relative humidity increased and that heating of the gas stream to reduce the relative humidity to 40 to 50 percent was beneficial. Air stripping followed by GAC treatment to purify the off-gas was a good alternative to treatment of the water by GAC alone for several VOC treatment applications, even though steam regeneration of spent gas-phase GAC was not feasible. This advantage results because the natural organics that interfere with adsorption from the aqueous phase are not present in the stripper off-gas.

Symons and colleagues (1981) summarized THM adsorption data. Consistent with the Freundlich K values listed in Table 14-2, the brominated THMs are adsorbed much better than chloroform. Graese and colleagues (1987a) presented data from Cincinnati and Miami for an 80 percent chloroform removal criterion that showed that about 5000 to 6000 BVs of water could be processed before breakthrough. If the EBCT was less than 8 to 10 minutes, however, fewer BVs could be processed because of the short length of the MTZ. The performance will vary as the breakthrough criterion and the composition of the water change. In general, the data indicate that it is more efficient to adsorb DBP precursors than to adsorb the DBPs themselves.

Pesticides are common SOCs that require removal, and GAC has long been demonstrated to be effective (Robeck et al., 1965). GAC beds were evaluated for the removal of selected pesticides spiked into river water (Robeck et al., 1965). One activated carbon column was exhausted for removal of background organic matter as measured by carbon chloroform extract and chemical oxygen demand (COD). Pesticide-spiked sand-filtered river water was applied to the exhausted activated carbon column, and the effluent from it was applied to a second, fresh column. With concentrations of dieldrin as high as 4.3 $\mu\text{g/L}$, the effluent from the first column was 0.3 $\mu\text{g/L}$. Further reduction in the second column reached concentrations as low as 0.05 $\mu\text{g/L}$ and often below the detection limit of 0.01 $\mu\text{g/L}$.

At Jefferson Parish, La, 18 chlorinated hydrocarbon insecticides at a combined concentration of 18 to 88 ng/L were removed to less than about 5 ng/L for 1 year in an adsorber with an EBCT of 20 minutes (Koffskey and Brodtmann, 1981). Alachlor at concentrations of 13 to 593 ng/L was reduced to the limits of detectability during the same period. Atrazine was present at 30 to 560 ng/L and was removed essentially 100 percent by the postfilter adsorber (24 minute EBCT), but concentrations of 10 to 20 ng/L often were found in the effluent of the filter adsorber (14-minute EBCT). Other analyses at Jefferson Parish showed that phthalates, *n*-alkanes, and substituted benzenes at the nanogram per liter level were not removed by GAC.

TABLE 14-9 Summary of Field-Scale Breakthrough Behavior for a Range of Micropollutants

Compound	C_0 (ng/L)	$\sim BV_{10\%}$	Study
MTBE	100,000	3000	Rosner and Knappe, 2008 DOC ₀ = ~2.5 mg/L, EBCT = 9.6 minutes
Atrazine	2000	25,000	Bauldauf and Henkel, 1988 DOC ₀ = 2.3 mg/L, EBCT = 12 minutes
Atrazine	4000	21,000	Knappe et al., 1997 DOC ₀ = 2.0 mg/L, EBCT = 14 minutes
Bezafibrate	260	38,000	Termes et al., 2002
Carbamazepine	1030	47,000	DOC ₀ = 2.4 mg/L, EBCT = 5 minutes
Clofibric acid	1840	10,000	
Diclofenac	40	42,000	
Carbamazepine	550	12,000	Yu et al., 2009
Naproxen	500	7000	DOC ₀ = 4.4 mg/L, EBCT = 2.6 minutes
Nonylphenol	500	15,000	
Atrazine	64	22,000	Chowdhury et al., 2010
DEET	19	22,000	DOC ₀ = 2.1 mg/L, EBCT = 7.9 minutes
Deethylatrazine	20	40,000	
Deisopropylatrazine	136	38,000	
Flutolanil	20	>70,000	
Prometon	4	20,000	
Simazine	521	25,000	
Amidotrizoic acid	190	4000	Haist-Gulde and Baldauf, 2006
Bezafibrate	100	110,000	DOC ₀ = 1.0 mg/L, EBCT = 12 minutes
Carbamazepine	100	94,000	
Gemfibrozil	100	52,000	
Ibuprofen	100	25,000	
Iopamidol	64	9000	

Table 14-9 provides a summary of field-scale (full or pilot) breakthrough behavior for a range of micropollutants at influent concentrations below 4 µg/L and methyl-*tert*-butyl-ether (MTBE) at 100 µg/L. BVs at 10 percent breakthrough ($BV_{10\%}$) were used to characterize the breakthrough behavior.

Baldauf and Henkel (1988) evaluated atrazine breakthrough in a pilot test using a single-stage adsorber with a total depth of 2.5 m. Samples were taken at different depths corresponding to EBCTs of between 3 and 15 minutes. The influent to the GAC column was a groundwater with a DOC concentration of 2.3 mg/L and an average atrazine concentration of 2.2 µg/L. Figure 14-31a shows the breakthrough curves as a function of the volume of water treated, and Fig. 14-31b shows the same data as a function of the number of BVs treated. Figure 14-31a shows that atrazine reached the 0.1 µg/L maximum contaminant level (MCL) of the European Union (EU) very quickly at EBCTs of 3 and 6 minutes, whereas the longer EBCTs showed a much more gradual breakthrough. Figure 14-31b shows similar breakthrough behavior at each EBCT after the data are normalized on the basis of number of BVs treated, but the early breakthrough for EBCTs of 3 and 6 minute is still apparent. The CUR was in the range of 65 to 82 g/m³ for EBCTs of 3 and 6 minutes, and it decreased to approximately 21 g/m³ for EBCTs of 9 minutes and longer (Snoeyink and Knappe, 1994).

FIGURE 14-31 Atrazine breakthrough curves from groundwater: (a) breakthrough curves; (b) normalized breakthrough curves. (Source: Baldauf, G., and Henkel, M. (1988), *Entfernung von Pestiziden bei der Trinkwasser-aufbereitung*, in 20. Bericht der Arbeitsgemeinschaft Wasserwerke Bodensee-Rhein, Teil 7, 127.)

At the shorter EBCTs of 3 and 6 minutes, it appears that the MTZ was not fully contained within the bed, leading to the immediate appearance of atrazine in the effluent.

Figure 14-32 shows normalized atrazine breakthrough curves obtained from pilot studies that investigated different EBCTs and NOM preloading times, that is, time of operation before the application of atrazine (Knappe, 1996). Influent atrazine concentrations for the three pilot tests were about 4 µg/L. The data obtained with a GAC that was preloaded for 5 months demonstrated a great decrease in atrazine removal efficiency as the EBCT decreased; whereas an EBCT of 8.6 minutes resulted in a performance similar to that of virgin GAC, an EBCT of 2.3 minutes led to a removal efficiency that was nearly as low as that observed for a GAC that

FIGURE 14-32 Effect of EBCT on atrazine removal efficiency at different preloading times. (Source: Knappe 1996.)

was preloaded for 1 year and 8 months. In contrast, the GAC that was preloaded for 1 year and 8 months showed a uniformly low atrazine-removal efficiency that was not a function of EBCT. The reduction in atrazine capacity owing to NOM preloading primarily governed the observed breakthrough behavior.

Polynuclear aromatic hydrocarbons are removed effectively by GAC. Tap water spiked with 50 $\mu\text{g/L}$ of naphthalene was passed through a GAC column at Cincinnati, OH (Robeck, 1975). After 7 months of operation at 5 m/h (2 gpm/ft²), the nonvolatile total organic carbon (NVTOC) front for 50 percent removal had penetrated the first 51 cm (1.7 ft) of the bed, whereas the 50 percent removal point for naphthalene was only about 5 cm (0.2 ft) down the column. River bank filtration followed by activated carbon treatment reduced the concentration of polynuclear aromatic hydrocarbons in water by about 99 percent, whereas rapid sand filtration followed by ozonation or chlorination was not effective, probably because of the absence of GAC (Andelman, 1973).

Figure 14-33 shows the breakthrough of several pesticides and the PPCP N,N-Diethylmeta-toluamide (DEET) with the influent conditions listed in Table 14-9 (Chowdhury et al., 2010). Four of the five compounds shown in Fig. 14-33 yielded 10 percent breakthrough at BVs ($BV_{10\%}$) from 20,000 to 25,000, and 50 percent breakthrough occurred in the range of 40,000 to 50,000 BVs, whereas that for DOC was less than 10,000 BVs. The herbicide flutolanil was completely removed for more than 1 year.

Table 14-9 summarizes the influent concentration and $BV_{10\%}$ data from this study as well as others, in which influent concentrations were below 4 $\mu\text{g/L}$. Breakthrough behavior ranged from 7,000 BVs for naproxen in the high-TOC water to more than 70,000 BVs for flutolanil. Three of the studies evaluated atrazine adsorption and yielded similar performance, with $BV_{10\%}$ of about 22,000. The background DOM was similar in all three cases: 2.0 to 2.3 mg/L TOC. The influent atrazine concentrations ranged from 4000 to 64 ng/L, but as discussed in an earlier section, influent concentrations in the sub- $\mu\text{g/L}$ range do not affect the fractional breakthrough behavior when DOM is present. The effect of different influent DOM concentrations is evident in three studies of carbamazepine adsorption. The $BV_{10\%}$ values decreased from 94,000 to 12,000 as the background DOM concentration increased from 1.0 to 4.4 mg/L of TOC.

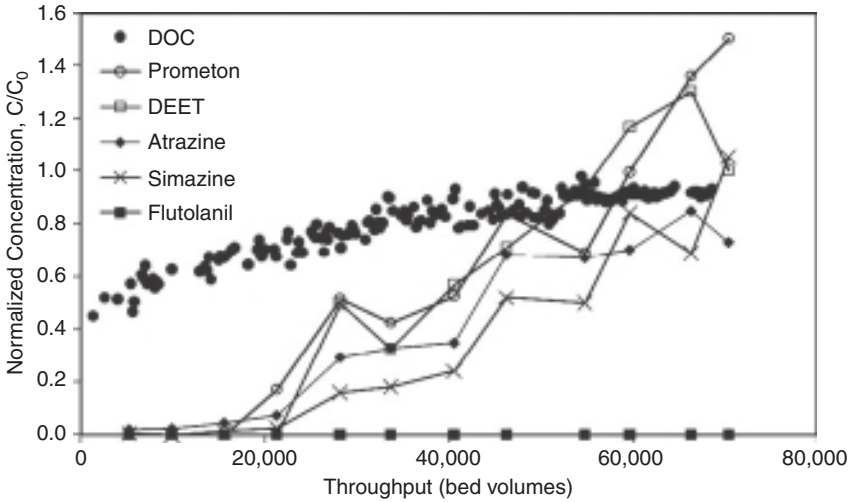

FIGURE 14-33 Breakthrough behavior of pesticides and the personal-care product DEET relative to DOC. (Source: Adapted with permission from Corwin, 2010.)

Performance of Filter Adsorbers. Filter adsorbers, which have resulted from the retrofitting of inert media (e.g., sand) beds, have proven to be effective for periodic taste and odor removal. However, their use for removing weakly adsorbed compounds, including THMs and some VOCs, is limited because of the short EBCT typically found in such systems (Graese et al., 1987a). The typical EBCT of operating sand replacement systems is about 9 minutes at operating flow rates but much less at design flow rates. Control of weakly adsorbing organic compounds with such short EBCTs would require replacement of GAC after only a few weeks or months of operation. Replacement at a high frequency would be operationally cumbersome and costly. In all cases, a thorough economic analysis is required to determine whether the costs associated with a higher CUR in a filter adsorber would be justified by the reduced capital costs of the filter adsorber.

Chowdhury and colleagues (1996), Hong and Summers (1994), Summers and colleagues (1994, 1995, 1997), and Wulfeck and Summers (1994) have shown that filter adsorbers operated in parallel may be a cost-effective approach for controlling DBP formation when the influent TOC concentrations are not high. They have shown that the CUR in several waters was not a function of EBCT in the range of 10 to 20 minutes. Based on the relationship shown in Fig. 14-27, a water with an influent TOC concentration of 2.0 mg/L and an EBCT of 10 minutes would lead to an effluent TOC concentration of 1.0 mg/L after 60 days of operation. If the filter adsorber effluents are blended, the replacement interval would be about 4 to 5 months. Regular backwashing of filter adsorbers has been shown to have little impact on the run time to 50 percent TOC breakthrough (Hong and Summers, 1994; Summers et al., 1997).

A review of the available data on the efficiency of GAC for turbidity reduction compared with sand or coal showed that GAC is as good or better (Chowdhury et al., 2010; Graese et al., 1987a). However, when turbidity loadings were high, a more rapid rate of head loss buildup was experienced because of the larger uniformity coefficient of GAC. When the turbidity loading was low, the difference in uniformity coefficient seemed to make little difference in performance.

A sand layer in the filter below the GAC is sometimes retained, often owing to state regulations on filter design. While the efficiency of turbidity removal by GAC indicates that

this is not always necessary for good performance, it may be useful if large-diameter GAC is used or if low levels of turbidity are desired. A sand layer below the GAC is a nuisance because the sand mixes with the GAC when GAC is removed. This mixed product interferes with reactivation of the GAC. After several GAC replacement cycles, makeup sand may be required to maintain the required sand depth. Gravel under the GAC can cause similar problems, but gravel is necessary to prevent the GAC from entering many types of underdrains.

Nozzle underdrains can be used that do not require either sand or gravel, and they can be used to provide both air and water for backwashing. These appear to have significant advantages over the types that require gravel. However, a pressure-relief device on the washwater influent line should be provided to prevent high-pressure damage to underdrains when and if the nozzles clog. Monitoring of the plenum pressure during backwashing can give advance warning of nozzle clogging problems.

The backwash system must be designed properly to prevent accumulation of mudballs in the GAC. Mudballs accumulate if the GAC is not cleaned properly. GAC is more difficult to clean because it has a density lower than sand and anthracite. Provision of good surface scour, or air scour, is important for good turbidity control.

Reactions of Inorganic Compounds with Activated Carbon

Activated carbon in water treatment may inadvertently contact oxidants such as oxygen, aqueous chlorine, chlorine dioxide, and permanganate and react with them. Virgin activated carbon has been shown by Prober and colleagues (1975) to react with 10 to 40 mg of aqueous O₂ per gram of carbon over a time span of 1700 hours, and Chudyk and Snoeyink (1981) found that 3 to 4 mg of O₂ per gram of carbon reacted over a time span of 130 hours. Some of this oxygen is converted to surface oxides (Prober et al., 1975).

Free Chlorine-Activated Carbon Reactions. The well-known reactions of HOCl and OCl⁻ with activated carbon are as follows:

where C* and C*O represent the carbon surface and a surface oxide, respectively. These reactions proceed rapidly, with the one in Eq. 14-12 (pH < 7.5) being faster than the one in Eq. 14-13 (pH > 7.5) (Suidan et al., 1976, 1977a, 1977b). Reactions of free chlorine with activated carbon will result in the production of organic by-products. The TOX on the surface increases as the extent of reaction increases, and some of these compounds may be found in the column effluent if the reaction proceeds for a long time (Dielmann, 1981).

Combined Chlorine-Activated Carbon Reactions. Bauer and Snoeyink (1973) hypothesized that the following reactions were taking place between monochloramine (NH₂Cl) and activated carbon:

Initially, all the NH₂Cl was converted to NH₃ and Cl⁻ in accordance with Eq. 14-14, but after a period of reaction, some of the NH₂Cl was converted to N₂(g) and HCl in accordance with Eq. 14-15. The rate of reaction was much slower than the reactions of either free chlorine or dichloramine with activated carbon (Kim and Snoeyink, 1980). Additional studies of this reaction were made by Komorita and Snoeyink (1985), who showed that the rate of reaction was high initially and then reached a plateau value. The higher initial rate is useful in design of some GAC dechlorination systems.

Dichloramine (NHCl_2) reacts rapidly with activated carbon according to the following reaction (Bauer and Snoeyink, 1973; Kim et al., 1978):

When excess ammonia was present, Kim and colleagues (1978) found evidence of the parallel reaction:

Bromate, Chlorine Dioxide, Chlorite, Chlorate, and Perchlorate Reactions with Activated Carbon. Other halogen oxides react with activated carbon. For example, BrO_3^- is converted to Br^- in ultrapure water on fresh activated carbon surfaces (Miller et al., 1995; Kirisits et al., 2000); however, NOM and anions such as chloride, bromide, sulfate, and nitrate can block and/or occupy reducing sites on activated carbon surfaces such that the abiotic bromate reduction capacity of GAC adsorbers is quickly exhausted (Kirisits et al., 2000). ClO_2 reacts rapidly with activated carbon, but the nature of the reaction changes as pH changes. At pH 3.5, Cl^- , ClO_2^- , and ClO_3^- are found in the effluent of a column receiving only ClO_2 , but Cl^- is the predominant product. At pH 7.9, the same end products are formed, but ClO_2^- is now the predominant species (Chen et al., 1982). When ClO_2^- solutions at pH 7 were applied to virgin GAC, ClO_2^- readily reacted, presumably in accordance with the reaction (Voudrias et al., 1983)

The reaction capacity of the fresh carbon was saturated after 80 to 90 mg of ClO_2^- reacted per gram of GAC. The chlorate ion was not reduced by activated carbon but was adsorbed to a slight extent (~ 0.03 mg ClO_3^- per gram), presumably by an IX mechanism (Dielmann, 1981). Similarly, abiotic perchlorate removal by activated carbon appears to occur via IX only, and calculated ion exchange capacities from fixed-bed experiments are low (~ 0.17 mg ClO_4^- per gram) (Brown et al., 2002).

Removal of Other Inorganic Ions. Huang (1978) reviewed the removal of inorganic ions by activated carbon. A number of ions can be removed from water by GAC, but the capacity for most substances is quite low. The gold-cyanide complex, for example, is adsorbed on GAC in a widely used method for recovering gold in the mining industry. Huang (1978) reviewed data that show some removal of cadmium(II) at higher pH values and that removal can be increased slightly by complexing before adsorption with chelating agents. The removal of chromium involves adsorption of Cr(III) or Cr(VI), and under some conditions, Cr(VI) is chemically reduced to Cr(III) by the activated carbon. Mercury adsorption is best at low pH. From 0.1 to 0.5 mmol Cu per gram at equilibrium concentrations of 8 mmol/L also have been observed to adsorb. Activated carbon also will catalyze the oxidation of Fe(II) to Fe(III).

GAC PERFORMANCE ESTIMATION

Isotherm Determination and Application

Useful information can be obtained from the adsorption isotherm. Isotherms can be used to show the variation in adsorbability of different types of organic compounds (see Table 14-2), the differences between activated carbons, and the magnitude of competitive effects (see Example 14-1). Because the adsorption capacity of a GAC

is a major determinant of its adsorption performance in columns, the isotherm can be used (1) to compare candidate GACs, (2) as a quality-control measure for purchased GACs (some variation from lot to lot of a given manufacturer's GAC is expected), (3) as an input function to mathematical models that can be used to predict performance (discussed later), and (4) to evaluate the residual adsorption capacity of GAC in a contactor that has been in use and thus is partially exhausted. Important limitations to the use of isotherms must be recognized if they are to be used properly, however. The purpose of this section is to demonstrate how isotherms can be used to estimate performance and to note several factors of importance in isotherm determination.

Types of Adsorbates. The determination procedures must take into account the adsorbate characteristics. The simplest procedure can be followed if a single nonvolatile adsorbate is present in an aqueous solution with no background organics that might compete for adsorption sites. This isotherm is not a function of initial concentration, and no precautions need be taken to avoid volatilization. The test is conducted by agitating known volumes of the solution with accurately weighed portions of GAC until equilibrium is achieved. The time required for equilibrium can be estimated using the information in Randtke and Snoeyink (1983) (see discussion in an earlier section of this chapter) and can be determined by measuring solution concentration versus time.

Other adsorbate-related factors must be controlled carefully during isotherm determination. Biological activity in isotherm bottles must be controlled either if the NOM is biodegradable, such as after ozonation of a natural water, or if the targeted micropollutant is biodegradable. Biological growth can be minimized if the isotherm is determined at low temperature, for example, less than 5°C. If the adsorbate is volatile, equilibrium must take place in a headspace-free vessel, and mixing of the system must take place by continual inversion of the test bottle. Control of pH is important for compounds whose adsorption is a function of pH, and other salts in solution can be important for ionic substances or for substances that compete with organic ions for adsorption sites. The reader is referred to Randtke and Snoeyink (1983) for a more detailed discussion of these factors.

When equilibrium is reached, the data are analyzed using the mass balance

$$q = \frac{(C_0 - C)V}{m} \quad (14-19)$$

where q is the amount adsorbed per unit mass of carbon at equilibrium (mol/g or mass/g), C_0 is the initial aqueous-phase concentration (mol/L or mass/L), C is the equilibrium aqueous-phase concentration (mol/L or mass/L), V is the solution volume (L), and m is the mass of carbon (g).

The data can be plotted to determine the Freundlich parameters or other isotherm model parameters as appropriate.

Example 14-3 Determination of Freundlich Isotherm Parameters

The following data were obtained from a single-solute isotherm experiment evaluating the adsorption of methyl *tert*-butyl ether (MTBE) on an activated carbon:

Mass of activated carbon in isotherm bottle (mg)	0	12.6	25.4	63.4	126.7	190.2	253.5	380.1
Aqueous-phase MTBE concentration at equilibrium (µg/L)	864	498	329	131	48.0	25.1	15.3	8.20

Each isotherm bottle was filled headspace-free with 254 mL of water and received the same mass of MTBE. Prepare an isotherm plot and determine the Freundlich isotherm parameters K and $1/n$.

Solution

Calculate solid-phase MTBE concentrations q from the data set given using Eq. 14-19. For the bottle containing 12.6 mg of activated carbon:

$$q = (C_0 - C) \times V/m = (864 - 498) \mu\text{g/L} \times 0.254 \text{ L}/12.6 \text{ mg} = 7.38 \mu\text{g/mg} = 7.38 \text{ mg/g}$$

that is, 7.38 mg of MTBE adsorbs on 1 g of activated carbon at an equilibrium aqueous-phase MTBE concentration of 498 $\mu\text{g/L}$.

Repeating the calculation for the remaining isotherm bottles yields:

Mass of activated carbon in isotherm bottle (mg)	0	12.6	25.4	63.4	126.7	190.2	253.5	380.1
Aqueous-phase MTBE concentration at equilibrium ($\mu\text{g/L}$)	864	498	329	131	48.0	25.1	15.3	8.20
Solid-phase MTBE concentration (mg/g)	—	7.38	5.35	2.94	1.64	1.12	0.850	0.572

Plotting the solid-phase MTBE concentrations q as a function of the aqueous-phase MTBE concentrations C yields Fig. 14-34 (note logarithmic scales).

Linear regression of the log-transformed data yields a slope of 0.612 ($1/n$ value) and an intercept of -0.807 ($\log K$ value). Thus the K value is $10^{-0.807} = 0.156 \text{ (mg/g)(L/\mu g)}^{1/n}$. The K value suggests that 1 g of the tested activated carbon can adsorb 0.156 mg of MTBE at an equilibrium aqueous-phase MTBE concentration of 1 $\mu\text{g/L}$. The Freundlich isotherm equation now can be used to estimate solid-phase MTBE concentrations at targeted aqueous-phase MTBE concentrations. For example, if an MTBE concentration of 10 $\mu\text{g/L}$ is targeted, then the tested activated carbon can adsorb

$$q = 0.156 \text{ (mg/g)(L/\mu g)}^{1/n} \times (10 \mu\text{g/L})^{0.612}$$

$$= 0.638 \text{ mg/g or } 0.638 \text{ mg MTBE per gram of activated carbon} \quad \blacktriangle$$

FIGURE 14-34 MTBE adsorption isotherm.

Adsorption from a mixture of adsorbable organic compounds (e.g., NOM) is more complicated because of the effect of the different adsorbabilities of compounds in the mixture. Figure 14-8 shows typical NOM adsorption isotherms. The small fraction of strongly adsorbable compounds is often overlooked when determining an isotherm because of the analytic difficulty of obtaining good data close to C_0 (i.e., for very small doses of activated carbon). The strongly adsorbable fraction is important because it is responsible, at least in part, for the slow approach of effluent concentration to influent concentration in column operation. Similarly, the small, but important, nonadsorbable fraction is often not detected if a sufficiently large dose of carbon is not added to the solution. Initial concentration affects the adsorption of a NOM (see Fig. 14-8). The difference in the isotherms is caused primarily by the different mass concentrations of strongly adsorbable compounds in each of the solutions. The same type of difference is expected if the amount of a single compound that is adsorbed in the presence of different concentrations of background organic matter is measured. The isotherm of the single compound will be a function of the initial concentration of background organic matter if competition occurs between them.

Activated Carbon. The major concerns related to activated carbon are (1) obtaining a representative sample for testing and (2) preparing the sample to obtain a rapid approach to equilibrium without destroying its representative nature. The adsorption capacity of some commercial activated carbons is a function of particle size because of the manufacturing process that is used (Randtke and Snoeyink, 1983); thus, selecting a sample for testing with the same particle size distribution as the bulk activated carbon is important. Activated carbon sizes may separate during shipment, so special equipment or techniques are required to obtain the representative sample. By using equipment such as a sample reducer and a sample splitter, representative samples from large quantities (bags) of GAC can be obtained. The sample reducer reduces sample sizes greater than 4.5 kg (10 lb) to representative samples that are smaller at a 16:1 ratio. Further reduction to a size that can be used for laboratory tests is possible using the sample splitter, or riffle; the particle size distribution and quality of the final sample then are representative of those of the original large quantity of GAC. Using such equipment to establish that a shipment of GAC meets specification is important. A simpler alternative that yields a good approximation of the characteristics of a batch is to sieve the sample and use only the particles in the dominant size range.

The time to reach adsorption equilibrium is an important function of particle size. The adsorption capacity of fresh GAC is not altered when it is crushed to a smaller particle size (Randtke and Snoeyink, 1983). The same is not true for used GAC, however. Crushing used GAC likely gives micropollutants access to pores that were blocked by preloaded NOM prior to crushing (Carter et al., 1992; Knappe et al., 1999). When determining the remaining adsorption capacity of GAC in operating GAC adsorbers, the used GAC therefore should not be crushed. As described earlier in this chapter, long equilibration times are needed to reach adsorption equilibrium when larger GAC grains are tested.

Avoiding significant biological activity should be possible if the sample is not seeded with microorganisms and the test time is 2 days or less. Prefiltration of the solution with a filter membrane having a 0.45- μm pore diameter will remove most bacteria from the sample. Postfiltration of the sample through filter paper having a 0.45- μm pore diameter will be necessary to remove the activated carbon before testing for the concentration of residual organics. Filter paper must be selected that does not interfere with the quantitative analysis of the test compounds either by removing a targeted pollutant or by contributing organic matter.

Isotherms can be used to obtain a rough estimate of activated carbon loading and bed life. These are useful in determining the applicability of GAC. Assuming that (1) all the GAC in an adsorber will reach equilibrium with the adsorber influent concentration and (2) the capacity obtained by extrapolating the isotherm data to the initial concentration is a

good value, the bed life, in BVs of water, can be calculated. These assumptions are consistent with the assumption that the length of the MTZ L_{MTZ} is negligible. For example, if q_0 is the mass adsorbed (mg/g) when $C = C_0$, the bed life Y , the volume of water that can be treated per unit BV of carbon, can be calculated by

$$Y = \frac{(q_e)_0 \text{ (mg/g GAC)}}{(C_0 - C_1) \text{ (mg/L)}} \times \rho_{GAC} \text{ (g/L)} \tag{14-20}$$

where C_0 is the influent concentration, C_1 is the effluent concentration that represents an average for the entire column run, and ρ_{GAC} is the apparent density of the GAC. C_1 is zero for a strongly adsorbed compound that has a sharp breakthrough curve and is the concentration of nonadsorbable compounds when such substances are present. An estimate of the activated carbon usage rate, the rate at which activated carbon is spent as defined in Eq. 14-10, is given by

$$CUR \text{ (g/L)} = \frac{(C_0 - C_1) \text{ (mg/L)}}{(q_e)_0 \text{ (mg/g)}} \tag{14-21}$$

Example 14-4 GAC Adsorber Bed Life and Carbon Usage Rate

Estimate the bed life and carbon usage rate for a GAC adsorber that is to treat water containing 1 mg/L of toluene from solution. The bed density of the carbon ρ_{GAC} is 500 g/L.

Solution

From Table 14-2, $K = 5.01 \text{ (mg/g)(L/}\mu\text{g)}^{1/n}$ and $1/n = 0.429$ for toluene. Applying the Freundlich equation (Eq. 14-2) gives

$$\begin{aligned} (q_e)_0 &= KC^{1/n} \\ &= 5.01 \text{ (mg/g)(L/}\mu\text{g)}^{0.429} (1000 \mu\text{g/L})^{0.429} \\ &= 97 \text{ mg/g} \end{aligned}$$

Applying Eq. 14-20, assuming that $C_1 = 0$, gives

$$\begin{aligned} Y &= \frac{(q_e)_0 \text{ (mg/g)}}{(C_0 - C_1) \text{ (mg/L)}} \times \rho_{GAC} \text{ (g/L)} \\ &= \frac{97 \text{ mg/g}}{1 \text{ mg/L}} \times 500 \text{ g/L} \\ &= 48,500 \text{ L H}_2\text{O/L GAC} = \text{bed life} \end{aligned}$$

If the EBCT is 15 minutes, 4 BVs per hour or 96 BVs per day can be processed. The bed life in days then is 48,500 BVs/96 BVs per day = 505 days. Applying Eq. 14-21 to obtain CUR gives

$$\begin{aligned} CUR &= \frac{(C_0 - C_1) \text{ (mg/L)}}{(q_e)_0 \text{ (mg/g)}} \\ &= \frac{1 \text{ mg/L}}{97 \text{ mg/g}} \\ &= 0.00103 \text{ g GAC/L H}_2\text{O} \end{aligned}$$

Note: The bed life will be reduced and the CUR will be increased under practical conditions where other organics are in the water that compete for adsorption sites. ▲

Several limitations exist to the use of isotherm data to estimate the CUR. For example, NOM preloading decreases the adsorption capacity of GAC as GAC service time increases (see Fig. 14-15). Furthermore, it provides no indication of the effect of biological activity. Finally, when competition does occur, its impact in a batch test often is not the same as in a column because the molecules will separate in a column according to their strength of adsorption. The NOM that adsorbs in the upper region of a column will be dominated by the strongly adsorbing fraction of organic matter, especially in the initial portion of a column run, whereas the more weakly adsorbing fraction of NOM will selectively accumulate in the lower reaches of the column. In a batch test, all carbon particles are exposed equally to each fraction of the NOM. Competitive effects of NOM on micropollutants may be much greater in a column for this reason (Zimmer et al., 1989).

One approach to better estimate the adsorption capacity in the field based on isotherm values is to increase the distilled water carbon usage rates based on the adsorbability of the compound. Ford and colleagues (1989) proposed a natural water correction factor be applied to the distilled water CUR. From their data, the following relationship between natural water CURs (CUR_{NW}) taken from full- and pilot-scale adsorbers and those from isotherms in distilled water (CUR_{DW}) can be developed:

$$CUR_{NW} = 0.7 CUR_{DW}^{0.5} \quad (14-22)$$

where the CUR is in pounds per 1000 gallons, and all values of CUR_{DW} were below 1 lb/1000 gal. While there was a large amount of scatter in the more than 75 data points evaluated, the square-root nature of the relationship shows that the more strongly adsorbing compounds, that is, low CURs, will be more affected by the presence of NOM. For example, a weakly adsorbing compound with a high CUR_{DW} of 0.1 lb/1000 gal will have a CUR in natural water of 0.22 lb/1000 gal, a 2.2-fold increase, whereas a strongly adsorbing compound with a low CUR_{DW} of 0.001 lb/1000 gal will have a CUR in natural waters of 0.022 lb/1000 gal, a 22-fold increase.

Bench-Scale Column Tests and Applications

Bench-scale column tests have been developed to obtain data that can be used to estimate the performance of large contactors and are helpful in screening GAC types. Crittenden and colleagues (1986, 1987, 1991) developed a procedure called the rapid small-scale column test (RSSCT) for designing bench-scale columns with ground GAC such that the data obtained could be scaled up to predict the breakthrough behavior of field-scale GAC columns. They used dimensionless parameters that characterize the advection, film mass transfer, intraparticle diffusion, and adsorption processes to develop the relationship between the breakthrough curves of large-scale columns (LCs) with GAC and small-scale columns (SCs) with crushed GAC. Based on the assumption that the internal diffusion coefficient was constant and not a function of GAC particle diameter, they found

$$\frac{EBCT_{SC}}{EBCT_{LC}} = \left(\frac{d_{SC}}{d_{LC}} \right)^2 = \frac{t_{SC}}{t_{LC}} \quad (14-23)$$

where d is the diameter of the GAC particle, and the inverse of the ratio d_{SC}/d_{LC} is the scaling factor. The ratio t_{SC}/t_{LC} is the time required to conduct a small-column test relative to the time necessary to conduct a large-column test. The constant diffusivity (CD) design

equation (Eq. 14-23) predicts that relative to a full-scale column with 1 mm diameter GAC, a column with 0.1 mm diameter GAC (scaling factor of 10) and an EBCT 0.01 times as large as that of a full-scale column will produce the same breakthrough curve. Furthermore, the time required to process a given number of BVs of water through the small column is 0.01 times the time required to process the same number of BVs through the large column.

Subsequent studies by Crittenden and colleagues (1987) showed that the internal diffusion coefficient could not always be assumed to be constant with respect to particle diameter. They developed a second relationship, termed the *proportional diffusivity* (PD) design, based on the assumption that the internal diffusion coefficient varied linearly with particle diameter, which yielded the following equation:

$$\frac{\text{EBCT}_{\text{SC}}}{\text{EBCT}_{\text{LC}}} = \frac{d_{\text{SC}}}{d_{\text{LC}}} = \frac{t_{\text{SC}}}{t_{\text{LC}}} \quad (14-24)$$

For the PD design, the preceding particle sizes (scaling factor of 10) would yield an EBCT_{SC} and a run time t_{SC} that is one-tenth as large as that at the full scale. While the time savings is not as much as can be achieved if the diffusion coefficient is constant with respect to particle diameter, factor of 100, it is still a factor of 10 smaller than the run time at full scale.

Particle sizes commonly used range from 0.05 to 0.2 mm, and column diameters range from 5 to 11 mm (Crittenden et al., 1987). Using these particle and column sizes yields RSSCT flow rates of 50 to 150 mL/min for the CD design and 5 to 20 mL/min for the PD design.

For NOM, the PD design approach (Eq. 14-24) has been shown to work in many waters. It is thought that the large-molecular-weight NOM diffuses more quickly in the macropores than in the micropores. When the GAC is ground, the micropore domain dominates because macropore transport is less important in transferring the NOM to the micropores. Thus the overall transport in small GAC particles is controlled by slow diffusion in micropores. Summers and colleagues (1995, 1996) reviewed use of the PD design for nine water sources and four GAC types. The 30 verification runs showed that the RSSCT predicted the pilot- or full-scale breakthrough behavior for TOC, UV absorbance, and precursors of THMs, HAAs, TOX, and CH. An RSSCT design and operation manual was developed for the treatment studies requirement by the USEPA's Information Collection Rule (Summers et al., 1996). Unfortunately, the a priori selection of the design equation, either CD (Eq. 14-23) or PD (Eq. 14-24), is not possible for specific organic compounds such as VOCs, pesticides, and PPCPs. While the scaling for NOM follows the PD approach, the fouling or competition it causes complicates the scale-up design for SOCs. In general, the adsorption capacity for these compounds is greater in the RSSCT than at the full scale (Corwin and Summers, 2010). One approach is to run one pilot-plant column using full-scale GAC with the water to be tested and then adjust the RSSCT design for the target compound. Recently, Corwin and Summers (2010) have proposed using a PD design with a fouling index for adjusting the scaling factor based on the influent concentration of the target compound.

The RSSCT technique is a useful technique because it significantly reduces the time required to obtain typical performance data and can be used effectively to screen GAC types and evaluate pretreatment impacts. However, there are limitations. A test that lasts only a few days cannot account for the changes in the influent concentration expected over a much longer time interval. In addition, the short-term test cannot determine the effect of biological activity in the full-scale column. It also cannot be used to determine the residual capacity of GAC that has been in service for a period of time because grinding this GAC to a smaller size affects the capacity, contrary to virgin carbon.

Pilot-Plant Tests

In most situations, pilot testing is recommended because it provides valuable data that can contribute to the design of efficient GAC systems. Batch equilibrium isotherm or bench-scale column tests or empirical models can provide a preliminary assessment of the technical and economical feasibility of GAC as a solution to a water quality problem. Bench-scale column tests also can be used to screen GAC types and evaluate pretreatment impacts. Long-term pilot testing can capture the day-to-day and season-to-season variation in contaminants, background DOM, and other water quality parameters that can affect adsorption and the type and level of pretreatment. Long-term pilot tests also can capture the potential for biodegradation of the target compound.

A pilot study should (1) show the effectiveness of the carbon through a CUR estimation, (2) permit a determination of the best design parameters to use for the full-scale system, and (3) establish the best operating procedure to use. A good estimate of the cost of the full-scale system then can be made. Although pilot testing is expensive, the excessive cost of operating an improperly designed system because of insufficient information may more than justify the cost of a pilot study to obtain that information. In addition, if the pilot study is carried out with direct utility personnel involvement, it provides an opportunity for them to become comfortable with this new technology.

Pilot testing is not always necessary. Confidence has increased in the use of RSSCTs for predicting the adsorption of NOM and DBP precursors. For small systems, the cost of a pilot study may not be justified by the potential savings that would be made possible by an optimized design. GAC adsorbers for VOC removal from small supplies may be designed on the basis of existing information, possibly supplemented with isotherm or small-scale column-test information, with an appropriate safety factor to compensate for the lack of a pilot test.

The pilot plant should be designed with the same pretreatment that will be used in the full-scale system. It should be operated at the location where the full-scale adsorber is to be constructed so that the water quality for pilot- and full-scale contactors is the same. This may require piloting pretreatment processes as well. A detailed chemical analysis of the water, including the concentrations of target compound(s), for example, SOCs, TOC, DBP precursors, and/or taste- and odor-causing compounds, needs to be conducted. In addition, other water quality parameters that may affect target compound adsorption, such as chlorine residual, pH, ammonia concentration, hardness, alkalinity, and turbidity, need to be measured. Preferably, these analyses will be done at different times so that the range of concentrations expected at the full-scale plant can be estimated accurately. Small-scale column tests on water samples preferably taken at different times, coupled with an analysis of the experience of others, can be used to screen different GAC types. The pilot plant then should be designed and operated to show whether these are optimal or whether they should be modified for best performance.

For postfilter adsorbers, three or four GAC columns in series, such as are shown in Fig. 14-23, provide maximum operating flexibility. Alternatively, one or two long columns with several taps can be used so that samples can be taken at different depths. For filter adsorbers, the GAC and other media, including underdrain media, would be contained in one column. The materials of construction may range from plastics such as clear acrylic and polyethylene to the more expensive stainless steel, polytetrafluoroethylene (PTFE), or glass. Kreft and colleagues (1981) showed no leaching of VOCs or TOC from as well as no adsorption of VOCs and TOC to clear acrylic columns and polyethylene tubing in a pilot plant. They did find that phthalates leached from transparent vinyl plastic tubing, so this material should not be used where phthalates will interfere. The possibility that some SOCs may be adversely affected by some materials of construction cannot be ruled out, however. Stainless steel, PTFE, and glass, while expensive, can be used if avoiding any question of possible organics added by plastic is necessary.

The total depth of the pilot-scale adsorber should be greater than the depth likely to be used in the full-scale plant. For the pilot-scale adsorber, depths in the range of 3 to 4 m (10–13 ft) should be used. Column diameter to average particle diameter should be greater than 30:1, or it should be demonstrated that short-circuiting does not occur if smaller ratios are used (Summers et al., 1996). Hydraulic loading rates of 5 to 12.5 m/h (2–6 gpm/ft²) are usually used. Within this range, the assumption can be made that at a given EBCT, GAC usage rate is not a function of flow rate. A pilot-plant design and operation manual has been developed for the TOC and DBP precursor treatment studies requirement of the USEPA’s Information Collection Rule (Summers et al., 1996).

Analysis of GAC Adsorber Data

The GAC effluent data collected at different EBCT values should be plotted as breakthrough curves to show the effect of EBCT on effluent quality. The effluent concentration C_{eff} or the normalized effluent concentration C_{eff}/C_0 can be used. If there is much variability in C_0 , then C_{eff} should be used. One measure of effluent concentration should be plotted against time of operation, volume of water processed (see Fig. 14-35), or throughput in

FIGURE 14-35 Breakthrough curves as a function of total volume of water treated.

BVs of water processed (Fig. 14-36). When GACs with different densities are used, the specific throughput in volume treated per mass of GAC is useful because GAC is sold on a weight basis. Because flow rate may vary with time, volume or throughput is the most useful. Because most full-scale plants use time, a double abscissa is suggested, with time

FIGURE 14-36 Breakthrough curves as a function of number of BVs processed.

being one of the independent variables. Using the number of BVs as the abscissa has the important advantage of normalizing the data collected at different depths and at different flow rates. Theoretically, as EBCT values increase, the C_{eff}/C_0 versus BV breakthrough curves eventually will superimpose as shown in Fig. 14-36. However, as has been shown in the discussions for NOM and SOCs, this may not occur because the background DOM affects the adsorption differently at different depths. The CUR, as originally defined in Eq. 14-10, can be calculated from the breakthrough curve for each EBCT:

$$\text{CUR}(\text{g/L}) = \frac{\rho_{\text{GAC}}(\text{g/L})}{\text{BV to breakthrough}} \quad (14-25)$$

where ρ_{GAC} is the apparent density of the GAC.

Parallel-Column Analysis. One of the objectives of pilot- or small-scale column testing should be to determine the CUR if GAC columns are to be used in parallel with staged blending of their effluents. Pilot- and bench-scale column data can be analyzed using the approach of Roberts and Summers (1982), who showed that the fraction, or concentration, of adsorbate remaining in the composite effluent of parallel adsorbers \bar{f} was given by

$$\bar{f} = \frac{1}{n} \sum_{i=1} f_i \quad (14-26)$$

where f_i is the fraction, or concentration, of the adsorbate remaining in the effluent from the i th adsorber, and n is the number of adsorbers in parallel, each of equal capacity. Values of f_i can be determined from a single breakthrough curve such as is shown in Fig. 14-37a, assuming that replacement of GAC in each adsorber will take place at equal intervals. Given that θ_n is the number of BVs processed through each adsorber in the parallel system at the time of replacement, the abscissa of the breakthrough curve for the individual contactor from 0 to θ_n is divided into θ_n/n equal increments. For a given value of θ_n , the value of f_i for each increment can be read from the figure, and Eq. 14-26 can be used to calculate the concentration in the blended water. For example, if 10 adsorbers are used in parallel, determination of \bar{f} for several different values of θ_n using Eq. 14-26 leads to the integral curve shown in Fig. 14-37b. By operating the 10 contactors in parallel, each adsorber can process 10,000 BVs of throughput if the effluent adsorbate criterion is 50 percent of the influent compared with 5000 BVs if only a single contactor were used or if all 10 contactors were operated in parallel but were replaced at the same time.

Data from an individual GAC pilot contactor, plotted as shown in Figs. 14-36 and 14-37a, are needed to develop the integral breakthrough curve shown in Fig. 14-37b. The integral curve is developed assuming (1) that each contactor will be the same size, (2) that each contactor will be operated for the same number of BVs θ_n before replacement, and (3) that only one contactor is replaced at one time at intervals of θ_n/n BVs for n contactors in parallel, that is, staggered operation. For a given value of n , f versus θ is calculated by applying Eq. 14-26 for different assumed values of θ_n . (The procedure is illustrated in Fig. 14-37 and related discussion for $\theta_n = 5000$ BVs and an n of 10.) The number of BVs to breakthrough then can be determined from the integral curve. Separate integral curves should be calculated for different numbers of adsorbers. An economic analysis then can be made for each parallel arrangement to determine the best choice.

Example 14-5 GAC Replacement Frequency for GAC Adsorbers Operated in Parallel

An ozone/GAC pilot plant was used to remove THMFP from a shallow reservoir supply after coagulation, sedimentation, and filtration. The GAC columns had a diameter

FIGURE 14-37 Integral breakthrough curve approach for characterizing performance of multiple parallel contactors operated in a staged blended effluent mode. (Source: Roberts and Summers, 1982.)

of 102 mm (ID or 4 in). Samples were taken from ports located 20 in (port 1), 44 in (port 2), and 64 in (port 3) from the inlet. A flow rate of 0.24 gpm (91 L/min) gave corresponding EBCT values of 4.6, 10.1, and 14.8 minutes. The data (except for points at large volumes processed at ports 2 and 3) are shown in Fig. 14-38. Calculate the GAC replacement frequency if four GAC adsorbers, each with 5-minute EBCT, are to be operated in parallel. The THMFP concentration of the blended GAC effluent is to be 25 $\mu\text{g/L}$. The C_0 for THMFP is 60 $\mu\text{g/L}$.

Solution

1. Plot the breakthrough curve (shown in Fig. 14-38) as a function of the BVs of water treated. To convert volume of water processed to BVs, divide the volume processed by the volume of GAC above the port. The volume of GAC above each port is 1.09, 2.39, and 3.48 gal for ports 1, 2, and 3, respectively. For example, the point (vol = 20,000 gal, $C_{\text{eff}}/C_0 = 0.28$) for port 2 in Fig. 14-38 corresponds to

$$BV = \left(\frac{20,000}{2.39} = 8400 \right) \left(\frac{C_{\text{eff}}}{C_0} = 0.28 \right)$$

in Fig. 14-39.

FIGURE 14-38 TTHMFP breakthrough curves as a function of total volume of water treated for example problem.

- Use Fig. 14-39 to obtain a good estimate of the breakthrough curve expected for a full-scale system. More emphasis is given to data from ports 2 and 3 because the depth of bed for these ports should be much greater than the critical depth. The EBCT for port 3 is also about 15 minutes and should have about the same amount of biological degradation as is expected for the full-scale system. Use the composite of the three curves as the resulting breakthrough curve, which is shown in Fig. 14-40.

FIGURE 14-39 TTHMFP breakthrough curves as a function of BVs treated for example problem.

FIGURE 14-40 Integrated TTHMFP breakthrough curve as a function of total volume of water treated for example problem.

- Determine the expected breakthrough curve when four columns in parallel are blended (integral curve) by applying Eq. 14-26, as discussed above.

Assumed values of θ_4	Corresponding values of f_i (from Fig. 14.39)	\bar{f}
8000 BVs $\left(\frac{8000}{4} = 2000\right)$	f_1 (2000 BVs) = 0.02 f_2 (4000 BVs) = 0.05 f_3 (6000 BVs) = 0.13 f_4 (8000 BVs) = 0.23 $\Sigma f_i = 0.43$	$\frac{1}{n} \Sigma f_i = \frac{0.43}{4} = 0.11$
12,000 BVs $\left(\frac{12,000}{4} = 3000\right)$	f_1 (3000 BVs) = 0.03 f_2 (6000 BVs) = 0.13 f_3 (9000 BVs) = 0.35 f_4 (12,000 BVs) = 0.52 $\Sigma f_i = 1.03$	$\frac{1.03}{4} = 0.26$
16,000 BVs		0.36
20,000 BVs		0.48

- Use the integral curve to determine the number of bed volumes that can be processed for a blended effluent concentration, C_B , of 25 $\mu\text{g/L}$ ($C_{\text{eff}}/C_0 = 25/60 = 0.42$). As shown in Fig. 14-40, each column can be operated for 22,000 bed volumes. At this time, the effluent concentration of the single contactor will be 40 $\mu\text{g/L}$ ($C_{\text{eff}}/C_0 = 0.67$), but because it is blended with effluent from the other three columns, which have lower effluent concentrations, the blended water will remain below 25 $\mu\text{g/L}$.

Given the EBCT of 15 minutes (or 96 BVs/day), each adsorber can be operated for 22,000 BVs/(96 BVs/day) = 230 days before GAC replacement. For a single contactor, the 25 $\mu\text{g/L}$ effluent standard was exceeded at 11,000 BVs, or 115 days, thus blending yields a run time that is twice that of a single contactor. Because carbon must be replaced at equal intervals and the life of each adsorber is 230 days, one of the four adsorbers will be replaced every $230/4 = 59$ days. ▲

Series-Column Analysis. The advantage of series operation of columns was discussed earlier. The pilot test should be designed carefully to show the reduction in activated carbon usage rate that can be achieved by such operation.

The simplest case is if only a single compound with no competing adsorbates is present in the water to be treated. The breakthrough curves for each column in a two-column series are shown in Fig. 14-41a. Each column is equal in size and thus has the same EBCT. The run can be terminated when the effluent concentration in the second column reaches C_B because moving column 2 to position 1 and placing a fresh GAC column in position 2 should give the same breakthrough curves shown in Fig. 14-41a between V_1 and V_2 . The

FIGURE 14-41 Breakthrough curves as a function of total volume of water treated for two columns in series. (a) Fresh GAC in each column at the start of the run, and (b) column 1 was in the second position until C_B was reached and then moved to the first position, and fresh GAC was in column 2.

activated CUR (g/L) then is the mass of GAC in one column (g) divided by the total volume of water processed between replacements, that is, $V_2 - V_1$ (L). The number of BVs processed is $(V_2 - V_1)$ divided by the volume of GAC in one column.

The situation is more complex if competing organics are present with the contaminant or if a mixture of compounds is to be removed. The run must begin with fresh GAC in each position and then must be operated until the C_{eff} in the second column reaches C_B . The data should be plotted as shown in Fig. 14-41a. Column 2 then must be moved to position 1,

a fresh GAC column must be placed in position 2, and operation must continue until C_{eff} for the second column again reaches the breakthrough concentration. These data should be plotted as shown in Fig. 14-41*b*. However, volume V_3 probably will not be the same as volume $V_2 - V_1$ because of the effects of competition. The activated carbon usage rate (g/L) for this case now becomes the mass of GAC in one column (g) divided by V_3 (L).

The plots in Fig. 14-41 show that column 1 is completely saturated when column 2 reaches C_B . If this does not happen, a lower activated carbon usage rate probably can be achieved with more than two columns in series. The pilot test to determine this CUR, assuming competing organics are present, must be run until the column initially in the last position rotates into the first position, followed by continued operation until this sequence of columns reaches breakthrough.

Modeling of GAC Breakthrough Behavior

The modeling of the breakthrough behavior of organic substances in GAC systems can be divided into mathematical models based on the fundamentals of transport and adsorption and empirical models based on performance of existing systems.

Mathematical Models. Several useful mathematical models of the adsorption process are available and have been reviewed (Weber and Smith, 1987; Sontheimer et al., 1988; Worch, 2008). These models have led to a better understanding of the adsorption process to determine high-priority areas for future study and to determine potential cost-effective ways to design and operate activated carbon systems. At this time (2010), the models do not permit accurate long-term predictions of micropollutant removal from a mixture of adsorbable organics. The complex and dynamic effects of NOM preloading reduce GAC effectiveness and complicate micropollutant adsorption modeling to such an extent that often only rough estimates of long-term GAC performance have been possible (Jarvie et al., 2005). The purpose of this section is to summarize what can be done with models and to refer the reader to other sources of information on the subject.

The homogeneous surface diffusion model (HSDM) and modifications of it have been used widely to predict performance of adsorption systems. Crittenden and Weber (1978*a*, 1978*b*) developed this model extensively, and it has been employed subsequently to accurately predict adsorption and desorption for single-solute and bisolute systems with similar-size adsorbates (Thacker et al., 1983, 1984). Hand and colleagues (1984) developed a simplified approach to solving the model. A major difficulty in extending the use of the model is the accurate description of the competitive interactions between adsorbates with different characteristics, especially size. The nature of the competition between micropollutants and natural organics also is not well understood and difficult to predict based on laboratory tests.

Some good success with the prediction of TOC adsorption (and other group parameters) from heterogeneous mixtures of organics has been achieved. Lee and colleagues (1981) treated humic substances as a single compound in the HSDM with some success. Summers and Roberts (1984) developed a solution to this same problem using the assumptions that DOC could be treated as a single compound and that it had a linear isotherm. Their model has an analytic solution, and they were able to obtain good agreement between predictions and the performance of operating systems. Sontheimer and colleagues (1988) developed the approach of simulating NOM solutions with many adsorbates by a hypothetical solution with only a few fictive components. The concentration and adsorption properties of the fictive components are assigned to give a composite adsorption isotherm that is the same as the isotherm of the mixture. The HSDM, combined with a competitive adsorption equilibrium model, then can be used to predict the performance of various types of adsorbers for adsorption of the mixture of fictive compounds.

Numerous studies have dealt with the problem of one or more target compounds in the presence of complex mixtures of organics by incorporating the effects of the background organics in the kinetic and equilibrium constants for the target compound(s) (e.g., Weber and Pirbazari, 1982; Smith et al., 1987; Carter and Weber, 1994; Jarvie et al., 2005). The target compound(s) then are modeled as though only they are present in the water. More recently, Schideman and colleagues (2006a, 2006b) provided a solution to the problem of modeling NOM effects on the breakthrough curves of micropollutants in the presence of background organic matter. In this model, background organic matter is represented by (1) a strongly competing compound with similar adsorption characteristics as the target compound and (2) a larger pore-blocking fraction that adversely affects adsorption kinetics, both external mass transfer and intraparticle diffusion, but not the adsorption equilibrium of the target compound. The extent of competition on the adsorption capacity of the target compound was related to the adsorbed concentration of the strongly competing compound at any point in time and space in the GAC adsorber. Similarly, the effects of NOM on film and intraparticle mass transfer of the target compound were related to the adsorbed concentration of the pore-blocking NOM fraction at any point in time and space in the GAC adsorber. By successively running the model first for the pore-blocking fraction, then for the strongly competing fraction, and lastly for the target compound, Schideman and colleagues (2006b) effectively described atrazine breakthrough curves obtained with bench-scale GAC adsorbers.

A good application of mathematical models is to use them to predict small-scale column and pilot-plant results and to determine factors that should be tested in pilot studies.

Empirical Models. Empirical TOC breakthrough models developed by Bond and DiGiano (2004) allow for prediction of the service time in 20 minute EBCT adsorbers with 12×40 mesh field-scale bituminous GAC operated to three effluent TOC threshold concentrations: 1.0, 1.5, and 2.0 mg/L. Model input parameters include influent TOC concentration (TOC_0) and pH. Model development was performed using linear regression techniques and included data from 57 RSSCTs run with conventionally treated waters reported in the USEPA's Information Collection Rule (ICR) database (USEPA, 2000). However, they were not developed or verified with field-scale (pilot- or full-scale) data.

Zachman and colleagues (2007a) and Zachman and Summers (2010) extended the approach taken by Bond and DiGiano (2004). Nonparametric (Zachman et al., 2007a) and linear regression (Zachman and Summers, 2010) techniques were used to develop four practical models to predict TOC breakthrough in bituminous GAC adsorbers for two field-scale GAC sizes (8×30 and 12×40 mesh) and two EBCTs (10 and 20 minutes). Model input parameters include two water quality variables, TOC_0 and pH, that affect performance. The dependent variables for the models were normalized breakthrough time and throughput in bed volumes (BVs) to six fractional ($\text{TOC}/\text{TOC}_0 = 0.2, 0.3, 0.4, 0.5, 0.6,$ and 0.7) effluent and three mass ($\text{TOC} = 1.0, 1.5,$ and 2.0 mg/L) effluent concentrations. The model has the general form

$$\text{BV}_x = A \times \text{TOC}_0^{-\alpha} \times \text{pH}^{-\beta} \quad (14-27)$$

Model development was performed using small-scale breakthrough data from 35 different source waters in the ICR database with 400 to 500 data points per model. External model validation was performed with small-scale breakthrough data from 14 source waters, and a scalability test was performed to verify the models' ability to predict breakthrough for field-scale GAC adsorbers using at least 100 data points per model.

Table 14-10 shows the model equations and the equations for estimating the model coefficients. The breakthrough predictions are an inverse function of influent TOC and pH, as discussed earlier in this chapter (see Figs. 14-42 and 14-43). Figure 14-42 shows a

TABLE 14.10 Four Models for Predicting TOC Breakthrough

			Normalized effluent concentration model	Mass effluent concentration model
			$BV_x = A - TOC_0^{-1} \times pH^{-1.5}$ $A = f(x)$, where $x = 20\%, 30\%, 40\%, 50\%, 60\%$, or 70%	$BV'_x = A' \times TOC_0^{-2} \times pH^{-1.5}$ $A' = f(x')$, where $x' = 1.0, 1.5$, or 2.0 mg/L
Model 1	12 × 40	10	$A = 196 \times x^2 - 5589 \times x + 252,922$	$A' = 1,158,032 \times x' - 198,903$
Model 2	12 × 40	20	$A = 164 \times x^2 - 1938 \times x + 245,064$	$A' = 1,199,245 \times x' - 72,818$
Model 3	8 × 30	10	$A = 178 \times x^2 - 6208 \times x + 238,321$	$A' = 1,125,073 \times x' - 429,296$
Model 4	8 × 30	20	$A = 202 \times x^2 - 5995 \times x + 261,914$	$A' = 1,164,886 \times x' - 260,446$

sensitivity analysis of model 2 (12 × 40 mesh GAC, 20 minute EBCT) to the influent TOC and pH. The importance of pretreatment to reduce the TOC and pH on extending service time clearly can be seen from this model. Figure 14-43 shows the application of model 2 and model 3 predictions to field-scale data not used in the development of the models. Zachman and colleagues (2007b) used the models to optimize the coagulation and GAC processes for TOC removal as a function of pH.

Kim (2006) and Kim and colleagues (2007) developed predictive models for MIB breakthrough based on the 35 RSSCTs. The three models were designed to predict the BVs treated to target effluent MIB concentration of 10 ng/L (BV₁₀) and 20 ng/L (BV₂₀) and to a 10 percent breakthrough (BV_{10%}). The models were created using multiple linear regression techniques in stepwise manner to determine significant predictors of breakthrough to

FIGURE 14-42 Model sensitivity analysis showing the impact of influent TOC and pH—Model 2: 12 × 40 mesh GAC, 20 minute EBCT.

FIGURE 14-43 Comparison of ZS model predictions and external experimental TOC breakthrough data for model 2 (12 × 40 mesh, 20 minute EBCT) and model 3 (8 × 30 mesh, 10 minute EBCT). Error bars represent confidence intervals at 95%. (Source: Zachman and Summers, 2010.)

the target effluent conditions. Models were first developed for fresh 12 × 40 mesh GAC at 10 and 20 minute EBCTs and then modified to account for 8 × 20 and 8 × 30 mesh GAC and GAC age. The model input includes influent TOC₀, influent MIB concentration, GAC particle size, and GAC age.

The following equation was found to work for all three models and is shown below for the BV₁₀ and the 12- × 40-mesh fresh GAC experimental data.

$$BV_{10}^{12 \times 40, \text{ fresh GAC}} = A_1 \times TOC^{x_1} \times MIB^{x_2} \tag{14-28}$$

where $A_1 = 99266$, $x_1 = -0.85$, and $x_2 = -0.2$.

The preceding model was developed using RSSCT breakthrough data from 12 × 40 mesh GAC particle size at EBCTs of 10 and 20 minutes. Also, this model does not take into account GAC age (or NOM preloading effect). Therefore, for more useful and accurate prediction, the model was modified to consider the impact of different GAC sizes and GAC age. To take into account the effect of NOM preloading time into the model, the GAC age coefficient as a function of GAC age α_1 was developed from the relationship between fresh and used GAC BV₁₀.

$$\alpha_1 \approx f \left(\frac{BV_{10}^{\text{used GAC}}}{BV_{10}^{\text{fresh GAC}}} \right) = 1 - (0.023 \times \text{GAC age}) \tag{14-29}$$

A GAC size coefficient for 8 × 30 mesh GAC ($\alpha_1 = 0.62$) also was calculated using RSSCT breakthrough data. Therefore, the overall MIB model considering the effect of influent

TOC, influent MIB concentration, GAC particle sizes, and GAC age is presented in following equation:

$$BV_{10}^{overall} = \alpha_1 \beta_1 (A \times TOC^{x_1} \times MIB^{x_2}) \tag{14-30}$$

α_1 = GAC age coefficient ($\alpha_1 = 1 - (0.023 \times \text{GAC age})$), if fresh GAC then $\alpha_1 = 1$
 β_1 = GAC size coefficient (if 12×40 $\beta_1 = 1$, if 8×30 then $\beta_1 = 0.62$)

The model has been used successfully to predict pilot-plant breakthrough data at two utilities. Matsui and colleagues (1994), Gillogly and colleagues (1999), and Kim (2006) all have shown that the removal under periodic episodes was a function of the GAC service time or DOM loading.

POWDERED ACTIVATED CARBON ADSORPTION

The primary advantages of using PAC are the low capital investment costs and the ability to change the PAC dose as the water quality changes. The latter advantage is especially important for systems that do not require an adsorbent for much of the year. The disadvantages, according to Sontheimer (1976), are high operating costs if high PAC doses are required for long periods of time, the inability to regenerate, the low TOC removal, the increased difficulty of residuals management (increased solids loading, residuals are more abrasive), and the difficulty of completely removing the PAC particles from the water.

PAC Application

PAC can be purchased and stored in bags and fed as a powder using dry-feed machines. PAC also can be delivered in bulk and stored dry in silos, from where it is dosed into the water. Alternatively, PAC can be bought in large quantities and fed as a slurry using metering pumps. Storage in bags requires specially designed and operated facilities to avoid generation of nuisance conditions from PAC dust. A survey by Graham and colleagues (1997) in 1995 of 95 utilities using PAC for taste and odor control indicated the following points of PAC addition in conventional plants: presedimentation (16%), rapid mix (49%), flocculation (10%), sedimentation (7%), and filter influent (10%). Twenty-three percent of the plants had the ability to apply PAC at multiple points. Another point of addition that should be considered, although it is not used commonly (7%), is a continuous-flow slurry contactor that precedes the rapid mix. The PAC can be intensely mixed with the water, enabling rapid adsorption onto the small PAC particles, and then incorporated into the floc in the rapid mix for subsequent removal by sedimentation and filtration. Table 14-11 summarizes some of the important advantages and disadvantages to each of these points.

Important criteria for selecting the point of addition include (1) the provision of good mixing, or good contact between the PAC and all the water being treated, (2) sufficient time of contact for adsorption of the contaminant, (3) minimal interference of treatment chemicals with adsorption on PAC, and (4) no degradation of finished water quality. The PAC must be added in a way that ensures its contact with all the flow.

Sufficient time of contact also is necessary, and the time required is an important function of the characteristics and concentration of the molecule to be adsorbed (Meijers and van der Leer, 1983). Figure 14-44 shows the dramatic effect that PAC particle size has

TABLE 14-11 Advantages and Disadvantages of Different Points of PAC Addition

Point of addition	Advantages	Disadvantages
Intake	Generally long contact time, good mixing	Some possibility (slight) of adsorbing compounds that otherwise would be removed by coagulation, thus increasing carbon usage rate
Rapid mix	Good mixing during rapid mix and flocculation; reasonable contact time	Some chance of reduced adsorption rate because of coagulant interference Contact time may be too short to reach equilibrium, thus requiring increased PAC dose
Filter inlet	Sufficient time to reach full adsorption capacity of PAC	PAC may penetrate the filter and deposit in clear well, distribution system, or cause consumer "graywater" complaints; requires good filter aid PAC dose is limited by the rate of head loss buildup and reductions in filter run length
Slurry contactor preceding rapid mix	Excellent mixing; no interference from coagulants	New basin and mixer may have to be installed

on the rate of adsorption of trichlorophenol (TCP) from a groundwater (Adham et al., 1991). The figure shows that 5 µm diameter PAC adsorbs TCP much more rapidly than the 20 µm diameter PAC. Some of the difference in rate in the curves shown in the figure is attributable to the lower capacity of the 20 µm diameter carbon, but the other fractions have the same capacity per unit mass of PAC (Adham et al., 1991). Even faster adsorption

FIGURE 14-44 CSTR model prediction versus PAC-UF performance for the adsorption of TCP from groundwater using all PAC size fractions (PAC dose = 15 mg PAC/L). (Source: Adham et al., 1991.)

kinetics have been demonstrated with submicrometer-diameter PAC (Matsui et al., 2008). Adsorption kinetics and equilibrium capacity depend on the type of adsorbate, the type of PAC used, and the competition from background organic matter. If insufficient time is allowed for equilibration, an increased PAC dose must be used to compensate.

Incorporation of PAC into floc particles is one factor that may reduce the rate of adsorption when PAC is added at the rapid mix (Sontheimer, 1976; Gauntlett and Packham, 1973). Gauntlett and Packham (1973) conducted jar tests that showed a lower removal rate of chlorophenol when PAC was added at the same time as alum compared with its addition in the absence of alum. They also found that addition of PAC a short time after alum addition gave a higher rate of removal than when it was added together with alum. They reasoned that PAC added after the alum adhered to the outer surface of the alum floc, thus avoiding rate interference. Najm and colleagues (1989) found little reduction, however, in the rate of TCP adsorption on PAC when PAC particles were incorporated into floc during alum coagulation of a groundwater. Similarly, Graham and Summers (1996) found that alum had only a small impact on the kinetics of TCP adsorption in both organic-free water and water with NOM. Also, Cook and colleagues (2001) showed that MIB and geosmin adsorption rates were not affected by the addition of coagulant in three of four Australian waters. In the fourth water, PAC performance was adversely affected by the presence of alum, however. When alum and PAC were added together at the rapid mix, Ho and Newcombe (2005) showed that increasing alum doses adversely affected MIB adsorption. For alum doses up to 40 mg/L, a PAC dose of 15 mg/L yielded MIB removals of approximately 50 percent; at an alum dose of 100 mg/L, MIB removal was only 20 percent with the same PAC dose. The incorporation of PAC into increasingly larger floc particles was cited as the reason for the deterioration in PAC performance.

Addition at the intake has the advantage of providing extra contact time and generally good mixing in the intake line. Adsorption of compounds that otherwise would be removed by coagulation, flocculation, and sedimentation might increase the required PAC dosage, but this has not been shown to be an important factor in studies to date.

Addition of PAC just before the filter is advantageous because the PAC can be kept in contact with the water longer, thereby better using its capacity. The average PAC residence time is equal to one-half the time between two successive backwashings, assuming that PAC is added continuously to the filter influent. Also, all the PAC could be added at once, just after backwash. The addition must be performed carefully to avoid having PAC escape the filter and penetrate the distribution system, however. The maximum dosage of PAC for this point of addition is limited by the ability of the filter to retain the PAC and by the head loss in the filter, which is expected to increase as PAC dosage increases. Selected polyelectrolytes may be added to retain the PAC, but careful monitoring of the filter to ensure that PAC does not penetrate it is required. The 0.45- μm membrane filter test involving filtration of a fixed quantity of filter effluent is a good method to determine if PAC is penetrating the filter (Greene et al., 1994). Comparison of the color of the filter pad with the color of filter pads that have been used to remove known quantities of PAC from water allows a good estimate to be made of the concentration of PAC that is escaping.

Sontheimer (1976) suggested adding a separate reactor between the sedimentation basin and the filter to increase the time of contact and noted that this procedure would have the advantage of having eliminated competing organics to the maximum extent possible by coagulation-flocculation-sedimentation before PAC addition. A major disadvantage is that the PAC would have to be removed from the water by another coagulation and filtration step, so the cost of this approach would be high.

Careful attention must be paid to the interaction of PAC with water treatment chemicals. Activated carbon is an efficient chemical reducing agent that will chemically reduce substances such as free and combined chlorine, chlorine dioxide, ozone, and permanganate, thereby increasing the demand for these substances and the cost of treatment. Reaction of activated carbon with chlorine will reduce the adsorption capacity of the activated carbon for selected compounds (Snoeyink and Suidan, 1975; McGuire and Suffet, 1984; Gillogly et al., 1998a).

As much as 50 percent of the MIB capacity was lost when 12 mg/L of PAC was reacted with 3 mg/L of free chlorine (Gillogly et al., 1998a). Lalezary-Craig and colleagues (1988) found a reduction in the ability of PAC to adsorb both geosmin and MIB when PAC was applied to water containing free chlorine and monochloramine, and the effect of the monochloramine appeared to be greater than that of chlorine. Furthermore, as chlorine is destroyed by PAC, more chlorine must be added to achieve the desired degree of disinfection.

Addition of PAC to a water that is supersaturated with CaCO_3 or other precipitates or an increase in pH to cause supersaturation just after PAC is added, such as in lime softening, may lead to coating of the particle with precipitates and to a corresponding decrease in adsorption efficiency. Greene and colleagues (1994) found that PAC added to a lime-softening basin was much less effective at removing atrazine than PAC added after the softening process. Also, adsorption at high pH is often poorer than at low pH because many organic contaminants are weak acids that ionize at high pH.

Various techniques of applying PAC to improve the ability of PAC to adsorb slow-diffusing compounds such as DBP precursors are available. For example, addition of PAC to solids contact clarifiers has the potential for improved adsorption efficiency because the carbon can be kept in contact with the water for a longer time (Hoehn et al., 1987; Lettinga et al., 1978). Najm and colleagues (1993) found that trichlorophenol reached equilibrium with PAC in a floc blanket reactor; thus lower PAC doses could be used than if PAC were added to the rapid mix followed by flocculation and sedimentation. Similar results were measured and/or predicted for atrazine and DOC adsorption in PAC-floc blanket reactor treatment systems (Campos et al., 2000a, 2000b)

PAC also can be used in conjunction with cross-flow microfiltration (MF) or ultrafiltration (UF) membrane systems. These membranes are effective for removal of particles and microorganisms (see Chap. 11), but pores in the membrane are relatively large, and dissolved organic matter readily passes through the membrane. Removal of organic matter such as pesticides, taste- and odor-causing compounds, and DBP precursors requires pretreatment of the water with an adsorbent. PAC particles are large enough so that PAC can be applied just before the membrane. This system is highly effective for removal of dissolved organic carbon (Adham et al., 1993; Anselme et al., 1997) and atrazine (Campos et al., 1998). Anselme and colleagues (1997) report that several full-scale plants in France are now operating such systems.

A more recent innovation involves the two-stage application of PAC in the floc blanket reactor (FBR)–PAC–UF process (Campos et al., 2000a; Degrémont, 2007). The flow diagram for this process is shown in Fig. 14-45. Fresh PAC is applied continuously just in

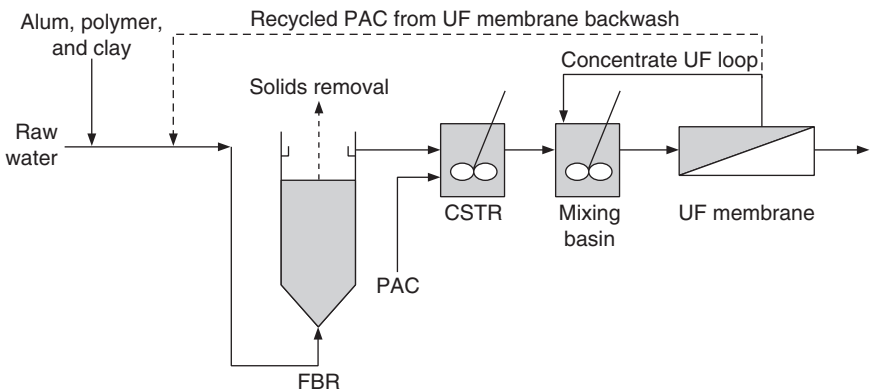

FIGURE 14-45 Schematic of an FBR-PAC-UF system.

advance of the UF process, where it tends to come to equilibrium with the concentration of organic matter in the UF process effluent. As the PAC and other particles accumulate on the membrane, head loss gradually increases until the membrane must be backwashed. The backwash effluent is recycled to the FBR, where the PAC is trapped in the floc. The PAC now tends to equilibrate with the concentration of organic matter in the effluent of the FBR. The solids residence time in the FBR is typically 12 to 36 hours, so there is sufficient time for extensive adsorption to occur. The FBR effluent concentration is much higher than the UF effluent concentration, so the amount of adsorption per unit mass of PAC is increased significantly. The benefit of a countercurrent two-stage process such as this depends on the type of organic matter being removed.

PAC Performance Estimation

Estimation of PAC Dose Using Jar Tests. Jar tests are the simplest way to determine an estimate of the PAC dose required to achieve a desired level of micropollutant removal in conventional surface water treatment plants. Jar tests can be used if water is available with a typical concentration of the micropollutant in question. Alternatively, the micropollutant can be spiked at a typical concentration into the water to which the PAC is to be added. The chemical doses, mixing times and intensities, and settling time should correspond as nearly as possible to those which will be encountered in the full-scale plant. The time of sampling should correspond to the estimated time of contact of the PAC in the plant, keeping in mind that well-coagulated PAC may settle out soon after the PAC enters the sedimentation basin. The percent removal of the micropollutant that was obtained in the jar test can be plotted against PAC dose. The resulting curve is independent of the initial concentration of the micropollutant and can be used to determine the required amount of PAC to be added (see Example 14-6). This dosage will only be an estimate of the full-scale plant dosage because of the many differences between contact in a jar test and in the plant. Therefore, the dosage may have to be modified based on full-scale performance of the PAC. Some bench- or pilot-scale testing also may be necessary to determine the best filter-aid polymer to prevent PAC from penetrating the rapid filter.

Often it is of interest to study the expected performance of PAC for many conditions, various contact times, several types of PAC, and various water quality conditions. Two cases are presented in the following example to illustrate the procedures for estimating performance.

Example 14-6 PAC Usage Rate for Atrazine and MIB Removal

Case 1

Conditions: PAC is to be applied in a way that equilibrium will be achieved, such as to the inlet of a filter. Atrazine concentrations ranging from 3 to 20 $\mu\text{g/L}$ must be lowered to a plant goal of 1 $\mu\text{g/L}$. The best PAC must be selected.

Approach: An atrazine isotherm should be determined for each PAC to be evaluated. The water sample for the isotherm tests should have the pH, mineral composition, and background organic matter concentration expected in the full-scale plant on a consistent basis. An initial concentration of 50 $\mu\text{g/L}$ or less of atrazine should be used for the test.

Data analysis: The data should be analyzed by plotting the remaining atrazine concentration (as a percentage of the initially added atrazine concentration) versus PAC dose, as shown in Fig. 14-13. One curve will be determined for each carbon. This curve can be used to determine the required PAC dose for each initial concentration expected. For example, if the initial concentration is 20 $\mu\text{g/L}$, the required percent removal is

$$\frac{(20-1)\mu\text{g/L}}{20\mu\text{g/L}} \times 100\% = 95\%$$

Assuming that Fig. 14-13 is valid for this water and one of the tested PACs, the required PAC dose to achieve 95 percent removal (5% remaining) is 30 mg/L. Repeating this procedure for each carbon under consideration and knowing the cost of each carbon allow the selection of the most cost-effective carbon to achieve the required 95 percent removal.

The required percent removal will decrease as the influent concentration decreases, given that the desired effluent concentration remains 1 $\mu\text{g/L}$.

Case 2

Conditions: MIB is present at 20 ng/L, and its concentration must be reduced by 75 percent to the threshold odor level of 5 ng/L. However, several points of addition must be evaluated, each of which has a different contact time, and the adsorption process does not necessarily reach equilibrium.

Approach: A plot of the percentage of adsorbate (in this case MIB) remaining in the water as a function of PAC dose at any contact time is independent of the initial adsorbate concentration if the diffusion coefficient is not a function of test conditions (Gillogly et al., 1998b). Thus the percentage of MIB remaining at each desired contact time can be determined and plotted as a function of PAC dose, as shown in Fig. 14-46. The jar test procedure for MIB adsorption has been described by Gillogly and colleagues (1998b). These tests should be conducted for each desired contact time. Assuming the same PAC and the same water with the same background organic matter as that studied by Gillogly and colleagues (1998b), Fig. 14-46 can be used to determine a PAC dose of 16 mg/L if a contact time of 4 hours is available. The required PAC dose increases to 30 mg/L if the available contact time is only 15 minutes. ▲

Estimation of PAC Dose Using Mathematical Models. Apart from the jar-testing approach, mathematical models are useful to predict PAC performance in continuous-flow reactors such as rapid-mix basins, flocculation basins, and intake pipes. For completely mixed reactors such as rapid-mix basins, the continuous stirred tank reactor (CSTR) model

is more appropriate, whereas the plug flow reactor (PFR) model is more suitable when PAC is added at the intake and flows with the water through a long pipe. Solutions for the CSTR and PFR models have been presented by Najm (1996).

Experience with PAC

The predominant reason for the use of PAC is taste and odor control, but it is also used for the control of other organic compounds such as pesticides, cyanotoxins, and DBP precursors. PAC doses range from a few to more than 100 mg/L but typically are less than 25 to 50 mg/L (Graham et al., 1997).

Taste- and Odor-Causing Compounds

Numerous studies have evaluated the effectiveness of PAC adsorption processes for taste and odor control. Among earthy-musty odorants, Lalezary and colleagues (1986) showed that activated carbon adsorption is least effective for MIB. Therefore, greater emphasis often is placed on evaluating MIB removal from drinking water. Gillogly and colleagues (1998a) demonstrated that percent MIB removal at a given PAC dose and contact time was independent of the initial MIB concentration. For a contact time of 4 hours, Gillogly and colleagues (1998a) reported MIB removals of approximately 60 to 90 percent with 12 mg/L PAC, the maximum PAC dose that could be applied at the plants participating in the study. Assuming a threshold odor concentration of 5 ng/L for MIB, the results of Gillogly and colleagues (1998a) showed that 13 to 33 mg/L PAC was required to control MIB-related odors in natural water with an initial MIB concentration of 50 ng/L. At an initial MIB concentration of 100 ng/L, PAC doses of 18 to 38 mg/L were required to control MIB-related odors. The PAC dose ranges reflect differences in the effectiveness of five commercially available PACs. A coal based PAC exhibited the largest MIB removal after a contact time of 4 hours.

To lower MIB concentrations in four Australian waters from 50 to 10 ng/L, Cook and colleagues (2001) determined that PAC doses in the range of 39 to 55 mg/L were required when the PAC contact time was 50 minutes. To achieve the same removals for geosmin, PAC doses of 21 to 29 mg/L were necessary. Newcombe and Cook (2002) further showed that mesoporous PACs, such as chemically activated wood based PACs, are more effective for MIB and geosmin removal at short contact times, whereas more microporous PACs, such as steam-activated coal- and coconut shell based PACs, are more effective when longer contact times are available.

Cho and Summers (2007a) evaluated MIB removal with three commercial PAC types at three doses (5, 15, and 30 mg/L) and at four contact times (10, 30, and 60 minutes and 24 hours) for six different waters with TOC concentrations in the range of 2 to 5 mg/L. Doses of 5, 15, and 30 mg/L yielded an average of 30, 50, and 65 percent MIB removal, respectively, with a contact time of 30 minutes and an average of 38, 55, and 75 percent MIB removal, respectively, with a contact time of 60 minutes. During the first 10 minutes of contact, 60 to 75 percent of ultimate MIB removal (24 hours) was achieved. The uptake of MIB was affected by DOC concentration. Higher DOC concentrations yielded lower MIB removals, which were attributed to NOM competition with MIB for PAC adsorption sites. Adding potassium permanganate (KMnO_4) with PAC decreased the overall efficiency of MIB removal compared with PAC alone. A simple relationship between percent MIB removal and percent DOC removal was found for all three PACs, suggesting that DOC measurements could serve as a surrogate for more expensive MIB analyses.

For 2t,6c-nonadienal, limited data by Burlingame and colleagues (1992) suggest that PAC can control both the cucumber odor and flavor associated with this compound. PAC doses as large as 24 mg/L were required to control the cucumber flavor in Delaware River water, and similar results were obtained by Krasner and colleagues (2004) for Colorado

River and State Project waters. Krasner and colleagues (2004) further showed that a PAC dose of 25 mg/L yielded at least 50 percent removal for 8 of 12 compounds responsible for fishy, grassy, and swampy odors in Colorado River and State Project waters.

TON removal is used commonly to measure PAC effectiveness. Reports of the effectiveness of PAC for TON removal are complicated because an odor may be caused by the combination of the effects of more than one compound or a compound may mask the odor of another compound, and the odor of the second may appear after the first compound has been adsorbed. Furthermore, odors may form after treatment through chemical or biological reactions in the distribution system (AWWA Research Foundation and Lyonnaise des Eaux, 1987), thus making PAC appear ineffective. A reliable catalog of odors that can be removed well by PAC does not exist probably because of the preceding complicating factors. As analytic capabilities improve and the ability to qualitatively and quantitatively analyze compounds that cause odor advances, however, development of such a catalog may be possible.

Pesticides. Gustafson and colleagues (2003) studied the removal of atrazine and the chloroacetanilide herbicides acetochlor, alachlor, and metolachlor by lignite and coal based PACs. In addition, the removal of the ethanesulfonic acid (ESA) and oxoacetic acid (OA) degradates of the chloroacetanilides was evaluated. For a given water and PAC type, removal of atrazine and the chloroacetanilides was similar, whereas removal of the ESA and OA degradates was lower. For a PAC dose of 20 mg/L and a contact time of 20 minutes, the lignite based PAC performed slightly better than the coal based PAC, whereas the reverse was true for contact times of 60 minutes and longer. For one tested surface water, a lignite based PAC dose of 20 mg/L produced atrazine and chloroacetanilide removals ranging from 66 to 74 percent after a contact time of 20 minutes. In contrast, ESA and OA degradate removals ranged only from 22 to 32 percent. An early study by Robeck and colleagues (1965) showed that PAC effectively removed the pesticides parathion, 2,4,5-T butyl ester, endrin, lindane, and dieldrin from Little Miami River water.

Greene and colleagues (1994) evaluated the effectiveness of PAC in a lime softening plant. Addition of 6 mg/L of lignite based PAC to the stabilization basin (residence time of 3.2 hours) lowered atrazine concentrations from 2.1 to 6.7 $\mu\text{g/L}$ in the basin influent to 0.2 to 3.5 $\mu\text{g/L}$ in the basin effluent. A PAC dose of 9.6 mg/L lowered atrazine concentrations from 2.1 to 8.5 $\mu\text{g/L}$ in the basin influent to 0.09 to 2.3 $\mu\text{g/L}$ in the basin effluent. PAC carryover to the filters produced additional atrazine removal such that atrazine concentrations in the filter effluent were less than 0.3 $\mu\text{g/L}$ at both tested PAC doses. At the same plant, the addition of approximately 10 mg/L of PAC to the stabilization basin lowered alachlor concentrations from approximately 0.5 to 1.1 $\mu\text{g/L}$ in the basin influent to less than 0.25 $\mu\text{g/L}$ in the basin effluent.

Cyanotoxins. Microcystin-LR has been the most widely studied cyanotoxin, and its removal is accomplished most effectively by mesoporous PACs (Donati et al., 1994). In a full-scale lime softening plant, more than 80 percent microcystin-LR removal was achieved with a PAC dose of 30 mg/L (Lambert et al., 1996). Newcombe and Nicholson (2004) calculated PAC doses required to remove 80 percent microcystin-LR and microcystin-LA by a chemically activated wood based PAC; 29 mg/L was required for microcystin-LR, whereas 95 mg/L was required for microcystin-LA after a contact time of 60 minutes. For the removal of the cyanotoxin cylindrospermopsin, Ho and colleagues (2008) determined that both a steam-activated coal based PAC and a chemically activated wood based PAC performed equally well. For a contact time of 30 minutes, 80 percent cylindrospermopsin removal was obtained with a PAC dose of 33 mg/L in the tested Australian water. For saxitoxins, removal of the most toxic variants is accomplished effectively by 30 mg/L of PAC and a contact time of 1 hour (Newcombe and Nicholson, 2004). Little information on the effectiveness of PAC is available on the adsorption of other cyanotoxins such as anatoxin-a and nodularin.

NOM and DBP Precursors. Najm and colleagues (1991b) provided a comprehensive review of the PAC adsorption literature and concluded that relatively high PAC doses are required to achieve substantial removal of TOC, DOC, and/or THM precursors. In some instances, a PAC dose of 50 mg/L yielded negligible TOC and THM precursor removal, whereas in others, the same PAC dose yielded up to 27 percent TOC removal and 49 percent THM precursor removal. Sufficient information about NOM characteristics, PAC characteristics, and PAC contact times was not provided, however, and factors responsible for the differences in TOC and THM precursor removal efficiencies therefore could not be identified.

More recently, Uyak and colleagues (2007) showed that the DOC-removal efficiency of PAC strongly depends on PAC type. For example, for two PACs, a dosage of 20 mg/L yielded approximately 5 percent DOC removal, whereas approximately 25 percent was achieved with another PAC at the same dosage. No information about PAC characteristics was provided that could help to explain the performance differences among the PACs. Cho and Summers (2007b) evaluated three commercial PAC types at three doses (5, 15, and 30 mg/L) and four contact times (10, 30, and 60 minutes and 24 hours) for seven different waters with TOC concentrations in the range of 2 to 5 mg/L. Doses of 5, 15, and 30 mg/L yielded an average of 7, 16, and 23 percent DOC removal, respectively, with a contact time of 30 minutes, with 40 to 50 percent of ultimate DOC removal (24 hours) achieved in the first 10 minutes.

Campos and colleagues (2000a) compared the DOC-removal efficiency of two commercially available PACs with mean diameters of 10 and 6 μm . Using PAC doses of 10 and 20 mg/L and a contact time of 30 minutes, they obtained DOC removals in the range of approximately 10 to 35 percent for the larger PAC and approximately 26 to 43 percent for the smaller PAC. The smaller PAC in this study exhibited higher micropore and mesopore volumes and a larger DOC adsorption capacity than the larger PAC. Thus higher DOC removals obtained with the smaller PAC were in part a result of its higher adsorption capacity and in part a result of faster DOC adsorption rates. The results of Campos and colleagues (2000a) and Cho and Summers (2007b) suggest that typical PAC doses for taste and odor control can yield meaningful DOC-removal percentages.

Emerging Contaminants. Using coal based WPH PAC, Adams and colleagues (2002) studied the adsorption of five sulfonamide antibiotics and the antimicrobial compound trimethoprim (TMP) from Missouri River water. After a contact time of 4 h, sulfonamide removals ranged from 49 to 73 percent, and TMP removal was approximately 55 percent at a PAC dose of 10 mg/L (Adams et al., 2002). Evaluating the removal of pharmaceuticals, endocrine-disrupting chemicals, personal-care products, and flame retardants from four drinking water sources with 5 mg/L of a coal based PAC, Westerhoff and colleagues (2005) obtained average removals ranging from 16 percent for the analgesic ibuprofen to 93 percent for the sunscreen ingredient oxybenzone after a contact time of 4 hours. Most of the tested emerging contaminants exhibited an adsorbability that was similar to or greater than that of the herbicide metolachlor.

THERMAL REACTIVATION OF GAC

Reactivation Principles

The reactivation process can be described as consisting of four basic steps (van Vliet, 1985): (1) drying, including loss of highly volatile adsorbates, at temperatures up to 200°C, (2) vaporization of volatile adsorbates and decomposition of unstable adsorbates to form

volatile fragments, at temperatures of 200 to 500°C, (3) pyrolysis of nonvolatile adsorbates and adsorbate fragments to form a carbonaceous residue or char on the activated carbon surface, at temperatures of about 500 to 700°C, and (4) oxidation of the pyrolyzed residue using steam or carbon dioxide as the oxidizing agent, at temperatures above about 700°C.

The drying step eliminates the 40 to 50 percent of the water associated with the spent GAC (Schuliger and MacCrum, 1973). The proportions of adsorbates that are volatilized (steps 1 and 2) or converted to char (step 3) depend on the nature of the adsorbate and the strength of the adsorbate-activated carbon bond (Juntgen, 1976). Oxidation to gasify the char is critical to returning the GAC as closely as possible to virgin conditions. The objective is to remove the char with minimal loss of the activated carbon in a manner that does not alter the structure and adsorption properties of the activated carbon.

Factors affecting reactivation product quality are primarily those which affect the oxidation step. Important factors are the type of oxidizing gas, the time and temperature of oxidation, the amount and type of adsorbate on the carbon, the type and quantity of inorganic substances that accumulate on the carbon, and the type of activated carbon. Reactivation studies indicate a tradeoff between the time required for reactivation and the temperature of reactivation: The higher the temperature, the shorter is the reactivation time (Juhola, 1970). The optimal temperature for reactivation has been shown to depend on the type of activated carbon (Juntgen, 1976).

In the application of activated carbon for purification of surface water and possibly groundwater, the need to remove adsorbed humic substances probably will control the reactivation step, even though the primary purpose in applying the activated carbon is to remove micropollutants. Certain inorganic substances, if present in the water being treated, may form a precipitate on the activated carbon surface or may accumulate on the activated carbon surface because of their association with the organic molecules that are being adsorbed. Knappe and colleagues (1992) and Cannon and colleagues (1993) found that calcium accumulated on many water treatment plant carbons. In agreement with others, they showed that calcium catalyzed the reaction of reactivated gases with GAC and made the recovery of micropores difficult.

Reactivation Furnaces

Common types of furnaces are the rotary-kiln, the multiple-hearth, and the fluidized bed furnace (Sontheimer et al., 1988). The multiple-hearth furnace is used most commonly. Scrubbers are used to remove particles from the off-gases, and afterburners, which are maintained at 750 to 1000°C by burning fuel with excess oxygen, are used to destroy organic compounds that are volatilized but not combusted to CO₂ during the reactivation step.

Reactivation Performance

Loss of mass during reactivation is important because of its impact on the cost of using activated carbon. DeMarco and colleagues (1983) reported total losses (transport plus loss in the furnace) of 16 to 19 percent in an experimental system at Cincinnati, whereas Koffskey and Lykins (1987) observed 9 percent loss (7% in the furnace and 2% during transport) at Jefferson Parish, LA. Proper design of the transport system is very important because of the high losses that can take place in a poorly designed system (Schuliger et al., 1987). Schuliger and colleagues (1987) noted that losses are a function of the transport system design, the type of adsorbate, the loading of adsorbate on the carbon, and the type of furnace.

Along with the loss in mass may come a change in pore size distribution. Pore size distribution has a significant effect on both rate of uptake and capacity for a particular

adsorbate. Modifying reactivation conditions to produce the best pore size distribution for a particular adsorbate should be possible, but research to show how this can be done and to show the desired pore size for a given application is needed (Sontheimer et al., 1988). It has been observed that the particle diameter becomes smaller during reactivation, with the disadvantage of creating higher head loss in fixed-bed adsorbers but with the advantage of allowing the rate of uptake of molecules to occur more rapidly. The decrease in particle diameter should be minimized as much as possible because this decrease normally correlates with loss in mass.

Generally, density, molasses number or decolorization index, iodine number, and similar parameters are used to measure the quality of the activated carbon. An improved procedure involves the use of the water to be treated to test the quality of the product with isotherms of RSSCTs. Changes in activated carbon quality produced by reactivation then can be expressed as changes in the length of time to breakthrough and the amount of material adsorbed at breakthrough for a column of a given design.

Kornegay (1979) analyzed the cost of reactivation as a function of furnace size. He showed rapidly increasing unit costs as activated carbon usage became smaller than 2270 to 2720 kg/day (5000–6000 lb/day). Kornegay (1979) noted that on-site thermal reactivation will not be economical if usage is smaller than 227 to 454 kg/day (500–1000 lb/day), whereas Hess (1981) proposed a lower economical limit of about 910 kg/day (2000 lb/day). Transport of spent GAC to off-site thermal reactivation facilities may be appropriate for intermediate values of activated carbon usage rate. The cost of reactivation then would include transportation to and from the site, the cost of makeup activated carbon, and (presumably) profit for the owner of the furnace. This approach to reactivation is common in Europe, where transportation distances are relatively short, the incidence of GAC usage for surface water is high, and the number of on-site furnaces is small. Further, assurance would have to be given that only water treatment plant activated carbon would be returned to a plant. Inclusion of reactivated activated carbon that had been used for municipal or industrial waste treatment would be unacceptable.

Reactivation By-Products

Activated carbon must be regenerated in a way that does not pollute the atmosphere. For this reason, scrubbers and afterburners are used to minimize particulate and gaseous emissions, respectively, from operating facilities. Off-gas control is important in controlling dioxins and furans that are produced during reactivation. Lykins and colleagues (1988b) studied operating reactivation systems at Cincinnati and Jefferson Parish and found these compounds in various effluent streams before treatment of these effluent streams, even though they were not on GAC entering the furnace. A small amount of the dioxins and furans do pass through the stack gas control equipment, but Lykins and colleagues (1988b) found the concentrations to be so low that the estimated cancer risk was negligible.

ADSORPTION OF ORGANIC MATTER BY OTHER ADSORBENTS

Synthetic Adsorbent Resins

The styrene-divinylbenzene (SDVB) resin with no functional groups has received much attention as an adsorbent. The resin was particularly effective for removal of chlorinated pesticides from an industrial wastewater (Kennedy, 1973). Regeneration was readily

accomplished with acetone or isopropanol, and the spent regenerant could be reclaimed for reuse. This resin also adsorbs phenols, although its capacity is somewhat less than that of weak-base resins (Kumugai and Kaufman, 1968). The SDVB resin did not remove TOC from Thames River water to an appreciable extent (Gauntlett, 1975). The weak-base phenol-formaldehyde (PF) resin had essentially no capacity for the earthy-musty-odor compound MIB (Chudyk et al., 1979). The SDVB adsorbent resin did adsorb MIB, but its adsorption capacity was lower than those of low-activity activated carbons made from bituminous coal. A general conclusion concerning resins is that they are not applicable as a general adsorbent for drinking water treatment. They are more selective than activated carbon and do not meet the criterion that an adsorbent must be able to remove a wide variety of compounds. They may be applicable in specific situations that require removal of only a particular contaminant.

Carbonaceous Resins

Several studies have evaluated carbonaceous resins as an adsorbent alternative to activated carbon (Hand et al., 1994; Melin, 1999; Knappe et al., 2007; Rossner et al., 2009). Targeted adsorbates in these studies were TCE, MTBE, and emerging contaminants. For MTBE, carbonaceous resins exhibited adsorption capacities that exceeded those of GACs prepared from coconut shells, coal, and wood. Melin (1999) reported that the MTBE adsorption capacity of the carbonaceous resin Ambersorb 572 was not affected by the presence of groundwater NOM, whereas that of a coconut shell based GAC decreased in the presence of the same NOM. Similar results were obtained by Hand and colleagues (1994) when they compared trichloroethene (TCE) adsorption capacities of the carbonaceous resin Ambersorb 563 and a coal based GAC in ultrapure water and groundwater. In the presence of groundwater NOM, the activated carbon adsorption capacity decreased by 35 percent relative to the single-solute adsorption capacity, whereas the carbonaceous resin adsorption capacity was not measurably affected after 10 weeks of NOM exposure (Hand et al., 1994). In contrast, Knappe and colleagues (2007) showed that river water NOM decreased the MTBE adsorption capacity of Ambersorb 563 relative to that obtained in ultrapure water. For the adsorption of an emerging contaminant mixture from lake water, Rossner and colleagues (2009) showed that a coconut shell based GAC produced higher removal percentages at a given dose than the carbonaceous resin Ambersorb 563. The activated carbon had a larger volume of pores in the size range of the targeted contaminants (~0.6–0.9 nm) than the carbonaceous resin, which likely explained the difference in adsorption uptakes.

Activated Carbon Fibers

Compared with GAC and PAC, activated carbon fibers (ACFs) have a relatively uniform and well-defined pore structure. Several research groups have investigated whether the adverse effects of NOM adsorption on micropollutant removal can be minimized through the use of ACFs (Pelekani and Snoeyink, 1999, 2000, 2001; Quinlivan et al., 2005; Karanfil et al., 2006). Pelekani and Snoeyink (1999) investigated the simultaneous adsorption of NOM and atrazine on two ACFs, one containing pores with widths of up to about 0.8 nm and one containing pores with widths of up to about 2 nm. Compared with the single-solute isotherm, atrazine adsorption was reduced by a factor of 10 on the ACF with the narrower pores. Pore blockage likely explained the reduction in atrazine adsorption in the presence of NOM. On the ACF with the larger pores, atrazine adsorption was reduced

by a factor of 3 compared with the single-solute isotherm, which was likely a result of direct competition between NOM and atrazine for adsorption sites. The data showed that pore blockage by NOM as a result of size exclusion more severely reduced the micropollutant capacity than direct competition between the micropollutant and NOM for adsorption sites.

Comparing different ACFs, Hopman and colleagues (1995) showed that NOM adsorption on one ACF was minimal. Furthermore, ACF that had been preloaded with NOM was able to adsorb the pesticide chlorotoluron ($C_0 = 2 \mu\text{g/L}$) from natural water to the same extent as fresh ACF. However, the authors did not state how long this ACF was preloaded, and no information about the physical and chemical characteristics of the ACF were given. To date, the results of Hopman and colleagues (1995) are unique in that the researchers were able to eliminate the adverse effects of NOM preloading on micropollutant removal from a natural water.

High-Silica Zeolites

Several studies have evaluated the use of high-silica zeolites for micropollutant removal from water (Ellis and Korth, 1993; Kawai et al., 1994; Knappe et al., 2007, 2010; Rossner and Knappe, 2008; Rossner et al., 2009). Because of their well-defined pore sizes, it may be possible to select high-silica zeolites that target the removal of specific micropollutants while minimizing access of interfering NOM constituents. For example, silicalite appears to be especially suitable for the adsorptive removal of MTBE and exhibits a larger MTBE adsorption capacity than activated carbons with a considerably larger BET surface area (Knappe et al., 2007). Furthermore, in a packed bed adsorber application, silicalite was immune to NOM preloading effects that markedly decreased the MTBE removal effectiveness of a GAC adsorber that was operated in parallel with the silicalite adsorber (Rossner and Knappe, 2008). In terms of material cost, high-silica zeolites (about \$7/lb and up) are more expensive than activated carbons (about \$1–2/lb). However, the results of Knappe and colleagues (2007) showed that the higher MTBE adsorption capacity of zeolites compared with activated carbon was sufficient to make up a large part of the cost difference. Apart from niche applications, in which the removal of a specific contaminant, such as MTBE, is targeted, high-silica zeolites cannot compete with the effectiveness of activated carbon. For example, high-silica zeolites with their uniform pores did not provide an effective broad-spectrum barrier against a mixture of 25 emerging contaminants (Rossner et al., 2009).

ASTM	American Society for Testing and Materials
AWWA	American Water Works Association
BAC	biological activated carbon
BET	Brunauer-Emmett-Teller
BPA	bisphenol A
BV	bed volume
CD	constant diffusivity
cNW	coagulated natural water

COD	chemical oxygen demand
CUR	carbon usage rate
DBP	disinfection by-product
DCBR	differential column batch reactor
DCP	dichlorophenol
DFT	density functional theory
DMP	dimethylphenol
DOC	dissolved organic carbon
DOM	dissolved organic matter
EBC	equivalent background compound
EBCT	empty bed contact time
EfOM	effluent organic matter
ESA	ethanesulfonic acid
FBR	floc blanket reactor
GAC	granular activated carbon
HAA	haloacetic acid
HSDM	homogeneous surface diffusion model
IAST	ideal adsorbed solution theory
ID	inside diameter
IUPAC	International Union of Pure and Applied Chemistry
LC	large scale
MCPB	4-(2-methyl-4-chlorophenoxy)butyric acid
MIB	2-methylisoborneol
MTBE	methyl <i>tert</i> -butyl ether
MTZ	mass transfer zone
NOM	natural organic matter
O&M	operation and maintenance
OA	oxoacetic acid
PAC	powdered activated carbon
PCB	polychlorinated biphenyl
PD	proportional diffusivity
PF	phenol/formaldehyde
PPCP	pharmaceutical and personal-care product
PTFE	polytetrafluoroethylene
RSSCT	rapid small-scale column test
SBA	short-bed adsorber
SC	small scale
SDVB	styrene-divinylbenzene
SOC	synthetic organic compound
SUVA	specific ultraviolet absorbance
TCE	trichloroethylene = trichloroethene
THM	trihalomethane
THMFP	trihalomethane formation potential
TOC	total organic carbon
TON	threshold odor number
TOX	total organic halogens
UF	ultrafiltration
UFC	uniform formation conditions
USEPA	U.S. Environmental Protection Agency
UVA	ultraviolet absorbance at a wavelength of 254 nm
VOC	volatile organic chemical

NOTATION FOR EQUATIONS

C	aqueous-phase concentration
C_0	initial or influent aqueous-phase concentration
C_B	breakthrough concentration
C_c	activated carbon dose
C_{eff}	effluent concentration
d	particle diameter
D_s	surface diffusion coefficient
f	fractional concentration
K	Freundlich isotherm constant
L_{MTZ}	length of mass transfer zone
n	Freundlich isotherm exponent
m	adsorbent mass
q	solid-phase concentration
R	particle radius
t	run time
V	volume
V_B	volume treated to breakthrough
Y	bed life
ρ_{GAC}	bed density
θ_n	number of bed volumes processed through each adsorber in a parallel system at the time of replacement

INTRODUCTION

Background

Since water demand for the growing world population is increasing rapidly, good quality water sources are becoming scarce, costs of water treatment are increasing, new contaminants are being found in water supply sources, and drinking water quality regulations are becoming more stringent; thus water utilities are looking for comprehensive water supply and treatment technologies to address these emerging challenges. It is well known from the hydrological cycle that the water quality of river or rainwater improves as it passes through the soil layer. Using this natural phenomenon, different natural treatment systems such as bank filtration, aquifer recharge and recovery, subsurface groundwater treatment, and soil aquifer treatment have been applied in many countries throughout the world to improve the quality of water from different sources in the process of drinking water production and, in some cases, wastewater reclamation/reuse. Natural systems have been in use for water and wastewater treatment from time immemorial. There is now renewed interest in these methods because natural treatment systems are robust and, if properly designed and operated, provide a comprehensive, sustainable treatment of multiple contaminants present in water sources.

Natural water treatment systems rely on natural phenomena comprising different physical, chemical, and biological removal mechanisms that take place during soil passage for the improvement in water quality. Furthermore, water treated using natural systems is reported to have relatively high biological stability, thus minimizing the potential of regrowth in the water distribution system. The suitability and performance of such natural treatment systems, however, depend on hydrogeological conditions, source water quality, process conditions applied, and water quality goals to be achieved by the treatment.

This chapter provides an overview of different soil passage-based natural treatment systems that can be applied as the main treatment or as pretreatment for drinking water treatment and wastewater reuse applications. Furthermore, it outlines water quality improvements from and design considerations for these natural treatment systems and finally presents some case studies.

Managed Aquifer Recharge (MAR) for Water Treatment and Wastewater Reuse

MAR is the infiltration or injection of a source water, such as river or lake water, treated wastewater, or urban stormwater, into an aquifer under controlled conditions with the intention of storage and/or treatment of the water. Water can be introduced into the aquifer by a number of methods, including infiltration via basins or galleries or by use of injection wells. The use of MAR has the potential to provide benefits for water resources and environmental management because it can augment quantity as well as improve the quality of water. There are different MAR systems designed to increase the quantity and improve the quality of water. MAR systems for water quality improvement or water treatment include:

1. Bank filtration (river or lake)
2. Artificial recharge and recovery (ARR)

3. Subsurface groundwater treatment
4. Soil aquifer treatment (SAT)

RIVER (RBF) AND LAKE (LBF) BANK FILTRATION

Bank filtration, as an engineered system for water treatment, has been employed dating back to the nineteenth century. During bank filtration, river or lake water is extracted indirectly by drawing it through the subsurface prior to use. Extraction is accomplished by an infiltration gallery or line of wells (horizontal, vertical, or at an angle) located at a short to intermediate distance from the bank of the river or lake. During extraction, the groundwater discharge into the river decreases, and the groundwater table near the waterline may decrease below the river water level. Consequently, surface water enters the aquifer and flows to the gallery or wells. While bank filtration systems generally are not operated to provide storage of surface water underground, they do provide water quality improvements during subsurface transport. To ensure a satisfactory purification, in terms of conventional parameters, of the surface water in the ground, the distance between the river/lake and the extraction well should be such that the travel time exceeds 30 to 60 days (Huisman and Olsthoorn, 1983).

Bank filtration is a traditional, efficient, and well-accepted method of surface water treatment in Europe. For more than 100 years, RBF has been used in Europe for public and industrial water supply along the Rhine, Elbe, and Danube rivers (Grisczek et al., 2002a). River and lake BF sites have been operated for over a century to provide drinking water to cities such as Zurich, Dusseldorf, and Berlin. In Dusseldorf, situated on the Rhine River, RBF has been practiced since 1870. Schubert (2002a) reported that the groundwater derived from infiltrating river water provides water supply in densely populated and industrialized regions: up to 50 percent of potable supplies in the Slovak Republic and 45 percent in Hungary. In the Netherlands, the first river bank filtrate was pumped for public drinking water supply around 1879 along the Rhine River at pumping station Nijmegen (KWR, 2004). About 15 percent of the drinking water in the Netherlands is produced from infiltration of surface water (dune and bank filtration) (Hiemstra et al., 2003). RBF systems also have been supplying drinking water to several communities in the United States for nearly half a century (Ray, 2008).

Nowadays, BF is of considerable interest because of its utility as a cost-effective treatment technology. BF enhances water quality by using the adsorption, biodegradation, and natural disinfection that occurs as surface/reclaimed water moves through geological media. Bank filtration is an excellent protection tool to dampen peak concentrations and shock loads resulting, for instance, from chemical spills or failures at industrial or municipal wastewater treatment plants (Schmidt et al., 2008). Underground passage reduces the effects of concentration peaks because of the varying distances covered by the water as it moves from the river/lake to the well. It also dampens temperature fluctuations. In the production well, the withdrawn water is a mixture of water that left the river/lake at different times within a large period. Well-operated BF facilities situated in favorable hydrogeological settings can provide relatively inexpensively high-quality water that needs minimal additional treatment (Grunheid et al., 2005). Because of its ability to reduce dissolved organic carbon (DOC), disinfection by-product (DBP) precursors, and microbiological contaminants such as *Giardia lamblia* and *Cryptosporidium parvum*, there is now increasing interest in RBF in the United States (Ray et al., 2002; Tufenkji et al., 2002; Weiss et al., 2003). The U.S. Environmental Protection Agency (USEPA) Long Term 2 Enhanced Surface Water Treatment (LT2) Rule provides 0.5 and 1.0 log removal credits for travel distances of 7.6 and 15.2 m (25 and 50 ft), respectively, in BF systems (USEPA, 2007).

Removal Mechanisms

Several mechanisms are responsible for improvement of water quality during river/lake BF. During infiltration and travel through the soil and aquifer sediments, surface water is subjected to a combination of physical, chemical, and biological processes such as (1) filtration, (2) solution precipitation, (3) ion exchange, (4) sorption and desorption, (5) complexation, (6) redox reactions, (7) microbial biodegradation, and (8) dilution that significantly improve water quality (Kuehn and Mueller, 2000; Hiscock and Grischek, 2002). Water quality improvements associated with BF include removal of organic matter, removal of suspended solids and odorous compounds, reduction in pathogens, and attenuation of shock loads of chemical contaminants. The top few centimeters of the bank materials act as a screen or filter medium to remove the suspended solids present in the water. Heavy metals, phosphorus, and hydrophobic organic compounds present in the water are removed by adsorption onto certain aquifer materials. In the presence of biomass, the organic matter is further biodegraded (initially under oxic conditions and later under anoxic conditions). The water quality is in most cases improved by dilution of the source surface water with native groundwater (i.e., mixing) if such groundwater is uncontaminated. A schematic of processes affecting water quality improvement during bank filtration is presented in Fig. 15-1. Table 15-1 compares BF with conventional above-ground treatment technology for removal of different contaminants.

Factors Affecting Performance of RBF/LBF Systems

The performance of RBF/LBF for water quality improvements depends on a number of variables: (1) river and lake water quality, (2) characteristic and composition of alluvial aquifer materials, (3) geochemistry, (4) filtration velocity and distance of the well(s) from the river or lake, (5) temperature of the water, (6) pumping rate, (7) soil and sediment characteristics at the river/lake-aquifer interface, and (8) groundwater dilution.

Hydrogeological Conditions. The effectiveness of BF for removing surface water contaminants depends largely on hydrological conditions, including well type and well location with respect to the source water, soil microbiology, characteristics of the bank material and

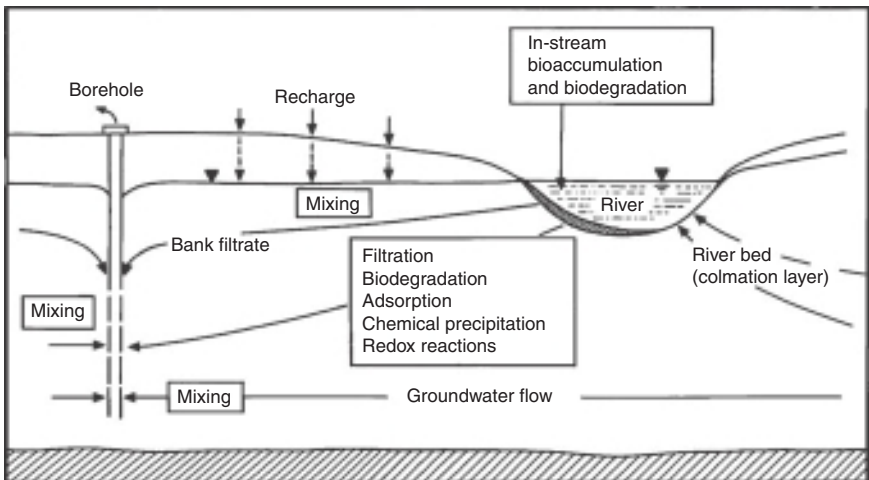

FIGURE 15-1 Schematic of processes affecting water quality during bank filtration. (Source: Hiscock, K. M., and Grischek, T. (2002). *Attenuation of groundwater pollution by bank filtration*. Journal of Hydrology 266(3-4), 139-144, with permission from Elsevier, Ltd., Oxford, UK.)

TABLE 15-1 Comparison of Bank Filtration and Conventional Treatment Technology

River water contaminant	Bank filtration	Engineering process (excluding biological)
Ammonia	Nitrification (aerobic)	Oxidation (chlorine), air stripping
Nitrate	Denitrification (anoxic)	Ion exchange, reverse osmosis
Particles	Filtration	Coagulation-flocculation/clarification/ filtration, membrane filtration
Microorganisms	Filtration, adsorption, decay (natural die-off)	Coagulation-flocculation/clarification/ filtration, disinfection, membrane filtration
Inorganic micropollutants	Adsorption, ion exchange, precipitation	Coagulation-flocculation, ion exchange, reverse osmosis
Organic micropollutants	Biodegradation, adsorption	Oxidation (ozone, AOP ^a), adsorption
Persistent micropollutants	None	Oxidation (ozone, AOP ^a), adsorption
Phosphorus	Adsorption, precipitation	Chemical precipitation

^aAOP = advanced oxidation processes.

streambed, and scouring characteristics (Sahoo et al., 2005). In many countries, alluvial aquifers hydraulically connected to a water course are preferred sites for drinking water production (Doussan et al., 1997). Such aquifers are relatively easy to exploit (shallow) and generally highly productive. Alluvium can consist of fluvial (river) deposits and lacustrine (lake) deposits ranging in thickness from a few meters to kilometers. Major deposits usually are found in the lower reaches of river basins forming flood plains.

The topographical relief is usually low, as are natural hydraulic gradients (slope of the groundwater level). The sediments range largely from highly permeable coarse gravel to low-permeable fine-grained silt. Groundwater levels are naturally shallow where the rivers are perennial but may be deeper in arid regions where river flow is intermittent.

The actual biogeochemical interactions that sustain the quality of the pumped bank filtrate depend on numerous factors, including aquifer mineralogy and the extent of the aquifer (Hiscock and Grischek, 2002). The geochemical context of river-aquifer transfers and their evolution thus is a reflection of interactions between biological and physiochemical mechanisms. In addition to influencing the chemistry, the bacterial activity may affect the hydrodynamic parameters of the porous medium (Doussan et al., 1997).

The extension of areas clogged by particulates and the permeability of clogged regions are influenced by river flow dynamics. Schubert (2002a) reported that the effect of clogging increases during flood events in the Rhine River owing to high concentrations of suspended solids and the high gradient between the river level and groundwater table. The interactions that concern the changes of permeability are governed by variations of the concentration of suspended solids in river water, hydraulic gradient from the river to the aquifer, and self-cleaning mechanisms by bed load transport.

In addition, small organisms have been observed seeking food along the silt deposits in the clogged areas. Such activities also influence the permeability of clogged areas through bioclogging, mainly during times of low hydraulic gradient between the river and aquifer. Clogging of river bed sediments can be both beneficial in terms of promoting the biodegradation of contaminants and also undesirable in reducing the hydraulic conductivity of the infiltration zone (Hiscock and Grischek, 2002).

Erosive conditions (i.e., scouring) in the river are advantageous because they limit the formation of a clogging layer. Floods also remove the clogging layer, which might be enriched with heavy metals and adsorbed organic compounds; however, some floods may have a negative effect if the production wells are located near the banks. Even if the wells are not flooded, the destruction of the clogging layer, changes in pore pressure, and higher

flow velocities in the aquifer can lead to an increased transport of dissolved compounds, previously adsorbed particles, bacteria, and viruses that potentially could result in contaminant breakthrough. In some settings, moderate floods may be useful in removing the clogging layer (Grischek et al., 2002).

The main hydrogeological factors that should be considered in design of MAR systems are (1) physical and hydraulic boundaries of the aquifer and degree of confinement, (2) hydrogeological properties of the aquifer and overlying formations, especially permeability, (3) hydraulic gradient of the aquifer, (4) depth to aquifer/piezometric surface, (5) groundwater quality, and (6) aquifer mineralogy.

Source Water Quality and Mixing with Native Groundwater. Source water quality is controlled by land use and climatic conditions, and during floods, rivers passing through agricultural watersheds often contain high concentration of farm chemicals. Contaminant concentration peaks often coincide with flow peaks. Ray and colleagues (2002b) observed that cyanazine and atrazine exceed their respective maximum contaminants levels (MCLs) and that elevated concentrations of pesticides and total organic carbon (TOC) occur during many flood occasions. While native groundwater may provide dilution if uncontaminated, landside groundwater may degrade water quality if, for example, contaminated by nitrate. Moreover, reductive dissolution under certain redox conditions may release iron and manganese into the recovered water.

Potential attraction of brackish groundwater from deeper strata is undesirable because of the high salt concentration of the pumped water. Attraction of an undesired quality of native groundwater may need extensive treatment owing to high hardness, iron, manganese, ammonium, nitrate, and/or sulfate.

Distance of the Wells from River Bank and Spacing of Wells. The distance of the production well from the river/lake affects the removal efficiency of contaminants as well as pumping rates. Thus wells located close to the water source generally will have higher capacity but relatively lower quality of bank filtrate. The spacing of wells also affects the drawdown and thus the pumping rates of the wells (Dillon et al., 2002). The retention times for BF sites in Europe are several weeks or even months, designed to eliminate biodegradable dissolved organic carbon (BDOC), pathogens, and degradable trace organic pollutants from the surface water to produce a biostable, high-quality water that can be distributed after little additional treatment without chlorine addition (Hiemstra et al., 2003). In contrast, U.S. practice generally reflects shorter travel distances and times, with more of a focus on *Cryptosporidium* removal.

Pumping Rates and Sediment Permeability. Pumping rates affect the drawdown in the wells and the ratio of the bank filtrate and native groundwater in the extracted water. Higher pumping rates also contribute to clogging of the river/lake bed. It is generally understood that the clogging of riverbed material in the vicinity of a well reduces infiltration rates and decreases the production yield from the well field. When this occurs, streambed infiltration areas extend significantly away from the production center of the well. This causes the water to travel for a longer distance, thus allowing the water to undergo geochemical and biological reactions. The growth of a bacterial biofilm may alter the porosity and permeability of the porous medium significantly, which might result in clogging of the river banks, especially at the river-sediment interface, where the bacterial activity is high (Doussan et al., 1997). However, the process is highly dynamic, with sloughing and degradation of biomass providing a generally steady state biomass profile.

Attributes and Limitations

The main attributes and limitations of BF systems are listed below (Ray et al., 2002a; KWR, 2004; IAH and IHP, 2005).

Attributes

1. BF is a sustainable natural treatment process, avoids or reduces the use of chemicals, and produces biologically stable water.
2. BF improves water quality by removing particles (turbidity and suspended solids), organic pollutants, microorganisms, heavy metals, and nitrogen.
3. BF dampens concentration peaks associated with spills in a river or lake.
4. BF dampens temperature fluctuations.
5. BF replaces or supports other treatment processes by providing a robust barrier for multiple contaminants and reduces the overall cost of water treatment.

Limitations

1. BF is site-specific and is feasible when local hydrogeological conditions, especially permeability, are favorable.
2. There can be leaching of the aquifer materials under reducing conditions (e.g., reductive dissolution when the redox shifts from oxic to anoxic), leading to increased concentrations of iron and manganese in extracted water.
3. One of the main problems is potential clogging of the river/lake bed owing to accumulation of suspended matter that is filtered out when river/lake water enters the aquifer, especially when the system is not sited and designed properly; complex processes in the clogging zone and subsequent aquifer are not fully understood.
4. BF and groundwater recharge may be only a limited barrier for certain contaminants such as persistent organic micropollutants.
5. Influences of surface water and operational conditions on water quality are poorly understood.
6. No methodology or tools are available to facilitate reliable transfer of successful experiences to other locations.
7. Quantitative prediction of the purification potential at a site is limited.

ARTIFICIAL RECHARGE AND RECOVERY (ARR)

ARR is an engineered system designed for intentional treatment, storage, and withdrawal of water in aquifers; storage depends on infiltration versus pumping rates. A schematic showing the main difference between bank filtration and infiltration (ARR) is presented in Fig. 15-2.

ARR methods are employed when the local geological conditions and/or water quality in the river/lake are not suitable for induced infiltration (BF) or when different source waters are available (e.g., stormwater). ARR can be employed without pretreatment of the source, or the source water can be treated to the required level (e.g., filtration) prior to recharge. Artificial recharge is also practiced to control seawater intrusion into coastal aquifers, control land subsidence caused by declining groundwater levels, maintain base flow in some streams, and raise water levels to reduce the cost of groundwater pumping. ARR systems are being used in a number of states in the United States to overcome seasonal imbalances in both potable and reclaimed water projects. The tremendous volumes of storage potentially available in ARR systems means that a greater percentage of the resource, be it raw water or reclaimed water, can be captured for beneficial use. Topper and colleagues (2004) reported that artificial recharge is being used in at least 32 states in the United States and at least 26 countries worldwide.

Artificial recharge can be accomplished by (1) surface spreading, (2) infiltration through the unsaturated zone (vadose zone injection wells), or (3) direct injection into groundwater.

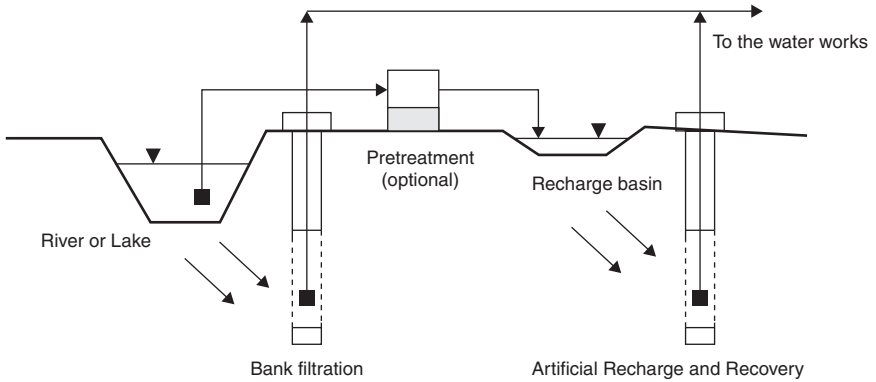

FIGURE 15-2 Schematic of bank filtration and infiltration. (Source: Adapted from with permission of AWWA, Kuehn, W., and Mueller, U. (2000). *Riverbank filtration: An overview*. *Journal AWWA* 92(12), 60–69.)

ARR systems are also further categorized as (1) aquifer storage and recovery (ASR), which involves injection of water into a well for storage and recovery from the same well, and (2) aquifer storage transfer and recovery (ASTR), which involves injection of water into a well for storage and recovery from a different well, generally to provide additional water treatment (Fig. 15-3). ASTR differs from ASR in that it is more applicable to confined aquifers

FIGURE 15-3 Schematic of aquifer storage and recovery (ASR) and aquifer storage transfer and recovery (ASTR). (Source: Dillon, P. (2005). *Future management of aquifer recharge*. *Hydrogeology Journal* 13(1), 313–316, with the permission from Springer, Germany.)

where infiltration is not feasible. Generally, surface infiltration systems can be used to recharge unconfined aquifers only, whereas confined aquifers can be recharged with wells that penetrate confining layers of the aquifer. Recharge by infiltration takes advantage of natural treatment processes as the water moves through the soil/aquifer and therefore is more attractive from a water quality improvement perspective, particularly in relation to the important role of the vadose zone. Furthermore, based on same degree of pretreatment, injection wells are much more vulnerable to clogging than surface infiltration systems because the infiltration rates around the boreholes or injection wells are much higher than in infiltration basins. Clogging is pronounced especially at the borehole interface between the gravel envelope and aquifer, where suspended solids can accumulate and bacterial growth tends to concentrate. A comparison of major engineering factors of three common artificial recharge systems is presented in Table 15-2.

Dune infiltration is a specific method of ARR practiced in coastal zones, in which the valleys between coastal sand dunes are flooded with water from rivers to infiltrate into the underlying sediments and create a recharge mound. The mound can play an important

TABLE 15-2 Comparison of Engineering Factors for Three Major Artificial Recharge and Recovery (ARR) Systems

	Recharge basins	Vadose zone injection wells	Direct injection wells
Aquifer type	Unconfined	Unconfined	Unconfined or confined
Pretreatment requirements	Low technology	Removal of solids	High technology
Estimated major capital costs (US\$)	Land and distribution system	\$25,000–75,000 per well	\$500,000–1,500,000 per well
Capacity	100–20,000 m ³ /ha/day	1000–3000 m ³ /day per well	2000–6000 m ³ /day per well
Maintenance requirements	Drying and scraping	Drying and disinfection	Disinfection and flow reversal
Estimated life cycle	>100 years	5–20 years	25–30 years

role in preventing saline intrusion as well as providing a source of water that is abstracted further inland. This technique has been used for centuries and is highly developed along the coast of the Netherlands, where rivers are the source of water for recharge (Hiemstra et al., 2003; IAH and IHP, 2005).

Recently, an innovative technology using a wick has been used for the artificial recharge of the treated effluent to groundwater. This technology is capable of recharging with a significantly smaller footprint than conventional methods of spreading basins. A *wick* is essentially a column, about 10 m deep and about 2 m in diameter, filled with medium (stone) that acts as a conduit to discharge water to the surrounding aquifer and groundwater. In terms of hydraulic loading/infiltration, a wick can be considered as intermediate between spreading basins and injection wells (Owen et al., 2008).

Infiltration Rates and Operation

The range of infiltration rates for in-channel and off-channel artificial recharge systems is about 0.3 to 3 m/day, including any effects caused by clogging. Systems with year-round recharge and periodic drying and cleaning of the bottom typically have hydraulic loading rates of about 30 to 300 m/yr. If the basin bottoms are not covered by sediment or other clogging material and groundwater levels are sufficiently low to not affect infiltration, infiltration rates are about the same as the vertical hydraulic conductivity of the soil, which may be about 0.3 m/day for sandy loams, 1 m/day for loamy sands, 5 m/day for fine sands, 10 m/day for coarser sands, and 20 to 50 m/day for fine or clean gravel. Sand and gravel mixtures have lower hydraulic conductivities than sand alone (Bouwer and Rice, 1984). To achieve optimal infiltration rates, a number of features need to be considered in the design process, including clogging, water depth, and groundwater level (Bouwer and Rice, 1984). In SAT, clogging is managed by alternating wet (infiltration) and dry (off-line) cycles. In the Netherlands, the residence times of infiltrated water underground ranges from 30 to 400 days (Tielemans, 2007).

Factors Affecting Performance of ARR Systems

Like BF systems, the performance of ARR systems for water quality improvements depend on a number of variables: (1) characteristic and composition of aquifer materials, (2) source

and quality of recharge water, (3) degree of pretreatment, (4) method and rates of infiltration, (5) temperature of the water, (6) type of ARR system (ASR or ASTR), and (7) pumping rate.

Attributes and Limitations

The main attributes and limitations of ARR systems are listed below.

Attributes

1. ARR systems can be used for seasonal storage of water in areas where water demands are significantly greater in summer than in winter, or vice versa. With these wells, drinking water treatment plants can be built to meet average rather than maximum daily demands.
2. Recharge water can be treated to the required degree to minimize clogging of the aquifer and to avoid contamination of the aquifer.
3. Infrastructure required for storage is small and cost-effective, and there are minimal water losses compared with, for example, evaporative losses in surface storage.
4. The quality of local groundwater can be improved by recharging with high-quality injected water. Recharge with less saline surface waters or treated effluents improves the quality of saline aquifers.

Limitations

1. Recharge rate may decrease with time owing to precipitation of calcium carbonate, iron oxides, and other compounds in the aquifer, long-term dissolution and collapse of calcareous soils, dispersion and swelling of clay, and air binding.
2. There can be leaching of the aquifer materials when the redox shifts from oxic to anoxic, leading to increased concentrations of iron and manganese in extracted water.
3. There is a potential for contamination of the groundwater by the recharge water if the quality control of the injected water is not adequate.
4. Excessive land area may be needed for spreading basins.
5. Not all recharged water may be recoverable owing to movement beyond the capture zone of the extraction well or mixing with poor-quality groundwater.

SUBSURFACE GROUNDWATER TREATMENT

Subsurface or in situ groundwater treatment involves infiltration of oxygen-rich water into a well and pumping of the groundwater from the same or a different well. This type of treatment is used to remove iron, manganese, ammonium, and arsenic from groundwater. These processes are known as the *vyredox* or *nitredox* methods (van Beek, 1983; Braester and Martinell, 1988; Rott et al., 2002). The method relies on the phenomenon that oxygen present in infiltration water will oxidize soluble iron in the groundwater and form layers of iron hydroxides on the media around the well, which subsequently act as adsorbent for Fe(II) and As(III)/As(V) present when groundwater is pumped from the same or a nearby well. The ratio of the quantity of extracted groundwater to the quantity of infiltrated oxygen-rich water (extraction versus infiltration ratio) is relatively high (it depends on the oxygen concentration of the infiltration water and the type and concentrations of the contaminants intended to be removed or avoided during this treatment process).

Iron oxidation and removal are based on the transformation of the soluble form of iron (Fe^{2+}) to an insoluble form (Fe^{3+}), as shown by the following stoichiometric equations. More extensive coverage of Fe oxidation is provided in Chap. 7.

Equation 15-1 shows that 0.14 mg of oxygen is required to oxidize 1 mg of Fe(II). The removal of Fe(II) by adsorption onto iron oxide surfaces and its subsequent oxidation in the presence of oxygen and regeneration of adsorption sites are given by the following equations:

where $\equiv \text{S}$ represents the adsorption surface (iron hydroxide) (Sharma, 2001).

From these equations, the amount of iron-free water that can be extracted from a given aquifer can be estimated. For example, if the iron concentration in groundwater is 5 mg/L and the oxygen concentration in the recharge water is 7 mg/L, the extraction ratio for iron-free water would be around 10, assuming that all oxygen in the recharge water would be used in oxidation of iron in the aquifer. These equations also show that for a given iron concentration in groundwater, the higher the concentration of oxygen in recharge water, the higher is the ratio of extracted iron-free water to recharge water. However, it should be noted that, in practice, this ratio is affected by flow velocities, reaction times, oxidation kinetics of the contaminant to be removed, oxygen heterogeneity of the aquifer, and other oxygen-consuming processes in the aquifer. Rott and colleagues (2002) reported that the ratio of the delivered water volume to infiltrated water volume (efficiency coefficient) ranges between 2 and 12 depending on the aquifer and raw water quality.

Many of the available methods for arsenic removal from water depend on the adsorption of arsenic onto oxides and oxyhydroxides of iron (see Chap. 12). Spent oxide adsorbents normally are not regenerated but are disposed of as stable wastes. Subsurface treatment for arsenic removal relies entirely on these same principles but accomplishes it in the subsurface as an in situ process. When iron is removed in the aquifer, arsenic is removed along with it. By creating renewable iron oxide filters in the aquifer surrounding a production well, arsenic levels in the delivered water are reduced to below the drinking water standard without creation of an arsenic-laden waste stream. Filters are renewed by in situ oxidation of ambient dissolved ferrous iron, which then forms iron oxide and oxyhydroxide-coated geomeia. Oxidation processes are both abiotic and biotically mediated. In aquifers where ambient iron concentrations are insufficient to bring about desired levels of arsenic removal, additional iron is introduced into the aquifer and then oxidized (Sarkar and Rahman, 2001; Miller, 2006; Rott et al., 1996; Rott and Friedle, 1999).

This method of groundwater treatment is attractive because there is no use of chemicals, and the production of sludge is avoided. However, there is potential for contamination of aquifers. Other limitations could be the clogging of the aquifer, excessive bacterial growth around the well, and corrosion of the well screen owing to high oxygen concentration in infiltration water (van Beek, 1983; Rott, 1985).

SOIL AQUIFER TREATMENT (SAT) FOR INDIRECT POTABLE REUSE

SAT is a managed aquifer recharge as well as wastewater treatment technology that, in combination with other available wastewater treatment technologies, can produce effluent of acceptable quality for indirect potable reuse. SAT is similar conceptually to ARR, and together they can be used for wastewater effluents, urban stormwater, or surface water. This technology uses physical, chemical, and biological processes in the soil matrix and aquifer for wastewater treatment. It is a low-cost and appropriate option for wastewater reclamation in developing countries as well as developed countries. It is also considered appropriate for replenishment of underground water to avoid exhaustion of groundwater resources and lowering of groundwater levels. Furthermore, artificial recharge of groundwater basins with SAT effluent contributes to the sustainability of surface water and groundwater resources within the context of integrated water resources management (Asano and Cotruvo, 2004; Rodriguez et al., 2009). A schematic of soil aquifer treatment system is presented in Fig. 15-4, and a comparison of typical SAT zones is presented in Table 15-3.

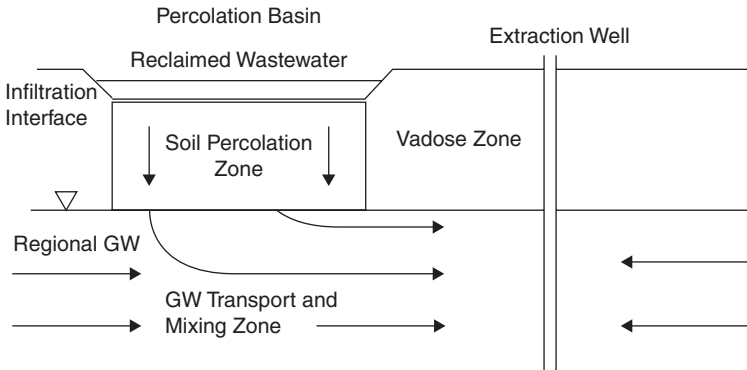

FIGURE 15-4 Schematic of soil aquifer treatment (SAT). (Source: Amy, G., and Drewes, J. (2007). *Soil aquifer treatment (SAT) as a natural and sustainable wastewater reclamation/reuse technology: Fate of wastewater effluent organic matter (EfOM) and trace organic compounds*. Environmental Monitoring and Assessment 129, 19–26, with permission from Springer, Germany.)

SAT has been practiced in different parts of the world using primary, secondary, and tertiary effluents from wastewater treatment (Fox et al., 2001; Nema et al., 2001). Furthermore, different pretreatment and posttreatment methods have been applied together with SAT to produce water quality suitable for the intended use. The principal design objective for SAT systems is additional wastewater treatment, beyond primary or secondary. Other design objectives can include (1) recharge of stream by interception of shallow groundwater, (2) recovery of water by wells or underdrains, with subsequent reuse, (3) groundwater recharge, and (4) temporary (seasonal) storage of renovated water in an aquifer (Crites et al., 2006). Furthermore, SAT also breaks the pipe-to-pipe connection involved in direct recycling of treated wastewater and serves as a natural psychological barrier that can help to promote public acceptance of (indirect) potable water reuse (Bouwer, 1993). SAT is relatively inexpensive, except in areas of high land costs. The biggest cost is pumping or otherwise collecting water from aquifers. SAT systems are also robust and do not require highly skilled technical personnel for operation (Bouwer, 1992).

TABLE 15-3 Comparison of Typical Soil Aquifer Treatment Zones

Process/parameter	Infiltration interface	Soil percolation	Groundwater transport
Treatment mechanisms	Filtration, biodegradation	Biodegradation, adsorption	Biodegradation, adsorption, dilution
Transport	Saturated	Unsaturated	Saturated
Residence time	Minutes	Hours to days	Months to years
Travel distance	Centimeters	3–30 m	Variable; 0 to several kms
Mixing	No	No	Yes
Oxygen supply	Recharge water	Unsaturated zone	Regional groundwater
Biodegradable carbon availability	Excess	Excess/limiting	Limiting
Redox conditions	Aerobic	Aerobic to anoxic (denitrifying)	Anoxic to anaerobic

Groundwater recharge with reclaimed wastewater is being used increasingly for replenishing aquifers used for municipal water supply. Indirect potable reuse based on groundwater recharge enjoys the following advantages over recycle based on discharge into surface waters (AwwaRF and AWWA, 2006):

1. Groundwater recharge provides additional water quality benefits because of SAT.
2. Seasonal and longer-term storage can be achieved without evaporative losses.
3. Groundwater recharge protects water against recontamination by birds and mammals (with coliforms and parasites) and possibly even by humans.
4. Groundwater recharge keeps sunlight away from water, thereby preventing growth of algae and associated water quality problems such as algae-derived tastes and odors and disinfection by-product formation; to avoid algal growth in a surface reservoir, the wastewater must be treated to remove nitrogen or phosphorus.
5. When reclaimed water is recovered from wells, it is conceived of as groundwater, an aesthetically superior and more publicly acceptable source.

Site selection is important to the success of a SAT system. The important factors in site evaluation and selection are (1) soil depth, (2) soil permeability, (3) depth to groundwater (depth of vadose zone), (4) aquifer thickness (depth from water table to bedrock/confining layer), and (5) groundwater flow direction and velocity. Depending on the local hydrogeological conditions and quality of the effluent available, SAT can be achieved using any of the three commonly employed recharge methods, namely, (1) recharge basins, (2) vadose zone injection well, or (3) direct injection well. The following factors should be considered in the design of SAT systems: (1) pretreatment requirements (degree of wastewater treatment, additional treatment), (2) infiltration (hydraulic loading) rate, (3) land requirement (taking into account wet/dry cycle), (4) number of wells (production capacity per well), (5) spacing between the wells, (6) distance of the wells from infiltration pond or injection well, (7) pumping rate (affects groundwater flow and velocity), (8) share of native groundwater in reclaimed water percentage, (9) water quality obtained from the SAT system, and (10) posttreatment requirements, if any.

Municipal wastewater effluent being recharged via infiltration basins usually is treated to secondary levels (biological treatment) and often chlorinated (in the United States) before being applied to infiltration ponds. The primary objective of water quality improvement is to remove all suspended solids and microorganisms. Removal of nitrogen species through nitrification/denitrification is also a key benefit, as is the reduction in concentration of dissolved

organic carbon (DOC) through biological processes. Phosphates and metals also can be removed but are retained in the soil by adsorption. In an indirect potable reuse system, the residual humic substances present in effluent organic matter (EfOM) impart color and serve as a precursor to disinfection by-products (DBPs) if extracted water is chlorinated on recovery, whereas the nitrogen-rich soluble microbial products (SMPs) present in EfOM represent a precursor to nitrogenous DBPs (N-DBPs). In addition to concerns about bulk EfOM, there are various effluent-derived trace organic compounds, including endocrine-disrupting compounds (EDCs), pharmaceutically active compounds (PhACs), and personal-care products (PCPs) that are present in secondary effluents. The presence of these organic micropollutants suggests their persistence through biological wastewater treatment processes (e.g., activated sludge) that embody short-term aerobic biodegradation (Amy and Drewes, 2007).

SAT Soil Requirements

Infiltration basins for SAT systems should be located in soils that are permeable enough to provide high infiltration rates. The soils, however, also should be fine enough to provide good filtration and quality improvement of the effluent as it infiltrates. The best surface soils for SAT systems are in the fine sand, loamy sand, and sandy loam range. Materials deeper in the vadose zone should be granular and preferably coarser than the surface soils. The vadose zones should not contain clay layers or other soils that could restrict the downward movement of water and form perched groundwater mounds (Pescod, 1992).

Hydraulic Loading and Operation

Infiltration basins in SAT systems are intermittently flooded to provide regular drying periods, for restoration of infiltration rates, and for aeration of the soil. This depends on pretreatment: Basins receiving highly treated water have longer flooding cycles. Flooding schedules typically vary from 8 hours dry to 16 hours flooding to 2 weeks dry to 2 weeks flooding. SAT systems therefore should have a number of basins so that some basins can be flooded while others are drying. The total annual infiltration amounts or hydraulic loading rates typically vary from 15 to 100 m/yr depending on soil, climate, quality of sewage effluent, and frequency of basin cleaning.

Intermittent application is critical to the successful operation of all land treatment systems. These drying periods are necessary to restore the infiltration capacity and to renew the biological and chemical treatment capability of soil system. The ratio of wetting to drying in successful SAT systems varies but is always less than 1.0. For those limited cases where primary effluent is used, the ratios generally are less than 0.2 to allow for adequate drying and removal of the applied solids. For secondary effluent, the ratio varies with the treatment objective from 0.1 or less where maximum hydraulic loading or only nitrification is the objective to 0.5 to 1.0 where nitrogen removal is the treatment objective. Typical hydraulic loading rates and wet/dry ratio of selected SAT systems in the United States are presented in Table 15-4. In general, operating conditions depend on a number of environmental factors, including temperature, precipitation, and solar incidence. Therefore, operating conditions must be adjusted to both local site characteristics and weather patterns (Crites et al., 2006; USEPA, 2006).

Water Depth

High hydraulic head produced by deep basin water result in high infiltration rates; however, they also tend to compress clogging layers. Contrary to intuitive expectations, deep basins

TABLE 15-4 Typical Hydraulic Loading Rates, Wet and Dry Periods, and Wet/Dry Ratios for Selected Soil Aquifer Treatment Systems in the United States

Location	Annual loading rate, m/yr	Type of effluent applied	Wet period, days	Dry period, days	Wet/dry ratio
Boulder, CO	30.3–48.5	Secondary	0.1	3	0.03
Ft. Devens, MA	28.8	Primary	2	14	0.14
Hollister, CA	15.2	Primary	1	14	0.07

can produce lower infiltration rates than shallow basins. The rate of turnover of the water in deep basins may be less than in shallow basins, allowing suspended algae to grow during longer exposure to sunlight. With deep basins (e.g., 10 m or more, as in old gravel pits), it can take a long time for all the water to infiltrate into the soil. Water actually may have to be pumped out of the basin to initiate drying. In addition to yielding higher infiltration rates, shallow basins (water depths about 0.5 m or less) have the advantage that drying can start quickly after the inflow of water into the basin has been stopped. In general, for artificial recharge of groundwater or SAT systems, the basin water depths preferably should be less than 0.3 m, and the basins should be hydraulically independent so that each can be flooded, dried, and cleaned according to its best schedule.

WATER QUALITY IMPROVEMENTS IN NATURAL TREATMENT SYSTEMS

In natural treatment systems, subsurface processes during soil passage improve the quality of the water. Results of several experimental and field studies have shown that water quality objectives can be met consistently for the longer term by natural treatment systems. The effects of natural treatment on some of the important water quality parameters are elaborated in the following paragraphs.

Particles and Turbidity

Suspended solids present in the source water used for BF, ARR, or SAT are usually relatively fine, and these solids accumulate at the interface of the water and soil layers. Particle transport in the aquifer is governed by movement of the groundwater coupled with retardation by attachment onto the surfaces and straining and trapping in interstitial pores. Except for medium and coarse uniform sands, soils are effective filters, and suspended solids are essentially completely removed from the water sources after about 1 m of percolation through the soil layer or vadose zone (Bouwer, 1985). Suspended solids typically are less than 2 mg/L in the extracted water as a result of filtration through the soil layer. Based on the studies at the RBF site at Louisville, Ky., Wang (2002) reported that although the turbidity of Ohio River water fluctuated significantly (from 3 to 599 ntu, with an mean of 45 ntu), the turbidity at the collector well remained consistently below 0.1 ntu. Furthermore, it was found that turbidity reduction increased with travel distance, with maximum reduction occurring in the first 0.6 m. In the case of an ARR system in the region of Marchfeld, Austria, the turbidity and suspended solids concentration of the recharge water decreased

from 9.9 ntu and 12 mg/L to 0.4 to 0.7 ntu and 1.0 mg/L, respectively, after soil passage (Neudorfer and Weyermayr, 2007).

In BF systems, fine materials present in river/lake water accumulate at the interface and reduce the infiltration rate, consequently causing clogging of the initial infiltration layer. Often these layers are scoured during high floods unless the penetration of the particles is deep in the soil layer. Similarly, infiltration basins for ARR and SAT require regular drying for infiltration recovery and periodic soil cleaning by raking or scraping. For loamy sands and sandy loams, few suspended solids will penetrate into the soil and then usually only for a short distance (a few centimeters, for example). In dune sands and other coarser soils, fine and colloidal suspended solids can penetrate much greater distances.

Microorganisms

Microorganisms may be removed from water during soil passage primarily by straining, inactivation, and attachment to the aquifer grains (in combination with inactivation). The number of infective enteric pathogens decreases with time and eventually decreases to near or below detection by natural processes. Temperature, humidity, pH, the amounts of organic matter in the soil and aquifer material, rainfall, sunlight, and competitive microorganisms all affect the survival of pathogens in water, soil, other unconsolidated material, and aquifer matrices (Schijven et al., 2002).

A summary of microbial removal data obtained from various field studies on riverbank filtration in the Netherlands is presented in Table 15-5. In principle, soil passage is an efficient

TABLE 15-5 Log Removals of Microorganisms During Bank Filtration

system for removal of microorganisms. Given sufficient flow path distance and time, microbial contaminants are removed or inactivated to levels protective of public health, minimizing risk levels. Under optimal conditions, BF can achieve up to 8 log virus removal over a distance of 30 m in about 25 days (Schijven et al., 2002). Greater removal efficiency may be expected for protozoa and algae (i.e., larger organisms) under the same conditions. Yao and colleagues (1971) stated that a minimum removal in filtration occurs for particles of about 1 μm , and thus one theoretically would expect slightly less removal for bacteria than for viruses (transport to surfaces with a higher diffusion rate than bacteria) during soil passage.

Bulk Natural Organic Matter

Natural systems are effective at removal of bulk natural organic matter (NOM). Adsorption and biodegradation are the dominant mechanisms for removal of organic matter during soil

passage. Aerobic, anoxic, and possibly anaerobic conditions promote biodegradation of organic carbon under different electron acceptors. Biodegradation is the primary sustainable removal mechanism for organic compounds during subsurface transport. The concentration of NOM and soluble microbial products (SMPs) that comprise the bulk of the dissolved and particulate organic carbon is reduced during soil passage because high-molecular-weight compounds are hydrolyzed to lower-molecular-weight compounds, and lower-molecular-weight compounds serve as substrates for microorganisms (NRC, 2008).

DOC removal is independent of the concentrations applied but depends on the concentrations of easily biodegradable organic carbon in the source water. It has been reported that during BF, there can be 50 to 90 percent reduction of biodegradable dissolved organic carbon (BDOC) and assimilable organic carbon (AOC), biodegradable portions of NOM, and 26 percent reduction in specific ultraviolet (UV) absorbance (SUVA) (see Chap. 3 for a discussion of SUVA) in UV-absorbing NOM (Weiss et al., 2004). Furthermore, BF can greatly reduce chlorine demand as well as trihalomethane formation potential (THMFP) and haloacetic acid formation potential (HAAFP) in river water; a 50 percent reduction in DBP formation potential was achieved for Ohio River water (Louisville, Ky.) that was abstracted 82 m from the river with a pumping rate ranging from 0.113 to 0.139 m³/s (Wang, 2002). Additionally, Lehtola and colleagues (2002) reported an average 53 percent removal of AOC along with 60 percent removal of overall TOC and 64 percent removal of microbially available phosphorus (MAP) during soil infiltration.

Trace Organic Contaminants

Removal of trace organic contaminants during soil passage is influenced mainly by their biodegradability and concentration level, redox conditions, adaptation of the biocommunity, travel time, and concentration of bulk organic matter present (to serve as a primary substrate/carbon source). BF and ARR reduce trace organics in water, including pesticides, personal-care products, endocrine-disrupting compounds, and pharmaceuticals to some extent (Massmann et al., 2006; Stuyfzand et al., 2007). Some micropollutants are more degradable under anoxic conditions than under aerobic conditions, and vice versa. Furthermore, the removal capacity of BF for organic micropollutants seems to be quite robust with regard to changes in surface water temperature and discharge (Schmidt et al., 2007).

Studies on trace organic contaminants removal during soil passage in the United States and Europe have revealed the occurrence of some pharmaceuticals, pesticides, and/or industrial chemicals in bank filtrate and treated water from recharge basins. The characteristics common to those compounds that are not attenuated are that they are hydrophilic (polar), and they have structural features that prevent enzymatic attack and render them resistant to biodegradation (Heberer, 2002; NRC, 2008). Compounds such as primidone, carbamazepine, and clofibric acid have been reported to be partly recalcitrant during underground passage. Polar organic molecules, such as complexing agents, pesticides, industrial products like aromatic sulfonates, pharmaceutical compounds, and personal-care products, are of recent concern (Schmidt et al., 2008). Under anoxic conditions, absorbable organic iodine (AOI) and x-ray contrast materials are decreased by bank filtration, whereby the AOI is decreased by 64 percent and the contrast material concentration can be reduced up to 95 percent depending on the compound present (Schittko et al., 2004). Table 15-6 summarizes the removal of some selected pharmaceuticals at the Lake Tegel bank filtration site in Berlin, Germany, which shows that depending on their log K_{ow} values (octanol water partition coefficient, an index of compound hydrophobicity), removal rates for different pharmaceuticals could range from low to very high. Log K_{ow} reflects both hydrophobicity affecting adsorption and compound complexity affecting biodegradation.

TABLE 15-6 Removal of Selected Pharmaceuticals at Lake Tegel Bank Filtration Site

Group	Compound (log K_{ow})	Surface water mean concentration (ng/L)	Mean removal at monitoring well 3303 ^a %
Low removal, 0%–50%	Primidone (0.91)	110	15%
	Propyphenazone (2.05)	190	35%
	Carbamazepine (1.58–2.45)	425	35%
Medium removal, 51%–90%	Clofibrac acid (1.58–2.45)	50	70%
	Diclofenac (1.13–1.90)	100	70%
High removal, >90%	Bezafibrate (4.2)	40	>97% (<LOD)
	Indometacine (4.27)	15	>95% (<LOD)

LOD = level of detection.

^aDistance of the well from Lake Tegel = 95 m (312 ft); Travel time = 3.9 months.

Nitrogen and Phosphorus

Significant biological nitrification and denitrification can occur during soil passage under aerobic and anoxic conditions. The major evolution of nitrogen species during river-to-groundwater transfer takes place in the first few meters of infiltration into the submerged riverbed sediments. This evolution depends on carbon mineralization and bacterial activity. Ammonium adsorption plays an important role in retaining ammonia in the soil long enough for biological conversion, especially at the start of system operations. In aerobic aquifers, ammonium is converted to nitrate by nitrification in the presence of oxygen. During soil passage, there may be a transition from anoxic (nitrate reduction) to anaerobic (iron and manganese reduction) conditions. In the case of SAT systems, during drying cycles, as the soil dries, air/oxygen enters the soil; consequently, oxidation of ammonia to nitrate by nitrifiers also may occur in the vadose zone. Once nitrate reaches deeper into the anoxic zone, heterotrophic denitrification converts nitrogen into nitrogen gas in the presence of organic carbon as an electron donor. Nitrogen removal is a function of detention time, carbon/nitrogen (C:N) ratio, and anoxic conditions. A C:N ratio greater than 3 is necessary to sustain high nitrogen removal efficiency (Fox et al., 2001). Primary effluent usually has a C:N ratio of 3 or higher, whereas for secondary effluent the ratio is about 1:1, and in river/lake water it could be lower. To overcome a low C:N ratio, a longer travel/detention time is required (Crites et al., 2006).

Phosphorus removal during soil passage is mainly by adsorption or chemical precipitation, which is controlled by the interaction of redox potential; pH; native iron, calcium, and aluminum minerals; and iron/phosphorus ratio (Rogers et al., 2005). In calcareous soils and at alkaline pH, phosphate precipitates with calcium to form calcium phosphate. In acid soils, phosphate reacts with iron and aluminum oxides in the soil to form insoluble compounds. Sometimes phosphate is immobilized initially by adsorption to the soil and then slowly reverts to insoluble forms, allowing more adsorption of mobile phosphate. In clean sands with near-neutral pH, phosphate can be relatively mobile (Bouwer, 1985). Ammonium removals of 25 to 98 percent and phosphorus removals of 4 to 84 percent during soil passage have been reported (Rice and Bouwer, 1984; Nema et al., 2001). Because nitrogen removal

is driven by biodegradation, it is sustainable; conversely, phosphorus removal is not truly sustainable because adsorption is the dominant mechanism.

Heavy Metals

Soils containing iron, aluminum, calcium, and magnesium have a high affinity for metal adsorption. Metal removal efficiencies vary with the constituent metal. Metals are significantly retained in most soils, but a high pH favors immobilization. Sontheimer (1980) found that heavy metal removal in the lower Rhine River exceeded 90 percent for chromium and arsenic and was greater than 50 percent for cadmium, zinc, lead, copper, and nickel. Heavy metal removal in SAT ranges from 50 to 90 percent. However, metals applied at low concentrations (below drinking water standards) may not be affected by soil passage (Crites et al., 2006). It is noted that longer-term metal removal in the soil layer is not sustainable because the soil minerals have limited adsorption capacities. Furthermore, under reducing conditions or from changes in pH, the already adsorbed metal may desorb or leach and reach deeper into the aquifer or ultimately appear in the extracted well water (Lin et al., 2004).

Comparison of Slow Sand Filtration, Bank Filtration, and Soil Aquifer Treatment

In general, BF and SAT can be considered as the extended version of slow sand filtration (SSF) because all of these systems have a *schmutzdecke*, where significant removals of microbes and BDOC can take place. BF and SAT, however, have higher removal efficiencies for different contaminants because they have considerable depth and a lower hydraulic loading rate (hence longer travel time) compared with SSF. Table 15-7 presents a comparative assessment of SSF, RBF, and SAT.

TABLE 15-7 Comparative Assessment of Slow Sand Filtration (SSF), Riverbank Filtration (RBF), and Soil Aquifer Treatment (SAT)

Aim	SSF	RBF	SAT
Depth/travel distance	1 m	10 m	>30 m
Residence time	>2 h (~0.1 day)	>10 days	>10 days
Hydraulic loading/infiltration rate	<0.5 m/h (<12 m/day)	<1 m/day	<1 m/day
Schmutzdecke/clogging layer	Yes	Yes	Yes
Flow regime	Saturated	Unsaturated and saturated	Unsaturated and saturated
Redox	Oxic (aerobic)	Oxic (aerobic) and anoxic	Oxic (aerobic) and anoxic
Turbidity	≤1 ntu	≤1 ntu	≤1 ntu
DOC removal	≥15%	≥50%	≥50%
Biostability: BDOC removal	50%	<LOD	<LOD
Trace organic contaminants removal	—	≥50% (except for few persistent PhACs)	≥50% (except for few persistent PhACs)
(Total) Nitrogen achievable	—	≤2 mg/L	≤2 mg/L
Microbial removal (viruses)	≥2 log	≥4 log	≥4 log

LOD = level of detection

DESIGN AND OPERATION OF NATURAL WATER TREATMENT SYSTEMS

The design and operation of natural water treatment systems depend mainly on (1) source water quality, (2) hydrogeological conditions at the site, (3) quantity of water to be abstracted, and (4) intended use of extracted water (water quality requirements). Design parameters for natural treatment systems include (1) number of wells (production capacity per well), (2) spacing between the wells, (3) distance of the wells from the bank, (4) share (percent) of river/lake water and native groundwater, (5) water quality obtained from the system, (6) post-treatment requirements, if any, and (7) capital and operation and maintenance (O&M) costs.

Type, Number, Spacing, and Distance of Production Wells

The numbers of production wells or gallery, their spacing and distance from the water source, and hydrogeological conditions have great impact on productivity. Generally, three types of wells have been used for BF: (1) horizontal collector wells, (2) vertical wells, and (3) angle wells. Horizontal wells have high production capacity; however, there can be more breakthrough of contaminants because the residence time is likely to be shorter. Compared with horizontal collector wells, vertical wells have relatively low production capacity but provide longer residence time. Angle wells are used when the depth/thickness of the aquifer is small (shallow aquifers). An angle well can help to increase the yield by lengthening the screen where water enters the well, potentially allowing more water to flow through the well (Williams, 2008).

The number of wells and their spacing influence the drawdown for a given production capacity. The total number of wells required for a given production capacity and given allowable drawdown in the well can be estimated using groundwater hydraulic models such as MODFLOW (USGS, 2008). The distance of the wells from the river/lake influences the travel time and the dilution ratio. In the Netherlands, the minimum recommended distance of a well from the bank is more than 20 m and preferably more than 100 m. The distance of the abstraction well from the surface water (bank) for 17 BF systems in The Netherlands ranges from 21 to 1500 m, with the resulting travel time ranging from 0.15 to 12 years (Hiemstra et al., 2003). The longer the distance of the wells from the river/lake, the smaller is the percentage of bank filtrate (more native groundwater) in the extracted water, and the longer the travel time, the better is the removal of the contaminants in the source water during soil passage. Therefore, there should be some compromise between the quality and quantity of extracted water by proper design and location of the wells.

The production wells have been constructed in clusters parallel to the bank, perpendicular to the bank, at a certain angle to the bank, or in parabolic configuration in order to optimize the quantity and quality of abstracted water. The best place for abstracting a large quantity of riverbank filtrate is on an island or within a meander, especially if the river has a steeper gradient than the groundwater in the connected aquifer and if the riverbed has high conductivity. The siting of BF schemes is an optimization task that needs a balance between the extracted volume of bank filtrate and the preservation of water quality owing to attenuation and the mixing process during BF (Grischek et al., 2006).

Hydraulic models such as MODFLOW (USGS, 2008) and the NASRI Bank Filtration Simulator (Holzbecher, 2006) can be used to estimate the ratio of bank filtrate and native groundwater in the extracted well water for a given design of the wells for a particular hydrogeological condition. The percentage of river/surface water in the bank filtrates in 17 systems in the Netherlands ranged from 20 to 98 percent, with an average of 63 percent (Hiemstra et al., 2003).

Hydraulic Loading Rates/Travel Time

Most BF sites in the world are located in alluvial sand and gravel aquifers having hydraulic conductivities greater than 10^{-4} m/s. The thickness of exploited aquifers ranges from 5 to 120 m. Different alignments of the abstraction wells with respect to river/lake are possible, which will influence (1) travel time and (2) the ratio of the bank filtrate and native groundwater in the water produced. At most sites in Europe, the distance between riverbank and production wells is more than 50 m, and travel times are more than 50 days. In the United States, the travel times are less than 50 days. This is so because in Europe BF is considered the primary treatment system, whereas in the United States it is considered a pretreatment system only. Table 15-8 summarizes the effects of RBF siting and management on water quality (Grisczek et al., 2006).

Surface infiltration systems require permeable soils and vadose zones to introduce the water into the ground and to the aquifer and unconfined and sufficiently transmissive aquifers to provide lateral flow away from the infiltration system without excessive groundwater mounding. Therefore, the hydraulic loading rate applied should match the hydraulic conductivity of the aquifer material. Basin infiltration tests and small-cylinder infiltrometers, double-ring (buffered) as well as single-ring systems, are useful for measurement and comparison of relative infiltration rates or hydraulic conductivity. However, it is noted that the hydraulic conductivity measurements can provide only a good estimate of maximum hydraulic loading rate attainable within the basins. Because of the decrease in infiltration rates with time owing to clogging and the need for regular drying and periodic cleaning of recharge basins or other surface infiltration systems, the actual hydraulic capacities (the amount of water applied per unit area in meters per year) therefore are much smaller than (only a few percent of) the infiltration rates (Bouwer, 2002; USEPA, 2006). Table 15-9 presents the suggested hydraulic rates for surface infiltration systems based on different field measurements.

Redox Conditions

Redox conditions in the aquifer significantly influence the water quality of the product water from natural treatment systems. The reader can find principles of oxidation-reduction chemistry in Chap. 3. Reducing conditions in the aquifer may cause the appearance of

TABLE 15-8 Effects of Design Parameters on Bank Filtration Efficiency

Aim	Long distance between bank and wells	Low abstraction along a line compared to high abstraction at a point	Siting of wells in a meander
Removal of suspended solids and particles	0	0	0
Removal of bacteria, viruses	++	+	0
Elimination of biodegradable compounds	+	+	0
Equilibration of temperature changes	++	+	0
Equilibration of changes in concentration of compounds in water	++	+	0
High proportion of bank filtrate in pumped raw water	--	0	++

+ = increase/improvement; - = decrease; 0 = no significant effect.

undesired metals such as iron, manganese, copper, cadmium, zinc, or lead in extracted water. Redox conditions also influence the behavior of a number of organic micropollutants, including pharmaceutically active compounds, halogenated organic compounds, pesticides, and disinfection by-products (Massmann, 2008). The redox conditions along the flow path are determined by the type and quantity of available degradable organic matter and the electron acceptors. Mainly, the oxygen concentration in the source water and the concentration of oxygen-consuming substances present in the water influence the redox conditions. If dissolved oxygen is removed during percolation through the vadose zone, anoxic conditions are likely to develop in the saturated zone because mechanisms for oxygen transport to the saturated zone are mostly due to natural aquifer recharge. Furthermore, mixing of the recharge water into the aquifer may create conditions that are not in thermodynamic equilibrium, consequently driving several redox reactions in the aquifer.

In BF systems, oxygen in the water depletes with the travel distance and ultimately may lead to iron and manganese reduction. For ARR systems, the oxygen concentrations in the aquifer can be increased by aeration and removal of oxygen-consuming contaminants during pretreatment; therefore, aerobic conditions could be more dominant. In SAT systems, a combination of aerobic conditions at the initial depth and anoxic conditions in the deeper layer is beneficial to facilitate organics removal and nitrification of ammonium in the upper layers, followed by denitrification in the subsequent layer. Furthermore, the existence of both aerobic and anoxic conditions in different zones also may favor the removal of specific micropollutants because the removal of trace organics is highly dependent on the redox conditions and concentration of bulk organic matter present (Massmann et al., 2006; Stuyfzand et al., 2007). In the case of ARR and SAT systems, intermittent application of the recharge water (wet/dry cycle) also helps to influence the redox conditions because oxygen can pass deeper in the soil layer during the dry period.

Redox conditions in the aquifer are also important for aquifer integrity in MAR systems. Changes in redox potential in an aquifer may have long-term consequences for aquifer integrity by either dissolution reactions (that dissolve the aquifer media) or precipitation reactions (that plug the aquifer) (NRC, 2008).

Clogging

Clogging of the banks and bottoms of the infiltration facilities is one of the main operational problems associated with natural treatment systems such as BF, ARR, and SAT. Depending on the type of system, clogging may be caused by physical (suspended solids, gas entrapment), chemical (precipitation), and biological (microbial growth) processes or combinations thereof. Furthermore, the suspended solids causing clogging of the banks and basin bottom can be inorganic (e.g., clays, silts, fine sands) or organic (e.g., algae, bacterial flocs, sludge particles, leaf litter).

Clogging is both a desirable and an undesirable process. Clogging may increase the removal efficiency of natural filtration because it is believed to have comparable characteristics to the

schmutzdecke in engineered slow sand filtration systems (see Chap. 10)—rich in organic matter with high concentrations of microorganisms. However, it may be detrimental because it leads to a decrease in hydraulic conductivity. The yield of the natural treatment systems therefore can be severely affected by clogging, which is a problem for the sustainability of the drinking water supply (Tufenkji et al., 2002; Schubert, 2004). Clogging rates increase with increasing infiltration rates because of the increased loading rates of suspended solids, nutrients, and organic carbon.

Clogging results in a reduction in the permeability and consequently lower infiltration rates. In the case of ARR and SAT systems, periodic removal of sediments (when the infiltration rate is reduced considerably) through scraping is necessary to restore the infiltration rate and to avoid fine material penetrating too deeply into the infiltration surface. Removing the material by raking or scraping is much better than mixing it with the soil. The latter practice leads to gradual accumulation of clogging materials in the top 10 to 20 cm of the soil, eventually necessitating complete removal of this layer, which can be expensive (Pescod, 1992; NRC, 1994). Furthermore, pretreatment of the source water (e.g., sedimentation, filtration, nutrient removal) considerably reduces the clogging of ARR and SAT systems.

In the case of a BF system, a clogging layer develops with time, thus reducing the infiltration rate. However, the flow and turbidity in rivers vary, and the clogging layer generally is scoured during periods of high floods. Experiences with RBF in the Netherlands indicate that there are serious risks of clogging in the case of a gravel river bed and on sites where sludge is strongly accumulating owing to structurally reduced river flows and hardly any such risks where the river bed is sandy and cleaned periodically by flood waves (Stuyfzand et al., 2004). Furthermore, proper location of intake structure and judicious design of screens and collection well (including type of well and abstraction rate) minimize the clogging effect. Clogging is more common among BF wells near the outer section of a bend. The yield of riverbank filtered water in the inner part of the bend is normally higher because of the movable ground of the riverbed, as well as the natural underground cross-flow owing to the river gradient (Schubert, 2002b).

Schubert (2006) suggested that reducing the pumping rate and in the long term maintaining adequate quality of river water may help to improve the situation in existing RBF plants with severe clogging problems. Based on their study of 11 RBF sites in the United States and Europe, Hubbs and colleagues. (2006) recommended that systems should be designed with the realization that a decline in the capacity in the first few years is possible. However, they suggested that the following measures can be taken to reduce the expected decline in yield:

1. Size the facility to minimize the impact of unsaturated conditions under the riverbed.
2. Design an extraction system that distributes infiltration stresses evenly along the riverbed.
3. Locate the facility to maximize the regenerative impacts of streambed scouring, with preference to locations with movable streambeds, avoiding areas of streambed armoring (areas with rocks or boulders deposited on the streambed and banks, either natural or man-made) and locations where very fine sediment is deposited.

SELECTED CASE STUDIES OF NATURAL TREATMENT SYSTEMS

Table 15-10 presents the salient features of some selected BF systems in the United States and Europe. Details of 17 different BF sites in the Netherlands are presented by Hiemstra and colleagues (2003). Furthermore, BF is now being used increasingly in Asia and Africa

TABLE 15-10 Selected Bank Filtration Systems in the United States and Europe

Site location	Well type (horizontal, H; vertical, V)	Number of wells	Design capacity of well field (m ³ /s)	River/lake system

(Ray, 2008; Shamukh and Abdel-Wahab, 2007). Short descriptions of a few selected natural treatment systems are presented in the following paragraphs.

Lake Bank Filtration: Berlin, Germany

About 75 percent of Berlin's drinking water is bank filtrate or artificially recharged groundwater. Lake Tegel, situated in the northwestern part of Berlin, Germany, has an area of about 4 km² and average and maximum depths of 7.9 and 16 m, respectively. The lake receives water from its two major tributaries, the Nordgraben and the Tegeler Fließ. This water is influenced by treated domestic wastewater effluent that constitutes about 15 to 40 percent by proportion (Grunheid et al., 2005; Pekdeger, 2006). The Lake Tegel bank filtration field site was established over 100 years ago. The waterworks at Tegel, one of the largest in Berlin, pumps about 50 million m³ per year from six well fields around the lake and from two on islands. Vertical wells are 30 to 60 m deep with a production capacity of 50 to 150 m³/h, and one horizontal well is 16 m deep with a production capacity up to 250 m³/h. The distance of the production wells from the bank ranges from 80 to 100 m. The travel time from the lake through the aquifer to various wells ranges from less than 0.5 to 3.2 months for shallow wells and 1.5 to 4.3 months for deep wells. The bank filtration system at Lake Tegel is characterized by highly transient well operation, whereby hydraulic head differences between lake and groundwater show strong temporal variations.

The DOC of lake water ranges from 6 to 8 mg/L and is reduced to 4.5 to 5.0 mg/L after bank filtration. The BDOC of lake water varies from 1.5 to 3.5 mg/L, with an average of 2.5 mg/L. There is almost complete mineralization of infiltrated BDOC. The nitrate concentration of the source water is reduced significantly during infiltration; however, there is dissolution of iron and manganese in the aquifer. The Fe^{2+} and Mn^{2+} concentrations in the bank filtrate range from 0.1 to 0.5 mg/L and from 0.3 to 0.6 mg/L, respectively. Furthermore, there is some increase in the calcium and bicarbonate concentration of the water owing to dissolution of CaCO_3 in the aquifer. The posttreatment of the bank filtrate before supply consists only of aeration followed by rapid sand filtration (for iron and manganese removal), with no chemical disinfection (Grunheid et al., 2005; Ameda, 2008).

Riverbank Filtration: Louisville, Ky.

The Louisville Water Company (Kentucky) has been using the alluvial aquifer along the Ohio River for water supply for many years. Based on extensive studies from 1940 to 1995, a full-scale RBF system of 0.88 m³/s (20 mgd) capacity was installed in 1999. The RBF facility is a horizontal collector well located on the bank of the Ohio River, about 30 m from the river. It is a 6.1 diameter caisson with seven horizontal laterals. The caisson is about 34 m deep from the ground level. The length of each lateral is 73 m for the four laterals oriented toward the river and 61 m for the remaining laterals. The laterals are 0.30 diameter stainless steel wire wound screens that are installed about 24 m below ground level (Wang, 2002; Hubbs et al., 2006). The average travel time is estimated to be 4 weeks (with a minimum of 2 days), and the percentage of river water in the bank filtrate is estimated to be around 78 percent.

The turbidity of bank filtrate was consistently less than 0.1 ntu. The TOC concentration of the river water ranged from 2.1 to 4.9 mg/L, with an average of 2.9 mg/L. The average DOC concentration was reduced to 2.1 mg/L after 2.75 m of filtration and was reduced further to 1.6 mg/L after some dilution from native groundwater. About 20 percent of the DOC in the river was biodegradable. The BDOC was reduced to less than 0.10 mg/L after 15 m of filtration. The average removals of total coliform and HPC were 3.8 log and 2.2 log, respectively (Wang, 2002).

The bank filtrate from the horizontal well undergoes conventional surface water treatment (coagulation, sedimentation, rapid sand filtration, and disinfection) before distribution. The Louisville Water Company is now expanding and improving the existing RBF facility. A RBF tunnel will extend from a location within the B. E. Payne Water Treatment Plant to the confluence of Harrods Creek and the Ohio River. The tunnel will be 2.41 km (1.5 mi) in length and 3 m (10 ft) in diameter, constructed in bed rock 45.7 m (150 ft) below the ground surface. The tunnel will convey RBF water to a new pump station, where it will be treated and supplied.

Riverbank Filtration: Düsseldorf, Germany

The City of Düsseldorf is situated in the northwest of Germany in the lower Rhine valley. The mean discharge of the Rhine River at Düsseldorf is 2200 m³/s, whereas the waterworks uses less than 2 m³/s (46 mgd). The width and dynamics of the Rhine River allow a sustainable application of RBF for drinking water supply. Riverbank filtration has been used as the first step for treating drinking water in the Düsseldorf waterworks since 1870. The raw water is abstracted from a quaternary aquifer with a proportion of 50 to 90 percent of bank filtrate. At present, 600,000 people are supplied with treated bank filtrate by four waterworks using vertical wells and horizontal collector wells. An average water demand of about 165,000 m³/day

(44 mgd) and a maximum demand of about 210,000 m³/day (55 mgd) are provided by this system. Depending on the hydraulic situation, the residence time of the bank filtrate in the aquifer varies from 1 week to several months. At the Flehe waterworks site, the production wells are situated at a distance of about 70 m from the riverbank. For the first 80 years of central drinking water supply in Düsseldorf, RBF alone without additional treatment (only disinfection) sufficed to provide safe drinking water (Schubert, 2002a; Eckert et al., 2006).

The concentration of suspended solids in the Rhine River varies between 10 and more than 400 mg/L, with a mean value of less than 40 mg/L. However, the raw water in the production wells is clear, with a turbidity of 0.05 ntu. The average DOC concentration in the well water varies between 1.0 and 1.2 mg/L. The mean reductions for total colony counts and *Escherichia coli* are 3 and 4 log, respectively (Schubert, 2002c).

The existing treatment plant, installed in 1967, consists of a combination of ozonation, biological filtration, and adsorption on granular activated carbon. This posttreatment system was introduced to remove iron, manganese, DOC, and taste and odor levels and meet drinking water quality requirements.

Riverbank Filtration and Artificial Recharge: Maribor, Slovenia

The City of Maribor, Slovenia, has been using bank filtration for control of water quality of local groundwater aquifers. Four wells of 0.075 m³/s (1.7 mgd) capacity each have been constructed on an island of the Drava River in Maribor to pump the bank filtrate. The island is under natural protection and at the same time represents a recreational area for the city. Some iron and manganese are present in the bank filtrate. This bank filtrate then is treated by applying sedimentation (lamella separators to remove fine sand), cascade aeration, and rapid sand filtration. The treatment plant also has facilities for ozonation, coagulation, and powdered activated carbon dosing for the removal of organic pollutants in bank filtrate, if any. However, at the present time, only lamella settlers, cascade aeration, and rapid filtration are in operation. In the rapid sand filters after cascade aeration, the iron and manganese generated by the bank filtration are eliminated.

The treated bank filtrate then is used for artificial recharge through three wells into the local groundwater aquifer to augment the existing 0.4 m³/s capacity of the aquifer and at the same time to protect the groundwater used for water supply against the endangering pollution from the city. Finally, groundwater is pumped from 13 wells located 300 m away from the recharge wells and supplied to the city after disinfection. Research is in progress to use and optimize the artificial recharge of the treated bank filtrate to achieve subsurface iron and manganese removal. Thus the water supply system in Maribor is a typical example of a combination of bank filtration and artificial recharge for water treatment and groundwater quality management (Rismal and Kopac, 2008).

Dune Infiltration: Leiduin, the Netherlands

The Leiduin water treatment plant is one of the two plants of Waternet (Amsterdam Water Supply Company) supplying water to the city of Amsterdam, The Netherlands. The raw water from Lekkanaal (a man-made side branch of the Rhine River) is pretreated at Nieuwegein and transported via three transport pipelines of 1200 to 1500 mm (about 4 to 5 ft) diameter for a distance of about 50 km (31 mi) to dune areas near the Leiduin water treatment plant. The total length of the transport pipe is 210 km (130 mi), and the total transport capacity is about 411,000 m³/day (110 mgd).

The standard pretreatment process employed at the Nieuwegein pretreatment plant is coagulation (with ferric chloride), sedimentation, rapid sand filtration, and pH correction

with caustic soda. The typical concentrations of suspended matter in raw water and pretreated water are 37.0 and 0.1 mg/L, respectively, whereas the corresponding DOC concentrations are 3.5 and 2.5 mg/L. After pretreatment, the water is transported to the nearby dune area for infiltration. The system consists of 40 infiltration ditches with a total length of 24.6 km (15 mi) and an average width of 35 m (115 ft). The water is transported to these ditches through open canals with a total length of 10 km (6.2 mi). The dune area used by Waternet is about 36 km² (14 mi²), of which 10 km² (4 mi²) is taken up by actual infiltration areas.

After the average residence time of about 100 days (ranging from 60–400 days), the infiltrated water is abstracted through drains and collected in an open basin. This ARR water then is further treated at the Leiduin water treatment plant by employing cascade aeration, rapid sand filtration, ozonation, pellet softening, two-stage biological activated carbon filtration, and slow sand filtration to achieve drinking water. No final disinfection is applied before supplying the water to the city of Amsterdam. The present production capacity is 192,000 m³/day (50 mgd) (van der Hoek, 2000; Tielemans, 2007).

Artificial Recharge: Graz, Austria

Artificial groundwater recharge has proved to be a sustainable solution for water supply for the City of Graz, Austria, for many decades. The first groundwater recharge system was operated in the 1920s, with the objective of increasing the capacity of the local groundwater aquifer. Later, with increasing pollution of the Mur River, infiltrating surface water threatened the quality of the local groundwater. The artificial recharge system then was redesigned to control the infiltration of polluted Mur River water into the aquifer. Later, in the 1980s, ARR systems were commissioned in Friesach and Andritz. The waterworks at Andritz maintains the quality of local groundwater using ARR and produces 21,600 to 27,600 m³/day (5.7–7.3 mgd), providing about 30 percent of the water demand of the City of Graz, with a population of 250,000. Raw surface water from Andritzbach catchments passes through sedimentation tanks, horizontal gravel filters, and cascade aeration before infiltration. Three different systems of lawn infiltration basins, sand basins, and infiltration trenches have been employed for artificial recharge. The sand basins and infiltration trenches operate continuously, while the lawn basins operate intermittently (10 days flooding and 20 days drying). The infiltrated water is later extracted from two horizontal collector wells [each 21.5 m (71 ft) deep with 26 laterals of length 20–30 m (66–98 ft)]. The underground passage ensures the high quality of the drinking water, which does not need any further treatment or disinfection before supply (Tischendorf, 2007).

Riverbank Filtration and Artificial Recharge: Aurora, Colo.

The City of Aurora, Colo., is currently constructing a \$754 million Prairie Waters Project as a sustainable water supply solution for the growing population of the city. The Prairie Waters Project is an example a multiple-barrier water treatment approach combining natural systems and conventional water treatment processes. The project uses an innovative natural purification process (combination of bank filtration and artificial recharge) to perform initial treatment of water from the South Platte River. The riverbank filtration along the South Platte River near Brighton extracts water from alluvium and removes nitrate, pathogens, and trace organic chemicals in about 10 days of travel time. Aquifer recharge and recovery then provides additional travel time for additional removal of nutrients and trace organic contaminants.

After the natural purification process, water will be piped 54.7 km (34 mi) south using a 1.5 m (60 in) pipeline to the Aurora Reservoir Water Purification Facility. The new treatment facility will use multiple treatment processes that include chemical softening

(to reduce hardness, iron, manganese, and scaling potential), advanced oxidation using ultraviolet (UV) light and hydrogen peroxide (to inactivate pathogens and oxidize remaining trace organics), rapid sand filtration (to remove remaining particles and pathogens), and activated carbon adsorption (to adsorb remaining trace organics and improve taste). Once completed, it will be one of the most advanced water treatment facilities in the United States and will be able to treat 190,000 m³/day (50 mgd) (Ingvaldstad, 2007).

Soil Aquifer Treatment: Dan Region, Israel

SAT has been practiced continuously on a large-scale in the Dan Region Project in Israel since 1977. It is the largest wastewater reclamation and reuse scheme in Israel and one of the largest in the world. About 330,000 m³/day (87 mgd) of effluent from the wastewater treatment plant of the Dan Region (Tel Aviv Metropolitan Area) are being recharged to the groundwater aquifer via spreading basins in four recharge zones built in areas of predominantly sandy soils—a northern recharge zone (Soreq) and three southern recharge zones (Yavne 1, 2, and 3). Each recharge zone consists of several recharge basins that are divided into sub-basins. The total area of the infiltration basins is 111 hectares (274 acres). The operation of the recharge basins is intermittent, that is, flooding for 1 to 2 days and drying for 2 to 4 days to maintain high infiltration rates through the upper soil layer and to allow oxygen to penetrate into the soil, thus enhancing and diversifying the soil purification capacity. The average hydraulic loading rate ranges between 0.3 and 0.6 m/day. The sites are mechanically ploughed approximately every 3 months to renew their percolation capacity. The average retention time within the aquifer is 3 to 12 months. An array of 78 recovery wells surrounds the spreading sites at a distance ranging from 500 to 1500 m (3000–4920 ft).

After SAT, the removal of total suspended solids and BOD is virtually complete, 100 percent and more than 98 percent, respectively. The average total suspended solids, BOD, and TOC of SAT effluent are less than 0.1 mg/L, less than 0.5 mg/L, and 2.4 mg/L, respectively. During SAT, complete nitrification and partial denitrification occur, which reduce the total nitrogen concentration from 22.8 to less than 2.1 to 8.76 mg/L. The reclaimed water pumped from recovery wells is conveyed to irrigation areas in the southern coastal plain and the northern Negev by a 120 km long (75 mi) pipeline (Kanarek and Michail, 1996; Ideolovitch et al., 2003).

ABBREVIATIONS

AOC	assimilable organic carbon
AOI	absorbable organic iodine
ARR	artificial recharge and recovery
ASR	aquifer storage and recovery
ASTR	aquifer storage transfer and recovery
BDOC	biodegradable dissolved organic carbon
BOD	biological oxygen demand
BF	bank filtration
C:N	carbon/nitrogen ratio
DBPs	disinfection by-products

DOC	dissolved organic carbon
EDCs	endocrine disrupting compounds
EfOM	effluent organic matter
HPC	heterotrophic plate count
LBF	lake bank filtration
MCLs	maximum contaminants levels
mgd	million gallons per day
NOM	natural organic matter
O&M	operation and maintenance
PCPs	personal-care products
PhACs	pharmaceutically active compounds
RBF	riverbank filtration
SAT	soil aquifer treatment
SMP	soluble microbial product
SSF	slow sand filtration
≡S	adsorption surface
TOC	total organic carbon
THMFP	trihalomethane formation potential

Indirect Potable Reuse Through Surface Water Augmentation	16.27		

INTRODUCTION TO POTABLE REUSE

With increasing demands on existing water supplies and limited access to new conventional water resources, some municipalities have begun to intentionally reuse treated municipal wastewater effluents to augment drinking water supplies. The practice of the purposeful addition of highly treated wastewater (i.e., reclaimed or recycled water) via an environmental buffer that is subsequently used to augment a drinking water supply is referred to as *planned or intentional indirect potable reuse* (IPR). Indirect potable reuse can occur through recharge of unconfined or confined aquifers, via surface spreading or direct injection, or by surface water augmentation into a stream or reservoir that serves as a source for drinking. In 2010, approximately 1,350 ML/d (355 mgd) of reclaimed water was used for IPR in the United States, which represents less than 1 percent of all municipal wastewater effluents generated in the country (Table 16-1). However, for municipalities practicing IPR, the contribution of reclaimed water to their drinking water supply can be as high as 30 percent, with some consumers receiving drinking water that originates by more than 50 percent from reclaimed water.

The immediate addition of reclaimed water to a drinking water distribution system is referred to as *direct potable reuse* (DPR). Since 1968, DPR has seen only one significant application worldwide with the commissioning of the direct potable reuse plant in Windhoek, Namibia (21 ML/d). In this case, advanced treated wastewater is fed directly into the distribution system providing up to 35 percent of the city's drinking water supply (du Pisani, 2006). Such direct use of reclaimed water for human consumption is currently not approved for any water system in the United States without the added protection provided by storage in an environment buffer (National Research Council, 1998). While planned IPR receives increasing interest among municipalities worldwide, questions remain regarding how much treatment and monitoring is needed to protect public health when reclaimed water is used for potable purposes. Water quality issues in IPR are associated with pathogens, organic chemicals, residual nutrients, and dissolved solids.

While the traditional maxim for selecting drinking water supplies has been to use the highest-quality source available (Pontius, 2003), in some regions once pristine surface water sources have evolved over time into unintentional indirect potable reuse systems, as wastewater from upstream dischargers has increased to substantial portions of the stream flow (Swayne et al., 1980; WEF/AWWA, 2008). Although planned and incidental or unplanned IPR systems may share similar water quality issues, this chapter provides guidance for systems that are *intentionally* designed and operated to augment drinking water supplies with reclaimed water.

Usually, a planned IPR scheme consists of the following six key components:

1. A *sewage collection system*, which incorporates discharge permits for industries, their monitoring and enforcement as required by USEPA regulations, and additional pollution prevention policies administered by the wastewater agency
2. A *conventional wastewater treatment* train, designed to minimize the presence of organic matter and pathogens, achieving a water quality that is suitable to be discharged to the environment meeting regulatory requirements as defined by the Clean Water Act (CWA)
3. *Advanced water treatment processes* which provide additional barriers to constituents of concern, such as residual organic chemicals, nutrients, dissolved solids, and pathogens
4. An *environmental buffer* or natural system integrated either via surface water or groundwater storage, to provide an opportunity to physically and chemically cut the connection to the source as well as offering time to respond to unforeseen process upsets
5. A *drinking water treatment* plant treating the augmented source water prior to delivery to consumers
6. An *overarching monitoring program*, that assures proper performance of conventional and advanced water treatment unit processes supplying a drinking water quality that is suitable for human consumption at all times

TABLE 16-1 Evolution of Indirect Potable Reuse Schemes and Employed Treatment Technologies

Project location	Type of indirect reuse	Project size ML/d (mgd)	First installation year	Current status	Treatment technologies				
					Suspended solids	Organic compounds	Residual nutrients	Residual salts	Pathogens
Montebello Forebay, County Sanitation Districts of Los Angeles County, CA	Groundwater recharge via soil-aquifer treatment	165 (44)	1962	Ongoing	Media filtration	Soil-aquifer treatment	Soil-aquifer treatment	None	Chlorination Soil-aquifer treatment
Upper Ocoquan Service Authority, VA	Surface water augmentation	204 (54)	1978	Ongoing	Lime clarification; media filtration	GAC filtration	Ion exchange (optional)	None	Chlorination

In the United States, IPR has been practiced for almost 50 years via surface water augmentation, soil treatment leading to groundwater augmentation, or direct injection into a potable aquifer. During this time especially during the last 15 years, IPR reuse schemes in the United States as well as worldwide evolved substantially regarding their capacity and the type and sequence of treatment processes employed (Table 16-1).

For projects favoring direct injection into a potable aquifer, use of *integrated membrane systems* (IMS) incorporating *microfiltration* (MF) or *ultrafiltration* (UF) followed by *reverse osmosis* (RO) have emerged as the industry standard. IPR schemes employing IMS are mostly located in coastal areas where concentrated waste streams (i.e., RO concentrates) may be conveniently discharged to the ocean. In the United States, Singapore, and Australia, utilities have favored IMS, in some cases coupled with subsequent *advanced oxidation processes* (AOP). For inland surface and groundwater augmentation projects, however, IMS are favored less due to the lack of waste stream disposal options. Instead, for these IPR applications various combinations of low-pressure membranes, granular activated carbon (GAC) adsorption/filtration, chemical oxidation (i.e., ozone, UV/AOP), and natural treatment processes have evolved. These practices underscore that multiple options exist for the design of IPR schemes that consider regional conditions but are unified in the goal to lower or eliminate the risk from constituents of concern. Given the nature of the source, public health concerns regarding IPR are foremost related to the presence of pathogens and trace organic chemicals in reclaimed water. Thus, IPR projects must integrate appropriate water treatment processes that are capable of providing effective, reliable, and redundant barriers to pathogens and trace organic chemicals. Fundamental to the design of IPR schemes is the concept of multiple barriers and an environmental buffer to ensure a drinking water quality that is fit for human consumption.

Although these technical components are important for any proposed IPR project, addressing the psychological dimension of IPR (i.e., “toilet to tap,” “yuck factor”) is essential for a successful project. In several cases over the last 15 years, this aspect of IPR evolved as the determining factor for success or failure of a project and outweighed the technical merit of some proposed projects resulting in their termination prior to completion (e.g., San Diego’s Water Recharge Project in 1998; Los Angeles Department of Water and Power’s East Valley Groundwater Recharge Project in 1998; Toowoomba’s Water Recycling Project, Australia, in 2006). From the early phase of a proposed project, communication with stakeholders and the general public is the key to success, building confidence that IPR is the best alternative to secure future water supplies and positioning the proposing utility as the trusted source of water quality (Ruetten et al., 2004).

In planning a successful IPR project, the following activities should be carefully considered: (1) source water characterization, (2) appropriate water treatment process selection, (3) quantitative relative risk assessment and development of a risk management strategy, (4) review of institutional and regulatory requirements, (5) communication with stakeholders and the public, and (6) assessment of capital and operational costs.

SOURCE WATER CHARACTERISTICS

Conventional wastewater treatment provides an effluent quality that, in the United States, is ultimately aimed at meeting the requirements of the Clean Water Act (CWA) and therefore in most cases is suitable to be discharged to surface waters. However, conventionally treated effluents remain composed of a wide range of naturally occurring and synthetic, trace organic and inorganic chemicals, residual nutrients, dissolved solids, and residual heavy metals, as well as pathogens. Thus, for potable reuse projects, compliance with established drinking water standards as promulgated by the Safe Drinking Water Act (SDWA) by

conventionally treated and reclaimed wastewater does not imply that the reclaimed water is safe for human consumption. In some states and depending on the designated use, surface discharge requirements under the CWA can be more stringent than compliance with SDWA drinking water standards. For example, the state of California's Toxics Rule requires more stringent THM standards (i.e., 5 µg/L instead of 80 µg/L as set by the SDWA) for a reservoir augmentation project discharging to surface water that is designated as a municipal drinking water supply. Thus, for an IPR project a thorough assessment of the source water quality is required that includes a wider range of microbial and chemical constituents than those required by current drinking water standards. Since general water quality characteristics of reclaimed water deviate from those of conventional drinking water sources, water treatment processes employed in IPR schemes must be capable of mitigating and eliminating these differences. Water produced in IPR schemes using advanced treatment processes sometimes requires restabilization to reduce the corrosive nature of the water, which may subsequently lead to deteriorating water quality. The three key elements to maintaining water quality for an IPR system are source control, attenuation of contaminants of concern through tailored treatment, and posttreatment stabilization.

Source Control

Source control is an USEPA regulatory management practice undertaken to minimize the discharge of some pollutants into the sewer. In many cases, wastewater agencies administer additional pollution prevention policies. These programs are conducted with the goal of reducing treatment costs, targeting chemicals of concern that are not primarily removed during conventional wastewater treatment (i.e., heavy metals, trace organic chemicals), and improving the reliability of final water quality. The approach is analogous to watershed management that may normally be exercised for conventional drinking water catchments (e.g., USEPA's Long Term 2 Enhanced Surface Water Treatment Rule; see Chap. 1). Accordingly, effective source control practices require the development and execution of a sewer discharge management plan. Monitoring and compliance assessments of point discharges to the sewer system are the first line of defense in IPR schemes representing the initial component of a multiple-barrier approach.

Contaminants of Concern

Contaminants of concern encompass a wide variety of pathogenic microbial organisms and chemical contaminants, which may be present in conventionally treated municipal effluents. Their presence is generally considered to be of concern due to their potential deleterious impacts on human health.

Pathogens. The control of pathogenic organisms is fundamental to the protection of public health for all potable water supplies as presented in Chap. 2. However, in the case of IPR, where municipal wastewaters make up a major component of source waters, the presence of significant initial concentrations of pathogens can generally be assumed. The diversity and concentrations of pathogens in treated wastewater effluents is highly variable and dependent on numerous locally specific factors. These factors include the patterns of infection within the community and the type of secondary and tertiary as well as disinfection processes employed at the wastewater treatment plant. In terms of their ability to contaminate drinking water supplies and their infectivity, the most significant human pathogens in reclaimed water include a range of bacteria, viruses, and protozoa as summarized in Table 16-2.

TABLE 16-2 Examples of Pathogens Occurring in Reclaimed Water

Pathogen type	Examples	Illness
Bacteria	<i>Salmonella</i>	Gastroenteritis, reactive arthritis
	<i>Campylobacter</i>	Gastroenteritis, Guillain-Barré syndrome
	Pathogenic <i>Escherichia coli</i>	Gastroenteritis, hemolytic uremic syndrome
	<i>Shigella</i>	Dysentery
	<i>Yersinia</i>	Gastroenteritis, septicemia
	<i>Vibrio cholerae</i>	Cholera
	Atypical <i>Mycobacteria</i>	Respiratory illness (hypersensitivity pneumonitis)
	<i>Legionella</i> spp	Respiratory illness (pneumonia, Pontiac fever)
	<i>Staphylococcus aureus</i>	Skin, eye, ear infections, septicemia
	<i>Pseudomonas aeruginosa</i>	Skin, eye, ear infections
Viruses	Enterovirus	Gastroenteritis, respiratory illness, nervous disorders, myocarditis
	Adenovirus	Gastroenteritis, respiratory illness, eye infections
	Rotavirus	Gastroenteritis
	Norovirus	Gastroenteritis
	Hepatitis A	Infectious hepatitis
	Calicivirus	Gastroenteritis
	Astrovirus	Gastroenteritis
	Coronavirus	Gastroenteritis
Protozoa	<i>Cryptosporidium</i>	Gastroenteritis
	<i>Giardia</i>	Gastroenteritis
	<i>Entamoeba histolytica</i>	Amoebic dysentery
Helminths	<i>Taenia</i> (<i>T. saginata</i> , <i>T. solium</i>)	Tapeworm (beef measles), neurocysticercosis
	<i>Ascaris</i>	Roundworm
	<i>Trichuris</i>	Whipworm
	<i>Ancylostoma</i>	Hookworm

Waterborne bacteria, such as *Campylobacter*, *Shigella*, and *Salmonella*, are important human pathogens as described in Chap. 2. However, these species are relatively susceptible to chemical disinfection practices (e.g., chlorination and chloramination; see Chap. 17) and thus can be effectively controlled by wastewater reclamation processes. Accordingly, bacteria are not a primary concern or driver to the implementation of advanced treatment processes in IPR schemes.

Viruses are widely recognized as the microorganisms representing the most significant risks to public health from IPR projects. Although they are generally susceptible to inactivation by chlorine disinfection, their high particle numbers in municipal wastewaters (Costan-Longares et al., 2008) and high infectivity require careful management to maintain adequate disinfection. Viruses responsible for numerous human illnesses, including gastroenteritis and hepatitis A, are known to be commonly present in municipal wastewater effluents. Effective monitoring presents an additional challenge to virus control since few laboratories possess the necessary expertise for proper analysis.

The enteric protozoan parasites *Cryptosporidium* and *Giardia* are notorious agents of waterborne disease and are commonly associated with reported outbreaks (see Chap. 2). *Cryptosporidium* in particular is reported to have been the cause of illnesses (and sometimes deaths) from drinking water supplies with full conventional treatment (coagulation

and flocculation, granular media filtration, and chlorine disinfection), usually under challenging or erroneous circumstances as reviewed by Hrudey and Hrudey (2007). In water, protozoa may produce cysts or oocysts that aid in their survival. As a result, some of these organisms, including *Cryptosporidium*, are highly resistant to chlorine disinfection and must generally be controlled by other means, such as ozone oxidation, membrane filtration, soil-aquifer treatment, or riverbank filtration.

Data regarding the reported occurrence of specific pathogens in reclaimed water is limited and more commonly, so-called indicator organisms are analyzed as surrogate measures for microbial water quality (see the discussion in the next section, System Reliability and Health Risk Considerations, and Chap. 2). A study undertaken at three water reclamation plants in Spain reported the occurrence of the pathogens cytopathogenic enteroviruses and viable *Cryptosporidium* oocysts along with a range of potential indicator organisms including total coliforms, *E. coli*, enterococci, spores of sulphite-reducing clostridia, somatic coliphages, RNA F-specific phages, phages that infect *B. fragilis* strain RYC2056, and phages that infect *B. thetaiotaomicron* strain GA-17 (Costan-Longares et al., 2008). The detection limit in both secondary and tertiary effluents was 1 CFU/100 mL for all measured parameters. All three of the tested facilities employed biological nutrient removal for secondary treatment. Tertiary treatment steps including disinfection were variable—Facility 1: coagulation/flocculation → sand filters → UV light → chlorine (5 ppm, 45 min); Facility 2: settling ponds → oxidation ponds → constructed wetlands; Facility 3A: coagulation/flocculation → sedimentation → multilayer filtration → UV, chlorine (0.3 ppm, 1 min); Facility 3B: coagulation/flocculation → sedimentation → multilayer filtration → chlorine (18 ppm, 90 min). Geometric mean densities of pathogens and indicator organisms, expressed as log (base 10) units, after secondary (prior to disinfection) and tertiary (after disinfection) treatment are illustrated in Fig. 16-1. Mean log reductions observed in this study for pathogens and microbial indicators during tertiary treatment are illustrated in Fig. 16-2. Although tertiary treatment processes were efficient in inactivating microbial indicators, these processes did not provide a pathogen-free water. Therefore, additional barriers for pathogens are needed in IPR applications.

Total Dissolved Solids. Domestic and commercial uses of public water supplies result in an increase of the mineral content in municipal wastewater. In some areas, the use of water softeners may be the major source of an increase in *total dissolved solids* (TDS). The increase in TDS in municipal wastewater effluents results in concentrations that are approximately 150 to 350 mg/L higher than the original potable water supplies (Asano et al., 2007). In a study reported by Drewes and Fox (2001), contributions of major ions in reclaimed water through human activities resulted in an average increase of 75 mg/L sodium, 45 mg/L sulfate, and 75 mg/L chloride, with small changes in hardness and minor ions.

In order to mitigate salinity problems associated with local water reuse activities, especially in inland applications, partial desalination of reclaimed water in IPR schemes may be required. For this reason, groundwater recharge schemes in Orange County, California, incorporated RO to reduce the concentration of dissolved solids to meet the groundwater basin objective for dissolved solids, which was equivalent to the USEPA drinking water secondary standard of 500 mg/L (USEPA, 1991).

Nutrients. Treated municipal effluents may contain numerous forms of nutrients that, if uncontrolled, may lead to excessive eutrophication of drinking water reservoirs in surface water augmentation projects. The most significant growth-limiting nutrients are most commonly nitrogen and phosphorus; however, other important micronutrients include potassium, calcium, magnesium, and sulfur. The risk of eutrophication can be managed by reducing the concentration of phosphorus and nitrogenous compounds through various treatment processes.

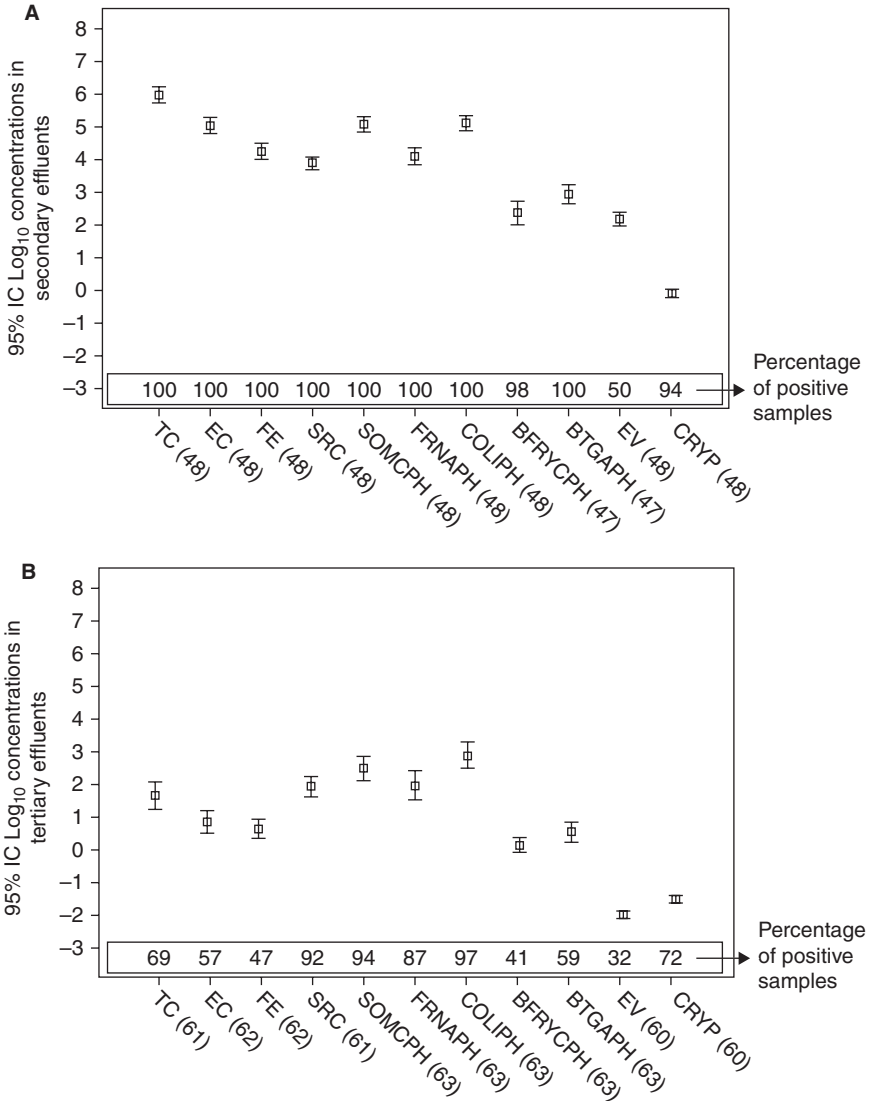

FIGURE 16-1 Microorganism concentrations (mean values and 95 percent confidence levels) in secondary (prior to disinfection) (a) and tertiary effluents (after disinfection) (b). In brackets is the number of analysis performed for every parameter. Indicator microorganisms' concentrations are expressed in PFU/100 mL and pathogens concentrations in PFU/1L. In reclaimed water, nitrogen (N) may be present in both ionic and non-ionic forms. The speciation and concentrations will depend on pH, redox conditions, and the efficiency of any BNR process deployed at the wastewater treatment plant. Cationic nitrogenous compounds include ammonium (in equilibrium with ammonia) and amines; anionic forms include nitrite, nitrate, and amino acids. A well-operated *biological nutrient removal* (BNR) process would be expected to produce an effluent with negligible amounts of ammonia, less than 5 mg/L of nitrate and nitrite and less than 1 mg/L of organic N (Table 16-3).

TABLE 16-3 Biological Nutrient Removal (BNR) Treatment Processes and Common Concentration Ranges of Nutrients in Reclaimed Water

BNR treatment processes	Range of NH_4 concentration (mg N/L)	Range of NO_3 concentration (mg N/L)	Range of dissolved organic nitrogen (DON) concentration (mg N/L)	Range of $\text{PO}_4^{3-} - \text{P}$ concentration (mg P/L)	References
Not nitrifying	15–45	0.1–5	0.3–1.7	1–8	Sedlak, 1991 Krasner et al., 2008
Partially nitrifying	0.1–10	5–20	0.3–1.3	0.4–8	Sedlak, 1991 Krasner et al., 2008
Nitrifying/denitrifying	<0.1–2	0.5–8	0.2–0.7	0.4–8	Sedlak, 1991 Krasner et al., 2008
Chemical P-removal	<0.1–10	5–20	0.3–1.3	<0.3–1.5	Sedlak, 1991 Krasner et al., 2008
Biological P-removal	<0.1–2	0.5–8	0.2–0.7	<0.1–0.6	Sedlak, 1991 Krasner et al., 2008

Advanced treatment processes that achieve additional nitrogen reduction are membrane separation (e.g., RO, nanofiltration (NF), and electrodialysis), ion-exchange processes, and biologically active filters.

Phosphorus (P) is present in reclaimed water predominantly as organic P and inorganic orthophosphate. Phosphorus may be partially removed biologically in the anaerobic zone of a BNR process. Residual orthophosphate may be removed in the treatment plant by precipitation and filtration using ferric or aluminum salts. Typical phosphorus concentrations in a BNR effluent designed for both nitrogen and phosphorus removal are in the 0.5 to 2.0 mg/L P range, decreasing to <0.3 mg/L if media filters are used (Table 16-3) (Sedlak, 1991).

Dissolved Organic Chemicals. The overall load of organic chemicals in water can be quantified in terms of the *total organic carbon* (TOC) concentration. Dissolved organic chemicals are described after 0.45 μm microfiltration as *dissolved organic carbon* (DOC) concentration. DOC in municipal wastewater effluents is composed of natural organic matter (originating from drinking water), soluble microbial products (generated during the activated sludge process), and small concentrations of a very large number of individual organic chemical contaminants (Namkung and Rittman, 1986; Drewes and Fox, 2000). These contaminants include industrial and domestic chemicals (e.g., pesticides, personal care products, preservatives, surfactants, flame retardants, perfluorochemicals, nanoparticles; see Chap. 2 regarding health effects and Chap. 3 regarding their presence in source waters), and chemicals excreted by humans (e.g., pharmaceutical residues, steroidal hormones), as well as chemicals formed during wastewater and drinking water treatment processes (e.g., disinfection by-products; see Chap. 19). Some representative examples of trace organic chemicals that may be present in treated municipal effluents are summarized in Table 16-4. Chemical contaminants may be present in reclaimed source waters or may be formed as by-products or metabolites via chemical or biological transformation during wastewater collection and treatment. Many of these chemicals may have an adverse effect on human health if present in sufficient quantities and not effectively removed during treatment (see Chap. 2). Potential chronic adverse health effects include carcinogenic, toxicologic, embryonic, and reproductive development impacts caused by interference with the endocrine system.

Anionic surfactants are used in commercial and domestic detergent products. Applications include dishwashing and clothes-washing detergents as well as hair shampoos. Linear alkylbenzene sulphonates (LAS) are the most common. Anionic surfactants are often present in high concentrations in raw wastewater (1–20 mg/L). However, conventional wastewater treatment is effective at eliminating these compounds resulting in much lower concentrations in final effluents. Drewes et al. (2009) studied the fate of LAS in six full-scale wastewater treatment plants and reported average concentrations in raw sewage of almost 6 mg/L that were reduced to approximately 4 $\mu\text{g/L}$ in treated effluents.

Depending on the service area and the extent of the source control program to minimize discharge of chemicals at the source, a wide range of synthetic industrial chemicals are often measurable in influents to a water reclamation plant. Examples include plasticizers and heat stabilizers, biocides, epoxy resins, bleaching chemicals and by-products, solvents, degreasers, dyes, chelating agents, polymers, polyaromatic hydrocarbons, polychlorinated biphenyls, and phthalates. Many of these chemicals are known to be toxic to a diverse range of organisms including humans. Biological processes, however, can significantly reduce these contaminants in reclaimed water to levels usually below drinking water maximum contaminant levels (Trenholm et al., 2008).

Volatile organic compounds (VOCs) are widely used as industrial solvents. Many are constituents of petrochemical products, and a number of halogenated compounds may be formed as by-products of chlorine disinfection. Some VOCs are suspected to be teratogenic or carcinogenic to humans. Because of their high potential to contaminate traditional

TABLE 16-4 Examples of Trace Organic Chemicals That May be Present in Reclaimed Water

Category	Representative examples		
Organic chemicals			
Surfactants	Alkane ethoxy sulphonates (AES)	Linear alkylbenzene sulphonates (LAS)	Secondary alkanesulphonates
Industrial products and by-products	Acrylamide	Dichlorobenzenes	Phthalates
	Alkyl phenols	Ethylenediaminetetraacetic acid (EDTA)	Polyaromatic hydrocarbons
	Alkyltin compounds	Epichlorohydrin	Polychlorinated biphenyls
	Bisphenol A	Hexachloro-butadiene	Styrene
	Chlorinated dioxins	Nitrilotriacetic acid	Trichlorobenzenes
	Chlorobenzene	Perfluorooctanoic acid (PFOA)	Vinyl chloride monomer
Volatile organics		Perfluorooctane sulfonate (PFOS)	
	Benzene	Ethylbenzene	Trichloroethene
	Carbon tetrachloride	Tetrachloroethene	Xylenes
	Dichloroethanes	Toluene	
Pesticides or their metabolites	Dichloromethane	1,1,1-trichloroethane	
	2,4-D	Chlorpyrifos	Heptachlor and epoxide
	Aldicarb	Diazinon	Lindane
	Aldrin/dieldrin	Dichloro-diphenyltrichloroethane (DDT)	Organic mercurials
	Atrazine	Diuron	Pyrethroids
	Chlordane	Endosulfan	Other insecticides, fungicides and herbicides
Algal toxins	Cylindrospermopsin	Nodularin	Saxitoxins
Disinfection by-products	Microcystins		
	Chloral hydrate	Cyanogen	Haloketones
	Chlorate	Formaldehyde	Monochloramine
	Chlorine dioxide	Haloacetic acids	Nitrosamines

Inorganic chemicals			
Nanoparticles	Carbon 60	TiO ₂	NiO ₂

potable water sources and supplies, they are tightly regulated in drinking waters. Many of them are environmentally conservative, so careful control is particularly important for planned IPR schemes.

Pesticides may enter municipal wastewater systems by a variety of means including stormwater influx and illegal direct disposal to sewage systems. Additional routes, of unknown significance, include washing fruit and vegetables prior to household consumption, insect repellents washed from human skin, flea-rinse shampoos for pets, and washing clothes and equipment used for applying pesticides outdoors. Pesticides have been designed and used to have detrimental effects on a wide range of biological species.

Algal toxins, such as microcystins, nodularins, cylindrospermopsin, and saxitoxins, are all produced by freshwater cyanobacteria (blue-green algae) (Leflaive and Ten-Hage, 2007; Funari and Testai, 2008; Schmidt et al., 2008). Many of these toxins are hepatotoxic and some are neurotoxic. Under suitable conditions, cyanobacteria may grow in untreated or partially treated wastewaters, producing these and other toxins (Barrington and Ghadouani, 2008; Furtado et al., 2009). Numerous algal toxins have been identified as having serious impacts on human and animal health after consumption of contaminated water.

Pharmaceuticals (and their active metabolites) are excreted to sewage by humans as well as direct disposal of unused drugs by households (Shon et al., 2006; Daughton and Ruhoy, 2009). Since pharmaceuticals are designed to instigate biological responses, their inherent biological activity and the diverse range of compounds identified in reclaimed water (and the environment) have been cause for considerable concern during the last decade (Drewes and Shore, 2001; Ternes and Joss, 2006). Specific concerns have not been raised for most classes of drugs, but issues regarding potent endocrine disrupting compounds, aquatic toxicity, and the spread of antibacterial resistance could have significant ecological implications.

Natural steroidal hormones, such as estradiol, estrone, and testosterone, are excreted to wastewater by mammals. During the last two decades, natural steroidal hormones have been linked to a range of endocrinological abnormalities in aquatic species impacted by wastewater effluents (Jobling and Tyler, 2003; Sumpter and Johnson, 2008). Snyder et al. (2008) conducted a comprehensive survey of finished drinking water qualities from 20 different sites in the United States and only three finished water samples exhibited estrogenicity above the method detection limit varying between 0.19 and 0.77 ng/L estradiol equivalents. These impaired finished waters were compared to common dietary items (e.g., beer, soy milk, soy baby formula) that without exception contained far greater estrogenicity than the drinking water samples. Beside these low detects, the authors concluded that there was no evidence of human health risk from consumption of these waters.

Antiseptics, such as triclosan, are commonly used in face washes and anti-gum-disease toothpaste as well as for a wider range of household products including deodorants, antiperspirants, detergents, dishwashing liquids, cosmetics and antimicrobial creams, lotions, and hand soaps. Triclosan has been frequently detected in wastewater effluents (Heidler and Halden, 2008; Trenholm et al., 2008).

Perfluorochemicals (PFCs) and their chemical precursors have been commonly used in many consumer products as discussed in Chap. 2. The recent detection of high levels of PFCs at some sites in the United States has led the USEPA to issue provisional health advisory values for *perfluorooctanoic acid* (PFOA) and *perfluorooctane sulfonate* (PFOS) (USEPA, 2009). These values of 0.4 and 0.2 µg/L for PFOA and PFOS, respectively, were issued out of concern that land-application of biosolids may have leached PFCs into groundwater. PFOS and PFOA have been detected in finished drinking waters in Japan, Spain, and Germany at levels up to 0.6 µg/L (Skutlarek et al., 2006; Takagi et al., 2008; Ericson et al., 2008), though little peer-reviewed data are available for finished U.S. drinking water. Concentrations of 90 to 470 ng/L PFCs have been reported in tertiary treated municipal effluents in California, predominantly PFOA (10–190 ng/L) and PFOS (20–190 ng/L) (Plumlee et al., 2008). Snyder et al. (2010) compared PFC occurrence of source water

samples from five different drinking water sites with secondary- and tertiary-treated effluents used at two IPR sites. In this study, the authors report PFOA concentrations varying between nondetect and 36 ng/L for raw drinking water and 15 to 28 ng/L for secondary- and tertiary-treated effluents and PFOS concentrations varying from nondetect to 23 ng/L in raw drinking water and 11 ng/L to 90 ng/L in secondary- and tertiary-treated effluents, respectively. Although, the relatively low affinity of PFCs for environmental solids (Higgins and Luthy, 2006) implies a potential for contamination of groundwater resources through reclaimed water used for irrigation or intentional groundwater recharge efforts, PFC concentrations observed in reclaimed water used for these applications were low and comparable to conventional drinking water supplies using surface waters (Snyder et al., 2010); this suggests a rather low potential for groundwater contamination.

Identification of all organic chemicals present in reclaimed water at a molecular level is neither possible nor practical. Although recent studies attempting to correlate exposure of single trace organic compounds via drinking water to their human health effects suggest no appreciable risk (Schwab et al., 2005; Snyder et al., 2008), these studies are limited to a few individual compounds and fewer data are available for mixtures of compounds. Presented with this uncertainty, the general approach in designing and regulating IPR projects is to ensure that the proposed treatment train includes one or several dedicated processes to significantly reduce the overall concentration of TOC. The technologies used to reduce the TOC content in IPR projects include soil-aquifer treatment and riverbank filtration, high-pressure membranes (RO and NF), granular or powdered activated carbon, biologically activated carbon, ozone, and AOP.

Disinfection By-Products. *Disinfection by-products* (DBPs) are formed by reactions between disinfection agents and other constituents of water; this topic is comprehensively discussed in Chap. 19. However, there are some DBPs that are of particular relevance to IPR applications due to the nature of the highly complex source water and/or the type of water treatment processes employed. High initial concentrations of organic components may lead to excessive production of certain DBPs in the absence of high ammonia concentrations. Similarly, the presence of ammonia in some source waters may lead to the formation of nitrogen-containing DBPs. The vast majority of the compounds of concern originate from chlorine-based disinfectants. Accordingly, excessive formation of well-known DBPs, such as trihalomethanes (THMs) and haloacetic acids (HAAs), must be carefully monitored and controlled. DBPs produced in reclaimed water from five wastewater treatment plants in Southern California employing secondary biological treatment, nitrification (with denitrification at three plants), filtration, and chlorine disinfection exhibited THM levels in the chlorinated effluent of 35 to 86 $\mu\text{g/L}$, whereas the levels of HAAs were 99 to 262 $\mu\text{g/L}$ (Krasner et al., 2008). Three other classes of DBPs exhibited relatively high concentrations: aldehydes (21–114 $\mu\text{g/L}$), chloral hydrate (44–76 $\mu\text{g/L}$), and haloacetonitriles (HAN) (14–33 $\mu\text{g/L}$) (Krasner et al., 2008).

Ozone treatment (ozonation) of reclaimed water may result in the formation of several groups of DBPs including bromate and carbonyl compounds, such as aldehydes. Bromate is a suspected human carcinogen, and some aldehydes including formaldehyde and acetaldehyde have been classified as probable human carcinogens by the USEPA. Advanced oxidation processes utilize the transient formation of hydroxyl radicals to degrade carbon-carbon and other chemical bonds. The range of by-products formed is a function of the nature of the organic matter present and the relative susceptibility of specific bonds for radical attack. Accordingly, a large number of unidentified low-molecular-weight products is expected to be formed during advanced oxidation of complex solutions.

Ammonia can occur in wastewater effluents, either as a result of incomplete nitrification or by controlled addition for chloramination. The presence of ammonia and suitable organic precursors can lead to the production of N-nitrosamines, such as *N-nitrosodimethylamine* (NDMA) and *N-nitrosodiethylamine* (NDEA). Some N-nitrosamines, including NDMA

and NDEA, have been classified as probable human carcinogens. The USEPA has added six of the nine N-nitrosamines, known to occur in reclaimed water, to the unregulated list of drinking water priority contaminants for ongoing monitoring and risk assessment (USEPA, 2007). The California Department of Public Health (CDPH) has set notification levels of 10 ng/L for NDMA and NDEA in drinking water. For reclaimed water used for ground-water recharge, rather than defining concentration limits, CDPH has established performance criteria in terms of achieving a minimum of 1.2 log NDMA and 0.5 log 1,4-dioxane reduction through AOP whether NDMA or 1,4-dioxane are present or not (CDPH, 2008).

Dissolved Inorganic Chemicals. Heavy metals may be present in reclaimed water as a result of municipal and industrial discharges to sewers (Rule et al., 2006; Gasperi et al., 2008a; Gasperi et al., 2008b). Some heavy metals such as cadmium, chromium, and mercury have been associated with human health concerns. However, the occurrence of these contaminants is usually low due to effective source control programs. They are also predominantly adsorbed to wastewater particulates and biosolids (Carletti et al., 2008; Gasperi et al., 2008a) and, as a result, tend to be effectively removed during activated sludge processes (Carletti et al., 2008).

Suspended Solids/Particulate Matter. Suspended solids and other particulate matter include colloidal material, fine particles, and microorganisms, such as protozoan cysts and oocysts, bacteria, and viruses. Removing suspended solids improves the performance and efficiency of downstream processes used to provide additional disinfection and remove organic compounds and dissolved salts. Prior to the early 1990s, conventional water treatment processes, similar to those used in drinking water treatment plants, were used in many IPR projects to reduce the concentration of suspended solids. The treatment steps consisted of flash mixing and flocculation followed by clarification and granular media filtration through sand and/or anthracite. The use of an additional clarifier provided sufficient buffering capacity and treatment residence time to deal with the temporal variations in feed water suspended solids levels. This technology combination was embodied in the Californian Water Recycling Criteria requirements (State of California, 2000) and the Australian-New South Wales Guidelines for Urban and Residential Use of Reclaimed Water (NSW Recycled Water Coordination Committee, 1993).

By the late 1990s, filtration with low-pressure membranes (i.e., MF, UF) had become the preferred technology to control suspended solids in some IPR projects. Membranes require less space, use less energy, and do not generate a solid sludge; this collectively reduces the cost of reclamation significantly (Leslie et al., 1998). In the United States, low-pressure membranes for municipal applications were first used to treat secondary effluent at Orange County's Water Factory 21 in the late 1980s. Subsequent performance tests at this facility demonstrated that the levels of microorganisms, suspended solids, turbidity, and silt density index (SDI) in the filtered water were a factor of 3 lower than conventional processes (Leslie et al., 1999).

Posttreatment Stabilization

The final treatment step in IPR schemes provides, where needed, stabilization of the finished water quality by restoring alkalinity, hardness, and pH as required. The purpose of this stabilization is to reduce the aggressive or corrosive nature of the water toward materials used in treatment plants, conveyance, and storage systems (e.g., concrete, steel or copper, soil). The techniques to stabilize the water include pH correction with caustic or acidic solutions and restoration of alkalinity and mineral hardness through the addition of lime (Withers, 2005).

SYSTEM RELIABILITY AND HEALTH RISK CONSIDERATIONS

Considering the quality of the source, any IPR scheme needs to be designed to reliably supply a finished water quality that is safe for human consumption at all times. System reliability of a reuse project is defined as the probability of adequate performance for a specified period of time under predefined conditions. Several factors affect system reliability: (1) the variability of wastewater characteristics, (2) the inherent variability of biological treatment processes, (3) the inherent variability of advanced water treatment processes, (4) the reliability of mechanical plant components, and (5) the effectiveness of monitoring (Asano et al., 2007).

System reliability requirements may include standby power supplies, readily available replacement equipment, online monitoring of system performance and water quality, redundant process components that are critical for the protection of public health, flexible piping and pumping configurations, and emergency storage or disposal options.

Whether a particular reuse system is able to reliably produce and deliver drinking water that meets health targets can be evaluated through risk assessment. Thus, IPR projects must include an evaluation of the potential health risks and hazards that could compromise the delivery of safe drinking water that is derived from reclaimed water. Health concerns in IPR are primarily related to the insufficient removal of pathogens and trace organic chemicals present in reclaimed water. Although a number of comprehensive studies have been conducted to address the concern about potential health risks of unknown and unidentified chemicals in reclaimed water (Nellor et al., 1984; Lauer and Rogers, 1996; Sloss et al., 1996), there is currently no definitive measure of risk or safety for the use of reclaimed water to augment drinking water supplies.

Treatment Goals from a Health Perspective

The Safe Drinking Water Act gives the USEPA the authority to set drinking water standards (see Chap. 1). In doing so, the USEPA considers a range of factors in determining these standards for specific drinking water contaminants as described in Chaps. 1 and 2. The water quality of any potable reuse project using reclaimed water in the United States has to meet the drinking water standards as promulgated by the USEPA.

Established maximum contaminant level goals (MCLGs) and maximum contaminant levels (MCLs) are generally limited to traditional drinking water contaminants, known to occur in conventional water sources such as surface waters and groundwaters, and DBPs, known to be formed during disinfection of such water sources. These include a range of pesticides and industrial chemicals, but not chemicals that are associated with discharges from municipal wastewater effluents, such as pharmaceutical residues, personal care products, household chemicals, steroidal hormones, or emerging DBPs. Thus, considering the origin of reclaimed water, meeting current drinking water standards does not imply the finished water is fit for human consumption. Although some states have proposed additional water quality requirements for potable reuse, the design of IPR treatment schemes in general should consider processes that are capable of attenuating compounds that are currently unregulated or unidentified. Treatment goals for these compounds for a proposed IPR scheme might consider their toxicological relevance if this information is readily available (Schwab et al., 2005; Snyder et al., 2008) or occurrence levels in current or less impacted drinking water supplies (Benotti et al., 2009; Snyder et al., 2010).

Safe drinking water concentrations of many of these chemicals may potentially be derived on the basis of the same toxicological considerations used for the establishment of current MCLGs and MCLs (as described in Chap. 2). For example, acceptable daily intakes

(ADIs) have been developed for 26 active pharmaceutical ingredients on the basis of various end points from which an appropriate *point of departure* (POD) was determined for the calculation (Schwab et al. 2005). The POD for determining an ADI is commonly the “no observed adverse effects level” (NOAEL) for a given toxic end point. However, for many ADIs, the POD is the lowest dose resulting in an observable effect level (LOEL). Schwab et al. (2005) stated that for pharmaceutical substances, the therapeutic effect usually occurs at a dose considerably below those expected to result in toxicity, and thus a large proportion of the ADIs that they calculated were based on therapeutic effects or minor side effects, such as sensitivity to human intestinal microflora. However, others have reported that for some pharmaceuticals, the most toxic end point is not the therapeutic end point, but rather it is a side effect, such as carcinogenicity (Snyder, 2008).

In response to uncertainties associated with risk posed by these compounds in IPR applications, some scientists and regulators support the adoption of treatment technologies to minimize exposure of humans and aquatic ecosystems (for reservoir augmentation) to wastewater derived chemical contaminants until more data on potential risks are collected. This approach is common practice in the absence of a reliable method that is economically and technically feasible to measure a contaminant at particularly low concentrations. In these cases the USEPA sets treatment techniques for drinking water rather than an MCL. A treatment technique is an enforceable procedure or level of technological performance, which public water systems must follow to ensure control of a contaminant.

Other international agencies have adopted the concept of a ‘tolerable level of risk’ to assist in setting water quality guidelines or standards. In such cases, health targets are adopted to reflect an accepted tolerable risk level, which could be expressed in a variety of ways including

1. Tolerable risk of infection by a pathogen from drinking water
2. Tolerable increased cancer risk by exposure to carcinogens in water
3. Tolerable amount of disease burden

Health-based targets are used by the World Health Organization (WHO) to assess disease burdens and underpin the development of water safety plans. For chemicals that are known or suspected to cause cancer, the acceptable lifetime exposure is defined in the WHO “Guidelines for Drinking Water Quality” as that which will result in one excess cancer case per 100,000 people (World Health Organization, 2004).

For pathogenic organisms, the WHO has adopted the concept of *disability-adjusted life years* (DALYs) to derive water quality targets (World Health Organization, 2004). DALYs are used to objectively compare water-related hazards and the different health outcomes with which they are associated. The basic principle is to weight each health effect for its severity from 0 (normal health) to 1 (death). This weight is multiplied by the duration of the effect, which is defined as the time in which the disease is apparent. When the outcome is death, the duration is the remaining life expectancy. The product is then multiplied by the number of people affected by a particular outcome. It is then possible to sum the effects of all the possible outcomes due to a particular hazard. Accordingly, the DALY is the sum of years of life lost by premature death and years of healthy life lost in states of less than full health (i.e., years lived with a disability, which are standardized by means of severity weightings). WHO has defined a tolerable level of risk of 1 millionth of a DALY (one microDALY) per person-year (World Health Organization, 2004). This is equivalent to the loss of one DALY per million people per year. This could be interpreted as one person in a million losing 1 year of life or it could be interpreted as a larger number of people suffering less severe impacts. For a pathogen causing watery diarrhea (but rarely causing death), this reference level of risk has been determined to be equivalent to around 1 in 1000 annual risk of diarrhea to an individual, or about 1 in 10 risk of contracting diarrhea over a lifetime.

Assessment of Unidentified Chemicals

Analytical methods involving direct chemical measurements are limited in that they will only identify chemicals that are specifically targeted. This can only ever be a small subset of all the chemicals that may be present. Numerous decades of water quality monitoring have provided a reasonable (though always improving) understanding of which chemicals are likely to be present in drinking waters of conventional sources at significant enough concentrations to present an elevated level of risk. However, we have much less experience in dealing with the diversity of chemicals that may be present in reclaimed water.

Even if all of the organic chemical components in the specific reclaimed water could be identified, there would be scant toxicological data available for most of them and thus little basis for assigning risks. Other important limitations of chemical contaminant monitoring are that the potential additive toxicity of a large number of chemicals, each present at very low concentration, may not be identified unless each of the individual species is analyzed for and determined to be present at a concentration greater than analytical detection limit. Finally, there is some concern that the toxicity of complex mixtures is poorly understood and in some cases may amount to more (or less) than simply additive impacts from the summation of each of the contributing chemical species.

To overcome the limitations associated with the assessment of unidentified chemicals and unknown mixture interactions, many scientists have suggested that direct toxicological testing assessment of reclaimed water may be the only way to ensure safe concentrations of chemical contaminants (National Research Council, 1998). Toxicological testing involves collecting whole water samples and subjecting these to tests for a range of *in vitro* and/or *in vivo* toxicological end points, analogous to the toxicological testing described for individual chemicals in Chap. 2. Toxicological end points may include testing for mutagenic activity, carcinogenic activity, hormonal activity such as estrogenicity, or various forms of acute toxicity. Such testing will generally require at least a pilot-scale water treatment plant to be constructed in order to provide relevant samples for testing. Several IPR projects proposed in the past have conducted toxicological testing for their advanced water treatment process trains to demonstrate the absence of adverse human health effects from consumption of the product water (e.g., Denver Potable Water Reuse Demonstration Project, Tampa Water Resource Recovery Project, San Diego's Total Resource Recovery Project, Singapore's Water Reclamation Study). Findings from these studies revealed that exposure to advanced treated water from IPR facilities did not cause any abnormalities or adverse health effects (Western Consortium for Public Health, 1997; National Research Council, 1998; NEWater Expert Panel, 2002).

Health Risk Assessment

Health risk assessments are typically characterized by four distinct steps as described in Chap. 2: hazard identification, dose-response assessment, exposure assessment, and risk characterization. Undertaking a comprehensive health risk assessment for an IPR scheme is a considerable task, and contributions from specialists in the fields of wastewater engineering, advanced water treatment, drinking water management, toxicology, infectious diseases, and statistics may be required. The data obtained will be used for a variety of purposes including projecting final water quality prior to implementation, demonstrating that the proposed scheme can be operated safely, seeking regulatory approval for construction, and identifying *critical control points* (CCPs) for ongoing reliable safe supply of water. A CCP is a point, step, or procedure at which controls can be applied to a hazard such that risks associated with that hazard can be prevented, eliminated, or reduced to acceptable levels.

A health risk assessment might be established to identify and quantify risks in absolute or relative terms. An assessment undertaken to determine risks in absolute terms could involve estimating the exposure of a particular pathogen or chemical contaminant and determining the consequential increased likelihood of identified adverse health outcomes on the basis of the known infectivity of the organism or toxicity of the chemical. Alternatively, a relative risk assessment could compare the degree of exposure to a pathogen or chemical from a new reclaimed water source relative to the exposure from a preexisting water source. Such an approach can be useful for demonstrating reduced or increased risks associated with exposure to a particular contaminant in the absence of quantitative toxicology/or/infectivity data.

In the past, health risk assessments for water reuse schemes focused on the estimation of chemical and pathogen concentrations expected when a treatment train is operating under normal performance conditions. Although many unit processes employed in treatment facilities provide extremely high quality water under normal conditions, treatment upsets, system failures, and human error can jeopardize the reliability of the treatment system and pose a potential risk to public health that is likely going to exceed the risk associated with normal operation. Thus, few assessments effectively account for the issues of treatment plant reliability and associated water quality variability (Khan, 2009).

For contaminants for which environmental or health impacts are predominantly associated with long-term exposure (e.g. carcinogens), occasional short-term events may be relatively unimportant since the effect is dependent upon the long-term average dose; however, for contaminants with health effects associated with acute exposures (e.g., pathogens or acute chemical toxins), individual events resulting in short-term increases in exposure may be highly significant (Haas and Trussell, 1998). Accordingly, any adequate assessment of health risks from a water reuse scheme needs to include a thorough assessment of potential hazardous events.

The vast majority of observed waterborne disease outbreaks in developed countries during the last few decades have been associated with hazardous events, such as unusual weather patterns, plumbing errors, or treatment failures (Hrudey and Hrudey, 2007; Rizak and Hrudey, 2007). Potential hazardous events can be assessed as a function of their likelihood of occurrence and their consequences if they do occur. Qualitative descriptors for likelihood and consequences are summarized in Tables 16-5 and 16-6, adopted from the "Australian Guidelines for Water Recycling" (EPHC, 2008).

Consequences of hazardous events may be evaluated in terms of change in contaminant concentrations and exposures that may be the result of a specific hazardous event occurring. For example, changes in contaminant exposure could be assessed for a treatment failure situation where an acceptable disinfection dose may not be achieved, and this can lead to increased exposure to viable pathogens.

The likelihood and consequences can then be combined to provide a qualitative estimation of risk, using a suitable risk matrix (Table 16-7). Risks that are judged to be high will generally be the focus of CCPs. Techniques for quantitatively assessing the likelihoods of

TABLE 16-5 Qualitative Measures of Likelihood

Level	Descriptor	Example description
A	Rare	May occur only in exceptional circumstances; may occur once in 100 years
B	Unlikely	Could occur within 20 years or in unusual circumstances
C	Possible	Might occur or should be expected to occur within a 5- to 10-year period
D	Likely	Will probably occur within a 1- to 5-year period
E	Almost certain	Is expected to occur with a probability of multiple occurrences within a year

specific hazardous events could be investigated including the use of historical data, such as weather patterns and frequencies of power failures or plumbing errors. Techniques for assessing the likelihood of treatment failures have also been established using a range of mechanical reliability measures (Shultz and Parr, 1982; Olivieri et al., 1996; Eisenberg et al., 1998; Eisenberg et al., 2001).

Probabilistic Exposure Assessment. Exposure to a contaminant from a water reuse scheme may be determined as a function of its concentration in conventionally treated wastewater and removal by multiple treatment processes, each with variable capability to reduce the concentration of the contaminant (Haas and Trussell, 1998; Tanaka et al., 1998). Water quality of IPR schemes is naturally variable as concentrations of trace chemicals in source waters vary over daily and weekly periods. Furthermore, the performances of advanced water treatment processes, such as RO and AOP, vary depending on a range of factors including hydraulic flow rate, water composition, and temperature. As a result, final concentrations of chemical hazards in water, and hence exposure to them, are variable parameters.

A useful way of dealing with variable parameters in mathematical risk calculations is by describing it, not as a point value but as a distribution of water quality values (Olivieri et al., 1999). A *probability density function* (PDF) is a mathematical function that represents a distribution in terms of the probability or frequency of occurrence of specific values within the distribution.

TABLE 16-7 Qualitative Risk Estimation

Likelihood	Consequences				
	1-Insignificant	2-Minor	3-Moderate	4-Major	5-Catastrophic
A Rare	Low	Low	Low	High	High
B Unlikely	Low	Low	Moderate	High	Very high
C Possible	Low	Moderate	High	Very high	Very high
D Likely	Low	Moderate	High	Very high	Very high
E Almost Certain	Low	Moderate	High	Very high	Very high

A range of anticipated exposures requires computing sums, multiplications, and other transformations on multiple PDFs; this is a mathematically challenging task and, in some cases, impossible. For this, probabilistic techniques can provide a powerful alternative approach (Olivieri et al., 1999; Khan and McDonald, 2009). The Monte Carlo model is currently the most widely used method for probabilistic health risk assessment and exposure assessment. In light of their increasing application, the USEPA has developed guidelines for probabilistic risk assessment (USEPA, 1997). The general principle is illustrated in the example provided in Fig. 16-3. In this case, the final contaminant concentration is determined as a function of the concentration of contaminant X in the source water (e.g., tertiary treated effluent) and its subsequent removal during treatment by RO followed by AOP. The source water concentration and the degree of removal by the two advanced treatment processes are all variable parameters and thus they are all represented by PDFs. A Monte Carlo simulation is used to derive the final PDF of the concentration of the target compound X in the final effluent as a function of the three preceding PDFs. This requires randomly sampling each of the three preceding PDFs to derive a random prediction of final effluent concentration according to each random sample. Repeating this process with a sufficient number of random samples (typically 10,000 or more) enables the final effluent PDF to be gradually generated. Treatment performance PDFs for individual unit processes employed in an IPR scheme can be characterized by observed performance, challenge testing, or analysis of fundamental process variables. The outcome of this approach allows the consideration of source water quality variations and an assessment of the final product water quality variability for individual compounds of interest.

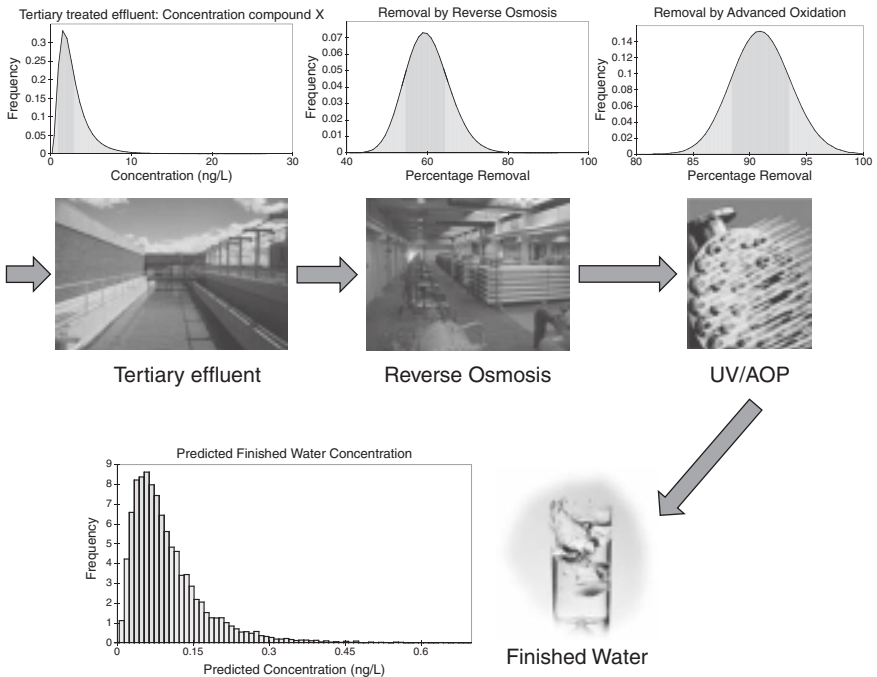

FIGURE 16-3 Illustration of exposure probability functions for compound X for an advanced water treatment train.

DESIGN OF POTABLE REUSE SCHEMES

This section provides information on the type of treatment processes being used in IPR projects to achieve high-quality water and discusses how these technologies reduce specific risk factors and how the efficacy of individual unit processes as well as the overall treatment train can be assured.

The Role of the Environmental Buffer

Potable reuse projects rely on the combination of an environmental buffer with a sequence of unit processes that are employed downstream of conventional wastewater treatment processes to improve water quality prior to introducing reclaimed water into a drinking water supply. IPR can occur through either of the following means or combinations using an environmental buffer:

1. *Surface water augmentation.* Reclaimed water is added to a reservoir, lake, stream, or river that has either the capacity or flow to provide attenuation and dilution.
2. *Groundwater recharge.*
 - a. Subsurface treatment leading to groundwater augmentation taking advantage of attenuation processes that occur in the vadose zone and saturated aquifer. These systems utilize spreading, recharge or rapid infiltration basins, vadose zone recharge wells or trenches, and riverbank filtration wells.
 - b. Direct injection introduces reclaimed water directly into a potable aquifer. Direct injection requires more stringent water-quality requirements since reclaimed water is introduced into the aquifer with little or no lag time. Direct injection can occur via direct-injection wells, deep vadose zone wells, or aquifer storage and recovery (ASR) wells.

Natural systems can be integrated immediately after the conventional wastewater treatment process, prior to or after advanced water treatment processes. It is noteworthy that the natural system or environmental buffer plays an important element in the design and operation of an overall IPR scheme since it provides an opportunity to physically and chemically cut the connection to the source (being sewage) as well as offering time, if needed, to respond to unforeseen process upsets. Decoupling from the source is achieved by blending with natural waters in the environment and reducing contaminants through natural attenuation processes. Although surface water environments offer opportunities for photolytic decay and some biological transformation of contaminants of concern (Fono et al., 2006), biological and physical attenuation processes are usually more efficient in subsurface environments (Amy and Drewes, 2007; Drewes et al., 2006).

Different requirements exist regarding the minimum retention time of reclaimed water in an environmental buffer prior to extraction. In groundwater recharge projects in California and Washington, regulations have been proposed or adopted, respectively, requiring 6 months of hydraulic retention time in the subsurface for surface spreading operations and for direct injection projects before the water can be recovered as a potable water source, mainly to provide additional protection to pathogens (Washington DOHC, 1997; CDPH, 2008). The Prairie Waters Project in Colorado utilizes a natural subsurface purification system with a hydraulic retention time of approximately 30 days. Since advanced water treatment processes are subsequently employed including several additional barriers for pathogen removal, a shorter retention time was deemed appropriate. Others have defined minimum setbacks (i.e., horizontal separation) between reclaimed water spreading operations and potable wells (e.g., 150 m (500 ft) in Florida; 1520 m (2000 ft) in Washington) (FDEP, 2006; Washington DOHC, 1997).

Multiple-Barrier Approach in IPR

The process of reducing the concentration of any microbial or chemical constituents of concern by applying a series of individual unit processes is referred to as the *multiple-barrier approach* to water treatment. The term *multiple barriers* was introduced in 1970 to describe the series of treatment steps to reduce the concentration of pathogens in a wastewater treatment process, where the receiving water was used as part of the water supply (Velz, 1970). For IPR projects, the concept of multiple barriers has been extended to include organic chemicals. Although the multiple barriers do tend to be relied on to provide cumulative steps toward the achievement of overall treatment goals, there is generally an expectation that they will accommodate a degree of treatment redundancy for pathogens. That is, the protection of public safety will be maintained even if a single treatment barrier fails (National Research Council, 1998). In the case of chemicals, the expectation is that a series of treatment steps will be used to reduce the overall chemical load. Given the wide range of different chemicals present in reclaimed water, multiple barriers should be designed to consider a sequence of diverse processes that are capable of targeting classes of chemicals encompassing different physicochemical properties. The requirement for redundancy normally associated with pathogen removal is not applied to multiple barriers for chemicals. This is because exposure to chemicals is more of a chronic risk, relating to long-term exposure, as compared with the acute risks associated with pathogens, for which even short-term exposures may have significant impacts on human health. From a public health standpoint, adequate and effective disinfection is the most essential process element that requires the highest degree of reliability and need for redundancy. The independence of multiple barriers is a key aspect of system reliability and safety.

Although the actual number of barriers for contaminants of concern might differ among different IPR projects, each scheme is characterized by a combination of *treatment barriers* that are suitable to control the concentrations of contaminants and *preventative measures* that control exposure to certain substances. Treatment barriers are individual unit processes employed at the water reclamation and the drinking water plants. In many cases, these include the use of a natural system, such as riverbank filtration or soil-aquifer treatment, to attenuate organic matter, pathogens, nutrients, and trace organic chemicals. *Preventative measures* include carrying out a source control program, management of the environmental buffer, maintenance of the distribution system, and an overarching monitoring program assuring proper performance of conventional and advanced water treatment unit processes. Sufficient redundancy for the removal of contaminants of concern should be provided to prevent any one system component from becoming absolutely vital to the protection of public health.

Multiple barriers established in IPR schemes are structured in five layers: source control program, conventional wastewater treatment, advanced water treatment, management of the environmental buffer, and drinking water treatment including management of the water distribution system (Fig. 16-4). The performance of each barrier is assured by conducting comprehensive and tailored monitoring programs.

Barrier 1: Source Control. Source control is a regulatory management practice to minimize the discharge of pollutants into the sewer. Best management practices of source control or source protection ensure sustainability and integrated pollution control of the wastewater. Control at the source reduces the treatment costs and improves the reliability of water quality. Effective source control practices involve the following elements:

1. Developing and executing a comprehensive plan for the management of the sewerage systems feeding the sewage treatment plants that supply source waters to the IPR systems

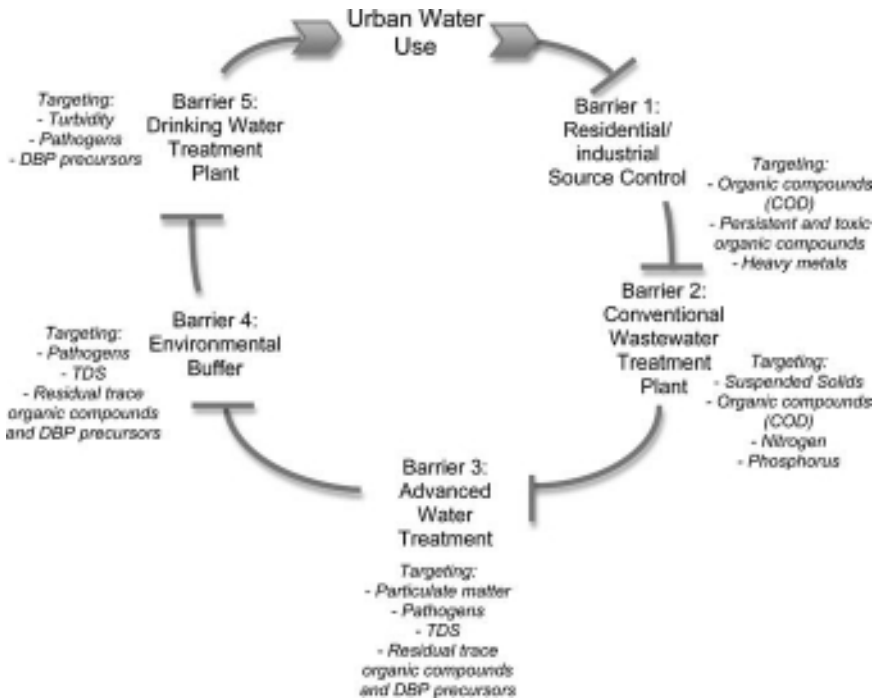

FIGURE 16-4 The multiple-barrier approach in indirect potable reuse.

2. Ensuring protection of reclaimed water from potentially polluting activities
3. Monitoring industrial and commercial discharge permits and compliance assessment
4. Creating awareness within the community of the impact of anthropogenic activities on water quality

Barrier 2: Conventional Wastewater Treatment. Conventional wastewater treatment processes consist predominantly of aerobic and anaerobic biological processes designed to minimize the impact of wastewater effluents discharged to the environment. Processes, such as activated sludge treatment and the use of trickling filters, are used to accelerate aerobic biochemical oxidation of assimilable carbon in order to reduce the occurrence of these processes in the environment which can lead to deoxygenation of waterways. These secondary treatment processes thus degrade easily assimilable organic compounds including proteins, sugars, and other biopolymers. Anaerobic and aerobic conditions are also commonly employed to enhance biological nutrient removal (BNR) by processes, such as nitrification and denitrification and biological phosphorus removal. In order to meet water quality standards, many treatment plants have changed or enhanced their biological treatment to remove nutrients and as a consequence the quality of conventionally treated effluents can vary widely (Table 16-3).

Barrier 3: Advanced Water Treatment. *Advanced water treatment (AWT)* is a term coined to differentiate the treatment processes adopted for IPR from conventional wastewater treatment processes and to indicate a water quality after partial TDS and/or trace chemical

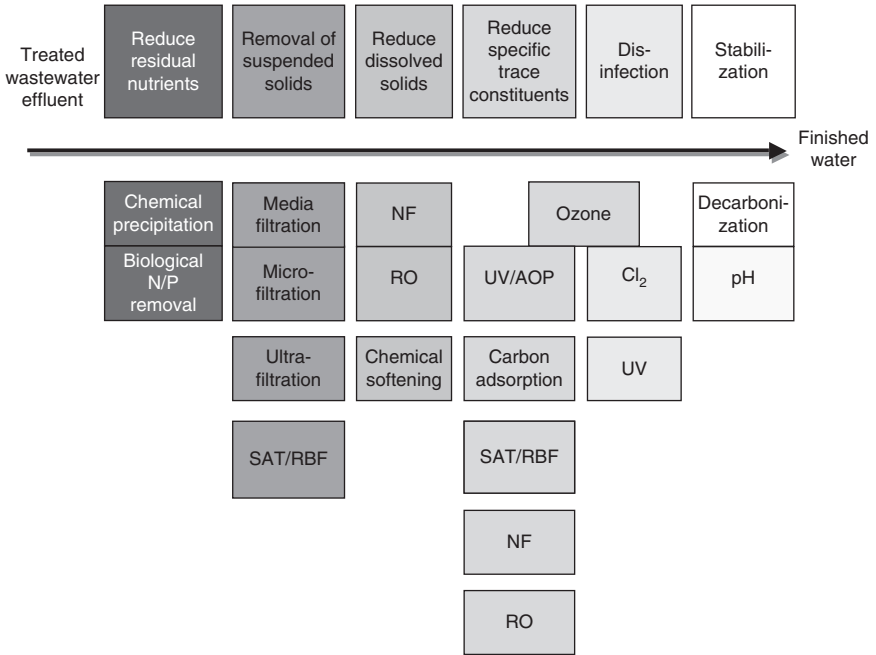

FIGURE 16-5 Treatment objectives of advanced water treatment and commonly employed treatment processes in water reclamation.

removal (Tchobanoglous et al., 2003). AWT processes are employed to meet various IPR treatment objectives, such as increasing the efficacy of disinfection, further decreasing residual nutrient concentrations, removing recalcitrant organic chemicals not metabolized during BNR, lowering the concentration of total dissolved solids, and increasing process redundancy. Various processes and treatment combinations have been employed or proposed to meet these treatment objectives (Fig. 16-5).

Barrier 4: Environmental Buffer. Management of the environmental buffer is another important component of the multibarrier approach; the buffer provides further treatment and/or dilution of reclaimed water, as well as allowing time to commission additional treatment steps or modifications at the reclaimed and drinking water treatment plant if *out-of-specification* reclaimed water is released prior to entering a finished water distribution system.

Attenuation processes in natural systems can result in a loss of identity of water and its wastewater origin. This disconnection from the source is considered a key element in building public trust in IPR.

Barrier 5: Drinking Water Treatment and Distribution System. The final drinking water treatment is mainly intended to address water quality issues associated with the storage, attenuation, blending, and conveyance of water that has been augmented by reclaimed water. In most cases, the treatment process consists of conventional unit processes usually employed for groundwater or surface water sources. A final disinfection residual is provided prior to delivery to the consumer.

Overarching Monitoring Program. In order to assure proper performance of conventional and advanced water treatment unit processes, an overarching monitoring program needs to be tailored to the specific barriers and local conditions of an IPR scheme. Details regarding the design of such a monitoring program are provided in the section Monitoring Strategies for Process Performance and Compliance following.

Indirect Potable Reuse Through Surface Water Augmentation

The practice of using reclaimed water to augment surface water used as a source for drinking is gaining popularity among water purveyors worldwide. The pioneering project of surface water augmentation in the United States was led by the Upper Occoquan Service Authority (UOSA), in Virginia, which began by augmenting surface water supplies in Fairfax County with reclaimed water in 1978 (Table 16-1). Since then, surface water augmentation projects were established in Clayton County (1985) and Gwinnett County (1990) in Georgia. Motivated by a severe drought and population growth, San Diego, California, proposed a surface water augmentation project in the late 1990s, which was terminated due to lack of public and political support in 1998. Ten years later, San Diego's IPR project is being reconsidered. In 2003, Singapore established their first IPR facility via surface water augmentation and has since added four additional facilities with a combined capacity of 467 ML/day as of 2010. Southeast Queensland, Australia, experienced its worst drought in 100 years from 2001 to 2008 with levels of the key drinking water reservoir, Lake Wivenhoe, falling below 17 percent of storage capacity. To counteract this trend, in 2008 the Western Corridor Project, which is designed to augment Lake Wivenhoe with reclaimed water if storage levels again fall below 40 percent of capacity, was established.

Upper Occoquan Service Authority, Virginia. Motivated by population growth, increasing urbanization, and a declining water quality of the Occoquan Reservoir, which is serving as the major raw water supply for people in northern Virginia, the Upper Occoquan Service Authority (UOSA) water reclamation system was established in 1978. The current Millard H. Robbins Jr. Water Reclamation Facility has a capacity of 204 ML/d (54 mgd) and is composed of advanced biological nutrient removal achieving complete nitrification and partial denitrification, lime clarification, two-stage recarbonation, multimedia gravity and pressure filtration, *granular activated carbon* (GAC) adsorption/filtration, ion exchange and breakpoint chlorination (standby), and disinfection (Asano et al., 2007). The BNR combined with the chemical treatment processes provides several-log reduction of viruses, phosphorus removal exceeding 99 percent, and significant reductions in organic and particulate matter, and heavy metals. Subsequent, multimedia filtration produces a reclaimed water quality with average suspended solids of 0.3 mg/L and a turbidity of less than 0.3 ntu. GAC adsorption/filtration serves as a process barrier for disinfection precursors, refractory synthetic organic compounds (SOCs), and other trace organic chemicals (Angelotti et al., 2005). Ion-exchange resins are only employed in standby mode to assure that discharge limits of less than 1.0 mg/L total Kjeldahl nitrogen (TKN) are met and drinking water standards of 10 mg/L nitrate nitrogen in the raw drinking water supply are not exceeded, especially during drought conditions.

Reclaimed water from the UOSA facility is discharged into Bull Run, a tributary of the Occoquan Reservoir. The discharge point is 9.7 km (6 mi) upstream of the headwaters of the reservoir and 32 km (20 mi) upstream of the drinking water supply intake. Reclaimed water currently accounts for about 8 percent of the annual average inflow to the reservoir, but during drought conditions may account for up to 90 percent. Since 2006, the Frederick P. Griffith Water Treatment Plant is treating raw water from the Occoquan Reservoir at a capacity of 454 ML/d (120 mgd) providing high-quality drinking water to the southern portion

of Fairfax County. The plant comprises coagulation/flocculation and multimedia filtration coupled with ozone and GAC filters, followed by final chlorination. The finished water quality exhibits average nitrate concentration of 1 mg N/L, TOC concentrations of 1.2 mg/L, and non-detect concentrations for 19 emerging trace organic chemicals (Fairfax Water, 2009).

In the future, the UOSA will be required to meet nutrient loading limits to protect the water quality of Chesapeake Bay. A plant expansion is underway to increase the treatment capacity to 242 ML/d (64 mgd) utilizing membrane bioreactors with chemically enhanced BNR followed by deep-bed GAC filtration (Asano et al., 2007).

Singapore's NEWater Project. The Singapore Water Reclamation Study (NEWater Study) was initiated in 1998 as a joint initiative between the Public Utilities Board (PUB) and the Ministry of the Environment and Water Resources (MEWR) to diversify Singapore's water portfolio and decrease the dependency on imported water from Malaysia. In 2000, a 10 ML/d demonstration plant was constructed at Bedok Water Reclamation Plant to produce *NEWater*. The reclaimed water from this plant was monitored regularly over a period of 2 years, when an expert panel gave an approval in terms of water quality and reliability (NEWater Expert Panel, 2002). By 2003, two *NEWater* Factories at Bedok and Kranji were operational producing 72 ML/d (19 mgd) of high-quality reclaimed water. Approximately 9 ML/d of this water was pumped into raw water reservoirs for blending and mixing (Tortajada 2006). A third plant at Seletar with a capacity of 24 ML/d was commissioned in 2004, and a fourth plant at Ulu Pandan with a capacity of 145 ML/d was brought online in March 2007, bringing the combined capacity of *NEWater* plants to 240 ML/d (64 mgd). Singapore's largest *NEWater* plant is the Changi plant that started with a treatment capacity of 68 ML/d (18 mgd) in 2009 and expanded to a total capacity of 227 ML/day (60 mgd) in 2010.

All *NEWater* plants are treating secondary effluents and subsequently utilize integrated membrane system followed by UV disinfection and chlorination. The largest amount of *NEWater* (438 ML/d or 116 mgd) is currently used for industrial (semiconductor manufacturing) and commercial use. In 2009 a small amount of *NEWater* (30 ML/d (8 mgd), or about 1 percent of the daily consumption of the country) began to be blended with raw water in the reservoirs that is subsequently treated for domestic use.

Western Corridor Project, Queensland, Australia. The *Western Corridor Recycled Water Project* (WCRWP) was constructed in South East Queensland, Australia during 2007–2008. The WCRWP has the capacity to produce up to 232 ML/d (61 mgd), which represents approximately 30 percent of the total current water supply needs for South East Queensland (Davies, 2009). The WCRWP utilizes treated effluents from six wastewater treatment plants to produce reclaimed water in three advanced water treatment plants suitable for both industrial and potable uses. The AWT plants, located at Bundamba, Luggage Point, and Gibson Island, incorporate the treatment processes of coagulation/flocculation and settling, MF, RO, AOP (UV/H₂O₂), and chemical stabilization and disinfection.

The scheme is designed to partially supplement potable water supplies by adding highly treated reclaimed water into South East Queensland's largest drinking water reservoir, Lake Wivenhoe. This water is then treated at the potable water treatment plant located at Mt. Crosby before distribution via existing potable water supply infrastructure. Water produced from the WCRWP is currently supplied directly to major industrial users including the Swanbank and Tarong Power Stations which previously drew water from the Lake Wivenhoe system. The concentrate of the IMS is discharged to the Brisbane River and the Pacific Ocean. Prior to discharge, the concentrate is further treated by a nitrification system followed by denitrification filters in order to meet discharge standards to the Brisbane River. After reservoir levels recovered and exceeded 60 percent of storage capacity in 2009, South East Queensland regulators decided that augmentation of Lake Wivenhoe with reclaimed water will only occur once the reservoir storage levels fall below 40 percent of capacity.

Comprehensive validation and verification testing during piloting and start-up of the facilities has been conducted and demonstrated that the reclaimed water quality meets and exceeds the requirements of the “Phase 2 Australian Guidelines for Water Recycling” (NRMCC et al., 2008) as well as the “Australian Drinking Water Guidelines”.

Indirect Potable Reuse Through Subsurface Treatment Leading to Groundwater Augmentation

In the United States, drinking water augmentation with reclaimed water was pioneered by the County Sanitation Districts of Los Angeles County (CSDLAC) and the Water Replenishment District of Southern California (WRD) by establishing groundwater recharge spreading operations with reclaimed water in Whittier, California, in the early 1960s. Although the spreading facilities received also untreated surface water and stormwater, subsurface treatment was recognized as being able to provide a barrier to pathogens, to reduce the concentration of nutrients and organic matter, and to attenuate trace organic chemicals present in reclaimed water (Fox et al., 2001).

Since this pioneering project, subsurface treatment for reclaimed water has been employed in various modifications, such as rapid infiltration basins, vadose zone injection wells, infiltration trenches, and riverbank filtration (see Chap. 15).

Recharge basins are often located in, or adjacent to, floodplains, characterized by soils with high permeability. It may be required that excavation is necessary for recharge basins to remove surface soils of low permeability. For vector control and to maintain permeability during operation with reclaimed water, recharge basins are usually operated in wetting and drying cycles. As the recharge basin drains, dissolved oxygen penetrates into the subsurface facilitating biochemical transformation processes and organic material accumulated on the soil surface desiccates allowing for the recovery of infiltration rates. In riverbank filtration, constant scour forces due to stream flow prevent the accumulation of particulate and organic matter in the infiltration layer. All subsurface treatment applications combine the benefits of no need for chemicals, low energy demand, residual free operation, temperature equilibration of the water, and a rather low degree of maintenance.

Different reclaimed water qualities have been applied to recharge operations ranging from primary effluents to highly treated water. Primary effluent has only been applied to demonstration projects and is not currently used for groundwater recharge. CSDLAC in Whittier, California, is applying tertiary-treated effluents to surface spreading operations. The Orange County Water District in Fountain Valley, California, is applying reclaimed water that has been treated with RO and advanced oxidation processes to surface spreading basins. The attenuation processes of subsurface systems include transformations of organic matter, oxidation/reduction (redox) reactions, nitrogen transformations, and inactivation of pathogens. The degree of water quality changes will depend on the feed water quality applied to recharge operations.

The removal of organic matter during infiltration is highly efficient and largely independent from the level of above-ground treatment, since biodegradable organic carbon that is not attenuated during wastewater treatment is readily removed during groundwater recharge (Drewes and Fox, 2000; Rauch and Drewes, 2004; Rauch-Williams and Drewes, 2006). However, organic matter represents an electron donor for microorganisms in the subsurface and reclaimed water after RO/AOP treatment usually lacks sufficient carbon levels to support the growth of microorganisms.

The removal of easily biodegradable organic carbon in the infiltration zone usually results in depletion of oxygen and the creation of anoxic conditions. Although this transition is advantageous regarding denitrification processes, it might also lead to the solubilization of reduced manganese, iron, and arsenic from native aquifer materials. If these

interactions occur, an appropriate posttreatment is required after recovery of the recharged groundwater.

Nitrogen removal needs to be carefully managed when not nitrified reclaimed water is applied with nitrogen concentrations in excess of 20 mg N/L representing a nitrogenous oxygen demand in excess of 100 mg/L. Ammonium is usually removed by cation exchange onto soil particles during wetting cycles, followed by nitrification of the adsorbed ammonium during drying cycles. Nitrate is not adsorbed to soils and, providing sufficient carbon is present to create anoxic conditions, can be denitrified during subsequent passage in the subsurface (Fox et al., 2001). Given the high carbon demand for denitrification, reclaimed water with nitrate concentrations in excess of 10 mg $\text{NO}_3\text{-N/L}$ should not be applied to groundwater recharge.

The combination of filtration and biotransformation processes during subsurface treatment is efficient for the inactivation of pathogens, especially viruses. From an extrapolation of tracer study data derived from a full-scale recharge basin study in the Montebello Forebay, California, a 7-log reduction of bacteriophage should occur within approximately 30 m (100 ft) of subsurface travel (Fox et al., 2001).

Montebello Forebay Spreading Operations, California. Jointly operated by the Water Replenishment District of Southern California (WRD) and CSDLAC, the Montebello Forebay spreading grounds started in 1962 representing the oldest IPR project in the United States. The spreading grounds are used for flood control, storm water conservation, and aquifer recharge using imported surface, storm, and reclaimed water. The San Jose Creek, Whittier Narrows, and Pomona Water Reclamation Plants (owned and operated by the CSDLAC) receive and treat residential and industrial wastewater (more than 90 percent is the former). The treatment processes at the water reclamation plants are composed of primary clarification, BNR including nitrification and denitrification, secondary clarification, tertiary dual-media filtration (anthracite and sand), and a chlorine contact basin. Prior to reuse, sulfur dioxide is added for dechlorination since the water is transferred to the spreading basins via a surface water body. Reclaimed water is diverted to a series of recharge basins along the Rio Hondo and San Gabriel rivers. The spreading operations are characterized by a shallow vadose zone of approximately 10 m (30 ft). Currently, the contribution of reclaimed water to recharge the local groundwater is limited to 35 percent. The reclaimed water blends with the aquifer and remains in the subsurface for approximately 6 months before it is contained in drinking water wells in the north and central portions of the central groundwater basin. For wells that are not subject to the USEPA Groundwater Rule, well-head treatment is provided using chlorine prior to injection into the distribution system.

Prairie Waters Project, City of Aurora, Colorado. In 2002 and 2003, a historic drought significantly affected the city of Aurora's water supplies and the city was faced with the short-term prospect of rationing water and a long-term unsustainable water resource portfolio in view of significant population growth. Since the city owns transbasin water rights from resources located on the western slope of the Rocky Mountains, which are entitled to reuse, the city decided to recover these resources from the South Platte River downstream of Denver, Colorado. The South Platte River receives treated wastewater effluents and runoff from the Denver/Aurora metropolitan area. Downstream of the Denver urban area, wastewater discharge can make up a significant portion (up to 60 percent annually) of the flow in the South Platte River (Krasner et al., 2008).

The city considered several different options for the recovery and treatment of this water. Because the short timeline to bring a new water supply online, the need for a streamlined permitting process, and the lack of an inland concentrate disposal option called for an environmentally sustainable solution and because of customer preferences, the city settled on a combination of natural purification systems with advanced engineered water treatment

processes to establish a project that could be operational by 2010 increasing Aurora's water supply by 20 percent.

The natural purification system, using a combination of riverbank filtration (RBF) wells and artificial recharge and recovery basins, is located along the South Platte River approximately 32 km (20 mi) downstream of Denver. The natural system provides a hydraulic retention time of approximately 30 days in the subsurface and removes particulate matter and pathogens, decreases TOC concentrations from 6–11 mg/L in the river to 3 to 4 mg/L after RBF, achieves nitrification/denitrification with nitrogen concentrations of less than 2 mg N/L, and achieves substantial reduction of trace organic chemicals. Three pump stations and a 56-km (35-mi) pipeline lift the recovered water from the natural purification system and convey it to the Peter Binney Water Purification Facility (BWPF) located at Aurora Reservoir, one of the city's current conventional supplies fed by Rocky Mountain snowmelt. At the BWPF, approximately 33 ML/d (9 mgd) of water recovered from the natural purification system is blended at a ratio of 1:2 with water from Aurora Reservoir, representing a total plant peak capacity of 190 ML/d (50 mgd). The treatment train of the BWPF consists of precipitative softening, followed by UV/AOP, biologically active carbon (BAC) filters, granular activated carbon filtration, and final disinfection. Prior to disinfection, the water is blended at a ratio of 1:2 with conventionally treated water from Aurora Reservoir (i.e., coagulation/flocculation). Partial softening is established to maintain a treatment goal of less than 400 mg/L TDS in the finished water. Advanced oxidation followed by BAC removes any residual trace organic chemicals and pathogens from the natural purification system, followed by GAC serving as a final barrier to trace organic chemicals and DBP precursors.

Indirect Potable Reuse Through Direct Injection into a Potable Aquifer

Direct injection of reclaimed water into a potable aquifer was pioneered in Orange County, California, with the establishment of Water Factory 21 in 1976. This project represented the precursor and benchmark for several subsequent IPR projects around the world, established by the West Basin Municipal Water District, California (1995), the Scottsdale Water Campus, Arizona (1999), the NEWater plants in Singapore (2003), the Groundwater Replenishment System replacing Water Factory 21 (2008), and the Western Corridor Project, Australia (2008). The core treatment processes of these projects are integrated membrane systems, in some cases coupled with subsequent UV advanced oxidation processes. Since all these projects (with the exception of Scottsdale, AZ) are located in coastal settings, the concentrate of the IMS from these projects is disposed via ocean outfalls.

Groundwater Replenishment System, Orange County, California. The *Groundwater Replenishment (GWR) System* was completed in 2008 with a capacity of 265 ML/d (70 mgd), representing the largest potable reuse project worldwide. It is a joint project between the *Orange County Water District (OCWD)* and the *Orange County Sanitation District (OCSd)*. Expansion plans are in preparation to increase the capacity to 380 ML/d (100 mgd) in the near future (Markus, 2009). Approximately half of the reclaimed water provided by this facility is used via surface spreading basins to recharge OCWD's groundwater basin, whereas the other half is used to maintain injection wells of the Talbert Gap Barrier to protect from seawater intrusion from the Pacific Ocean.

The precursor facility, Water Factory 21, operated from 1976 to 2004 reclaiming 60 ML/d (16 mgd) of secondary treated wastewater effluent using lime clarification pretreatment, RO, followed by UV/AOP and final disinfection. The GWR system adopted this approach, and the advanced treatment train consists of submerged microfiltration (MF), RO, advanced oxidation processes using low-pressure, high-output ultraviolet light and

hydrogen peroxide. The MF is used to separate suspended and colloidal solids including bacteria and protozoa from the secondary effluent. RO treatment reduces dissolved organic matter, regulated and unregulated trace organic chemicals, and viruses from MF filtrate. The subsequent, ultraviolet light/hydrogen peroxide process provides additional bacterial and viral inactivation and through hydroxyl radical formations can oxidize trace organic compounds. The product water undergoes additional chemical posttreatment using lime prior to groundwater injection and recharge. The finished water quality prior to groundwater injection is characterized by average TOC concentrations of 0.2 mg/L, total nitrogen concentrations of less than 1.7 mg/L, TDS concentrations of less than 34 mg/L, and NDMA concentrations of less than 1.6 ng/L.

Hueco Bolson Recharge Project, El Paso, Texas. The Hueco Bolson Recharge Project uses reclaimed water from the Fred Harvey Water Reclamation Plant and injects it directly into the primary drinking water source for the city of El Paso, Texas. The system has a capacity of 38 ML/d (10 mgd). The core treatment process consists of a two-stage biophysical *powdered activated carbon* (PAC) process. This process, which combines a conventional activated sludge system with the use of PAC, provides most of the removal of organic compounds and all of the removal of nitrogen compounds. Subsequently, high-lime treatment is used for the removal of residual heavy metals, pathogens, and phosphorus. After recarbonation, the water is sand filtered and ozone is used as primary disinfectant. GAC adsorption/filtration serves as a polishing process for removal of residual organic compounds (DBP precursors) and reduction of taste- and odor-producing compounds, and other regulated and unregulated trace organic chemicals. Through 11 injection wells, the reclaimed water is introduced into the Hueco Bolson aquifer, serving as water supply for the El Paso region.

Direct Potable Reuse

The determining factor for direct potable reuse is public confidence in, and reliance on, employed water treatment processes that always produce safe drinking water. Technological concerns are addressed by multiple-barrier systems, providing redundancy and diversity of processes that can remove the wide range of constituents of concern producing a water quality that meets drinking water standards and is safe to drink. In addition, process validation and verification approaches through real-time and frequent monitoring are available today and already embedded in many advanced water treatment plants practicing indirect potable reuse worldwide. What remains challenging is to overcome public and regulator perception to potable reuse. Direct potable reuse, however, offers opportunities to significantly reduce the cost for water collection and water distribution systems that might become more relevant in the near future making direct potable reuse a cost-effective application in the long term.

Windhoek's Goreangab Reclamation Plant, Namibia. Since 1968, Windhoek has pioneered direct potable reuse with the commissioning of the Goreangab Reclamation Plant in Windhoek, Namibia, which still today is the only commercial operation practicing direct potable reuse worldwide. Given the site-specific constraints, Windhoek chose direct potable reuse because it had no other choice. The current plant has a capacity of 21 ML/d (4.4 mgd) providing up to 35 percent of the city's drinking water supply during normal water consumption and up to 50 percent during severe drought conditions (du Pisani, 2006).

The plant design philosophy follows the multiple-barrier concept with established and optional treatment barriers. The treatment train consists of coagulation/flocculation, followed by dissolved air flotation and media filtration. The water is subsequently treated by

ozone/hydrogen peroxide followed by biological active granular activated carbon filtration. A final barrier is provided by ultrafiltration prior to final stabilization and disinfection. The finished water quality is subject to ongoing monitoring and testing. Windhoek has managed to overcome negative public perception with positive and proactive marketing providing a viable option of innovative integrated water resource management.

MONITORING STRATEGIES FOR PROCESS PERFORMANCE AND COMPLIANCE

In order to protect public health, careful attention must be given to proper selection of treatment processes that are capable of removing constituents of concern. Performance validation and verification of established treatment processes and compliance water quality monitoring are the most important aspects of overall system reliability. Reliability requirements include provisions for alarms, standby power supplies, readily available replacement equipment, standby treatment units, emergency storage or disposal provisions, flexible piping and pumping facilities, and trained personnel. Pipes or pumps that would allow bypass of critical treatment processes should not be installed. The facility should have procedures in place to operate during power failures, peak loads, equipment failure, treatment plant upsets, and maintenance shutdowns.

Monitoring and operating procedures for indirect potable reuse facilities need to be comprehensive, and several strategies exist to maintain performance integrity of treatment systems.

Real-Time Monitoring and Operating Strategies

The Phase 2 Australian Guidelines for Water Recycling (NRMMC et al., 2008) require a multiple-barrier approach to the management of risks with a strong focus on managing potential hazardous events. In order to illustrate the role of operating strategies and real-time monitoring to manage risks to process upsets, the AWT plants of the Western Corridor project in Southeast Queensland serve as an example. These facilities have established real-time monitoring to create critical control points, which allow the partially treated water stream to be diverted away from the next treatment step. At the beginning of the AWT plant processes, these monitored parameters include nitrate and ammonium concentrations, which indicate if the BNR processes in the wastewater treatment plant are operating appropriately. At the microfiltration step, membrane integrity is tested by automated pressure decay tests up to an hourly frequency, while at the RO step TOC is monitored as a surrogate parameter to detect any leakage of organic molecules through the membranes. At the disinfection/advanced oxidation step, the UV light dose and transmittance is constantly measured to detect lamp failure or opaque water, respectively. These real-time tests are complemented by laboratory tests (both chemical and microbiological) to confirm the data from the real-time sensors, as well as provide information on complex chemicals, such as trace organic chemicals, that cannot be measured in real time. The frequency of the laboratory tests will vary from weekly to annually with the frequency being responsive to the concentrations found, that is, to parameters whose values are rising or enter the recursive concentration range will be monitored more often until the cause of the excursion or violation is identified and rectified.

Simple water quality monitoring techniques, such as continuous turbidity monitoring, while suitable for coarse filtration systems, lack sufficient sensitivity to detect damage in fine filtration systems such as MF or UF membranes (Johnson, 1997). Monitoring

techniques that directly assess the integrity of membrane systems include pressure decay tests and diffusive airflow tests, while indirect tests that monitor the quality of the output include particle counting or particle monitoring or microbial challenge tests (see Chap. 11). Challenge tests introduce a known concentration of chemicals or microbial particles into the process and assess the effectiveness of the process by monitoring the final contaminant concentration in the filtrate.

Surrogate Measures and Indicator Compounds

In municipal wastewater effluents, the majority of nontraditional chemical contaminants are typically present at low concentrations (i.e., <300 ng/L) and most analytical methods are optimized to detect only a few compounds at a time. As a result, the effort required to perform a comprehensive analysis of all of the detectable chemical contaminants is unfeasible for all but the most sophisticated analytical laboratories.

Engineered treatment systems that can be used to control wastewater derived chemical contaminants in IPR employ physical, chemical, and biological processes to remove or transform the compounds. Published research on the mechanisms through which treatment processes act indicates that it should be possible to predict the extent of compound removal for compounds (termed *indicators*) exhibiting similar properties provided that those properties determine the behavior of the compound in the treatment process (Snyder et al., 2003; Bellona et al., 2004; Snyder et al., 2006; Deborde and von Gunten, 2008; Dickenson et al., 2009). Furthermore, the removal of specific compounds or families of compounds with closely related properties may be correlated with the removal of other routinely measured compounds or operational parameters (termed *surrogates*) that can be monitored continuously (e.g., conductivity, UV absorbance) (Drewes et al., 2009; Wert et al., 2009).

The most commonly used indicator organisms for pathogens are coliform bacteria, either fecal coliform or *E. coli*. However, since the 1980s, it has been increasingly recognized that coliform bacteria provide a poor indication of the presence of wastewater derived pathogens, such as viruses and protozoa. This is largely because many viruses and protozoa are much more resilient to treatment processes including UV and chemical disinfection as compared to coliform bacteria. Consequently, bacteriophages infecting enteric bacteria and spores of sulphite reducing bacteria have been suggested as more appropriate indicators for viruses and protozoa. Specific bacteriophages that have been recommended include somatic coliphages, F-RNA-specific bacteriophages, and phages infecting *B. fragilis*. Medema and Ashbolt (2006) have proposed that rather than producing a standard and monitoring requirement for all pathogens that could be transmitted through drinking water, the use of a suite of *index pathogens* be adopted.

Although the idea of using indicators (e.g., coliform bacteria) and surrogates (e.g., turbidity) as a means of predicting the behavior of difficult-to-measure contaminants is well established among researchers concerned with waterborne pathogens (see Chap. 2), it has not been adopted widely by regulators concerned about chemical contaminants. Recent studies have proposed a series of indicator compounds and surrogate parameters that were effectively used to assess the performance efficiency for trace organic chemicals of a wide range of advanced water treatment processes commonly employed in IPR schemes (Drewes et al., 2009; Dickenson et al., 2009). An example of chemicals, that have been identified as viable indicator compounds to assess the performance of ozonation processes, is presented in Table 16.8. A road map to adopt a monitoring strategy utilizing surrogates and indicators to assess the performance of unit processes in an IPR scheme has been proposed by Drewes et al. (2009) and is illustrated in Table 16-9. This indicator/surrogate concept has been adopted in the Australian "Guidelines for Water Recycling for Drinking Water Augmentation" (2008).

TABLE 16-8 Treatment Removal Categories for Indicators Compounds of Systems Using Ozone (Conditions: secondary/tertiary treated wastewater, O_3 :TOC = 0.6–1 mg/mg, ozone exposure $CT_{10} = 4\text{--}11^a$ mg min/L, pH 7–8, $\sim 20^\circ\text{C}$, Alkalinity < 300 mg/L as CaCO_3)

	Good removal		Intermediate removal		Poor removal
	90 percent		90–50 percent	50–25 percent	< 25 percent
Hydroxy Aromatic	Nonaromatic C = C	Alkoxy Polyaromatic	Saturated Aliphatic	Nitrosamine	Halogenated Aliphatic
Acetaminophen	Acetyl cedrene	Naproxen ^A	Iopromide ^D	NDMA ^D	Chloroform ^D
Atorvastatin (o-hydroxy)	Carbamazepine ^A	Propranolol ^A	Isobornyl acetate		TCEP
Atorvastatin (p-hydroxy)	Codeine		Meprobamate		T CPP
Benzyl salicylate	Hexylcinnamaldehyde	<i>Alkoxy Aromatic:</i>	Methyl dihydrojasmonate		TDCPP
Bisphenol A ^A	Methyl ionine	Gemfibrozil			
Estrone ^A	OTNE	Hydrocodone	<i>Nitro aromatic</i>		
Hexyl salicylate	Simvastatin hydroxy		Musk ketone		
Methyl salicylate	Terpineol	<i>Alkyl Aromatic:</i>	Musk xylene		
Nonylphenol ^A		Benzophenone			
Oxybenzone	<i>Deprotonated amine</i>	Benzyl acetate			
Propylparaben	Atenolol ^B	Bucinal			
Salicylic acid ^B	Caffeine	DEET			
TriclosanA	Diclofenac ^A	Dilantin			
	EDTA ^A	Dibutyl phthalate		$k_{03,app}$ ($\text{M}^{-1} \text{s}^{-1}$)	
<i>Amino/Acylamino Aromatic</i>	Erythromycin- H_2O	Diphenhydramine		A > 10^5	
Atorvastatin	Fluoxetine	Galaxolide		B $10^3\text{--}10^5$	
Sulfamethoxazole ^A	Metoprolol ^B	Ibuprofen ^C		C $10^0\text{--}10^3$	
Triclocarban	Nicotine	Indolebutyric acid		D < 100

TABLE 16-9 Application of the Surrogate/Indicator Framework to Assess Performance of IPR Treatment Trains

	Surrogate parameters	Indicator compounds
Piloting or/and start-up		
Step 1	Define operational conditions for each unit process making up the overall treatment train for proper operation according to technical specification	
Step 2	For each unit process, select surrogate parameter that demonstrate a measurable change under normal operating conditions and quantify this differential $\Delta X_i = X_{i,in} - X_{i,out} $	Conduct occurrence study to confirm detection ratio (mean concentration/detection limit) of viable indicator compounds is larger than 5 in the feed water of each unit process
Step 3		Conduct challenge or spiking study with select indicator compounds (5–10) during pilot- or start-up to determine the removal differentials under normal operating conditions $\Delta Y_i = (Y_{i,in} - Y_{i,out})/Y_{i,in}$
Step 4	Select viable surrogate and operational parameters for each unit process	Select 3–6 indicator compounds from categories classified as Good removal
Full-scale operation/compliance monitoring		
Step 5	Confirm operational conditions of full-scale operation and removal differential ΔX_i for selected surrogate and operational parameters	
Step 6	Operational monitoring: Monitor differential ΔX_i of select surrogate and operational parameters for each unit process or/and the overall treatment train on a regular basis (daily, weekly)	Verification monitoring: Monitor differential ΔY_i of selected indicator compounds for each unit process or/and the overall treatment train semiannually/annually

REGULATIONS AND GUIDELINES FOR DRINKING WATER AUGMENTATION

United States

U.S. Federal Guidelines. In the United States, there are no federal regulations that specifically address potable reuse. The USEPA has published a guidance document on water reuse (USEPA 2004) including guidelines for IPR. However, the document has no regulatory authority and does not make specific recommendations with respect to chemical contaminants. Several states have issued regulations or draft regulations pertaining to potable reuse of municipal wastewater effluents. However, these regulations differ in their guidance on whether potable reuse is an acceptable practice and, if so, what safeguards should be in place (National Research Council, 1998).

The majority of wastewater derived contaminants are not regulated in the United States. Moreover, a comprehensive list of emerging contaminants is not feasible. For instance, *endocrine-disrupting compounds* (EDCs) are a vast group of chemicals that have a toxicological impact and are not simply a list of specific chemical substances. There

are currently no federal regulations for pharmaceuticals in drinking water or natural waters. The U.S. Food and Drug Administration (FDA) requires ecological testing and evaluation of a new pharmaceutical only if an environmental concentration in water or soil is expected to exceed 1 mg/L or 100 µg/kg, respectively (FDA, 1998). In light of the recent data on the occurrence of pharmaceutical residues and personal care products in the aquatic environment, these policies may need to be reconsidered. While extensive monitoring programs are underway, toxicological studies conducted at environmentally relevant concentrations are necessary for intelligible regulations to be established. While no federal legislation specifically regulates EDCs and pharmaceutical residues in drinking or wastewater, individual states may regulate these compounds in the absence of any federal mandates. Among the states, California and Florida have made the most progress in establishing uniform approaches for assessing planned IPR and often serve as examples for regulators in other states. Therefore, it is appropriate to consider their regulations in some detail.

State of California. In the late 1980s, the *California Department of Public Health* (CDPH), formerly known as California Department of Health Services (Cal DHS), developed draft criteria for the use of reclaimed municipal wastewater to recharge groundwater basins that are sources of domestic water supply (Crook et al., 2000). The CDPH criteria, which set forth the agency's approach to writing permits for IPR systems, have been updated several times but have not been approved or finalized as of 2010. The CDPH draft groundwater recharge criteria are designed to ensure a groundwater supply that meets all the drinking water standards and other requirements more specific to water derived from wastewater effluent (CDPH, 2008). In formulating the proposed criteria, CDPH considered both acute health effects from microbial pathogens and potential long-term health effects associated with chemical constituents, particularly trace organic chemicals (Geselbracht and Crook, 2000). After receiving the final report prepared by a *science advisory panel* (SAP) submitted to the state in 1987, CDPH selected TOC limits in wastewater effluent prior to recharge as a means and surrogate of ensuring the lowest possible concentration of unregulated wastewater derived organic contaminants (Robeck, 1987). In its summary report, the SAP concluded that concentrations of organic carbon should be removed to "below 1 mg/L by reverse osmosis and essentially all identifiable trace organic compounds of significance should be absent in detectable concentrations."

The current draft criteria (CDPH 2008) couple an even more stringent TOC limit with the fraction of the drinking water supply that is derived from wastewater effluent as a factor in determining system performance requirements (quantified as TOC). This fraction is referred to as the *recycled water contribution* (RWC), which is based on a 60-month running average. The current draft regulations require that subsurface injection projects produce water with a TOC concentration as expressed in Eq. (16-1) prior to injection. Subsurface injection projects are required to treat 100 percent of the reclaimed water by RO and advanced oxidation processes (AOP) to provide sufficient removal of organic matter. For surface spreading operations, TOC must be equal to or less than 0.5 mg/L divided by the RWC in the reclaimed water prior to or after infiltration and prior to blending with the ambient groundwater. Therefore, surface spreading projects can receive credit for TOC removal that occurs within the vadose zone.

$$\text{TOC} \leq \frac{0.5}{\text{RWC}}$$

In recognition of the possible shortcomings of using TOC as a surrogate for wastewater-derived contaminants, the 2008 draft CDPH criteria, while not recommending additional monitoring for specific chemicals, do identify some specific pharmaceuticals, endocrine disruptors, personal care products, and other chemicals with a notification level that should be investigated (CDPH, 2008). The draft criteria provide a provision for CDPH to require monitoring of specific constituents based on (1) a review of the project engineering report;

(2) an inventory of constituents discharged into the wastewater collection system; (3) the affected groundwater basin; (4) a constituent's ability to characterize the presence of pharmaceuticals, endocrine disrupting chemicals, personal care products, and other indicators in municipal wastewater; and (5) the availability of a test method for a constituent. Thus, such non-regulated constituents will be selected for monitoring on a case-by-case basis. The inclusion of compounds for which no notification level had been established was controversial among water professionals because the basis for the selection criteria was unclear and little guidance was presented on analytical methods or detection limits required to quantify these chemicals in water samples.

State of Florida. Florida's water reuse regulations (FDEP 1999, 2006) include sections addressing high-rate infiltration basin systems and soil-absorption field systems, both of which may result in groundwater recharge. Because nearly all groundwater in Florida is classified as G-II, which is defined as groundwater containing 10,000 mg/L or less of TDS and is designated as a potable supply source, any land application system located over G-II groundwater could function as an indirect potable reuse system. If more than 50 percent of the wastewater applied to the system is collected after percolation, the system is classified as an effluent disposal system and not as beneficial reuse. Loading to these systems is limited to 0.23 m/d (0.8 ft/d), and wetting and drying cycles must be used. For systems having higher loading rates or a more direct connection to an aquifer than is normally encountered, the reclaimed water must receive secondary treatment, filtration, and high-level disinfection (no detectable fecal coliforms per 100 mL in at least 75 percent of the samples analyzed over a 30-day period, maximum of 25 fecal coliforms/100 mL in any sample, total-suspended-solid limit of 5.0 mg/L, and a minimum total chlorine residual of 1.0 mg/L after at least 15 min of contact at peak hour flow) and must meet primary and secondary drinking water standards.

The Florida regulations also include criteria directed at planned indirect potable reuse by injection into water supply aquifers and augmentation of surface supplies. The injection regulations pertain to G-I, G-II, and F-I groundwaters, all of which are classified as potable aquifers. Secondary treatment, filtration, and high-level disinfection are required. Reclaimed water must meet G-II groundwater standards prior to injection. G-II groundwater standards are very similar to primary and secondary drinking water standards. For injection into formations of the Floridian and Biscayne aquifers where the concentration of TDS does not exceed 500 mg/L, the regulations are more restrictive and specify that reclaimed water must meet drinking water standards, undergo activated carbon adsorption as an organic removal process, and meet average TOC and TOX limits of 5.0 mg/L and 0.2 mg/L, respectively, in the product water.

Australia

In 2008, Australia was the first country to develop national guidelines for indirect potable reuse with the release of Phase 2 of the Australian Guidelines for Water Recycling (AGWR): Augmentation of Drinking Water Supplies (NRMMC, EPHC, and NHMRC, 2008). Phase 1 of the AGWR (NRMMC & EPHC, 2006) was published in 2006 and addresses non-potable applications of reclaimed water. The Phase 2 Guidelines build on the risk management framework described in Phase 1 and provide additional detail relating to issues specific to IPR.

Management of water resources in Australia is the responsibility of the states, rather than the federal government. Accordingly, the state governments are responsible for approving and regulating the operation of IPR projects, and the federal government has no legislative or regulatory authority in this field. The AGWR are therefore not mandatory regulations in any state, unless the state governments independently choose to adopt them. Some of the state government regulatory agencies have explicitly endorsed the AGWR and will require proponents to adhere to them in order for a proposed water reclamation scheme to be approved or operated. Such

requirements are typically implemented through the provision of clauses in plant operating licenses. Other state governments may choose to deviate from the requirements of the AGWR or may refer to them for the development or adaptation of their own state-based guidelines.

The AGWR are notable for the risk management framework that they provide, rather than simply relying on end-product (reclaimed water) quality testing as the basis for managing water recycling schemes. The risk management framework used is based on the framework detailed in the Australian Drinking Water Guidelines (National Water Quality Management Strategy, 2004).

Assessment of the reclaimed water system must be carried out before strategies to prevent and control hazards are planned and implemented. The aim of the assessment is to provide a detailed understanding of the entire reclaimed water supply system, from source to end use. The hazards, sources, and events (including treatment failure) that can compromise reclaimed water quality are to be characterized and preventive measures needed to effectively control hazards and prevent adverse impacts on humans and the environment identified. Examples of potential hazardous events that should be considered are provided in Table 16-10. Hazardous events are assessed in terms of their likelihoods and consequences as described in the earlier section Design of Potable Reuse Schemes.

Chemical guideline values are tabulated in the Phase 2 AGWR along with maximum concentrations of the chemicals that have been reported from international studies of secondary- or tertiary-treated effluents. However, the guidelines note that the table should not be taken as exhaustive and that detailed assessment of individual systems, including surveys of industrial, agricultural, domestic, and urban inputs, needs to be undertaken to identify potential chemical hazards that could affect source water quality. In most cases, this assessment will need to be supported by extensive monitoring of the source water quality.

Where possible, guideline values were acquired from existing guidelines and standards, with the Australian Drinking Water Guidelines being the primary source. Where no existing guideline values could be identified, guidelines were developed from available health, toxicological, or structural information. The list of guideline values is not intended to be regarded as a mandatory set of parameters to be included in monitoring programs. However, key characteristics that need to be considered for system performance verification include

1. Microbial indicator organisms
2. Health-related chemicals
 - a. Those identified in the Australian Drinking Water Guidelines
 - b. Key organic chemicals of concern (e.g., NDMA)
 - c. Indicators or index chemicals for organic chemicals (e.g., contraceptive hormones)
3. Biological activity

The choice of specific parameters must be informed by hazard identification and risk assessment. These, in turn, should be informed by a consideration of source water quality, potential agricultural and industrial inputs, treatment processes, chemicals and by-products, and receiving water quality.

PUBLIC PERCEPTION TO INDIRECT POTABLE REUSE

It is widely recognized that the ultimate success of any indirect potable reuse project is determined by the level of public and key stakeholder acceptance. Communication of risks associated with chemicals present in reclaimed water is an important component of project implementation.

TABLE 16-10 Examples of Potential Hazardous Events

Stormwater catchments	
Chemical use in catchment areas (e.g., use of fertilizers and agricultural pesticides)	Major fires (firefighting chemicals), natural disasters, sabotage
Sewage overflows and septic system discharges	Accidental spills or discharge
Entry of livestock waste	Leaching from existing or historical waste-
Climatic and seasonal variations (e.g., heavy rainfall, drought)	disposal (e.g. landfill) or mining sites, and contaminated sites and hazardous wastes
Industrial discharges	Road washing
Sewer systems	
Discharges of domestic and household chemicals	Trade-waste discharges, including accidental and illegal discharges
Discharges of toxic material	
Infiltration of stormwater	Infiltration of waste from contaminated sites
Infiltration of saline groundwater to sewer	or waste disposal sites (e.g., landfill)
Water reuse and drinking water treatment systems	
Chemical dosing failures	Poor reliability of processes
Disinfection malfunctions	Power failures
Equipment malfunctions	Sabotage and natural disasters
Failure of alarms and monitoring equipment	Significant flow variations through water treatment systems
Formation of disinfection by-products	
Inadequate	Use of unapproved or contaminated water treatment chemicals and materials
Backup for key processes	
Equipment or unit processes	Failure of staff to respond appropriately to alarms or fluctuations in treatment processes
Filter operation and backwash recycling	
Mixing of treatment chemicals and coagulants	
Receiving waters (reservoirs, rivers, and streams)	
Short-circuiting	Inadequate storage (e.g., during winter or other times of low recycled water usage)
Forest fires and natural disasters	
Climatic and seasonal variations (e.g., heavy rainfall, drought)	Leakage from storage to groundwater
Cyanobacterial blooms	Birds and vermin
Livestock access	Accidental spillage from public roads
Inadequate buffer zones and vegetation	Sabotage
Distribution systems	
Cross-connections with lower quality water or storages holding industrial chemicals	Biofilms, sloughing and resuspension or regrowth
Inadequate repair and maintenance, inadequate system flushing and reservoir cleaning	Formation of disinfection by-products
Inappropriate materials and coatings or material failure	Pipe bursts or leaks
	Sabotage and natural disasters
Users of drinking water	
Leaching of metals from piping and fittings	Inadequate auditing and inspection of internal plumbing systems
Unauthorized plumbing work leading to cross-connections to lower quality water	Use of inappropriate plumbing and construction materials

Different communities and different stakeholders within communities will have varying views of any contentious initiative, including IPR. For many communities planning for the future, the role of IPR is untested. Hence, issues that may influence community response to IPR proposals are likely to include those associated with public health, population growth, environmental health, economy and finance, available technology, and emotional factors.

Community views of potable and nonpotable water reuse have been a topic of interest to social scientists since the early 1970s. In the United States, acceptance of potable reuse applications was measured at 48 percent in 1971, but this appeared to have fallen significantly to 26 percent (California) by 1979 and 29 percent (Denver) in 1985 (Bruvold, 1988). By 2002, support in the United States for direct potable reuse was reported at only 18 percent while support for indirect potable reuse was at 40 percent. The difference in support for the two approaches highlights important differences in perceptions of them. Furthermore, the measured degree of support reported for potable reuse schemes tends to be dependent on how the survey questions are stated. For example, questions about “potable water reuse policy” have consistently scored a more positive response than those about “intentions to drink the reclaimed water” (Marks, 2004).

During construction of the Western Corridor Recycled Water Project in Queensland, Australia, the state government commissioned some professional telephone polling to gauge support. The following questions were posed to 800 people (Galaxy Research, 2008):

In February the first part of the government’s water grid is due to come on line. This will include the recycling of wastewater in South East Queensland. Do you support or oppose the inclusion of purified recycled water in the new water grid? Would you support or oppose the inclusion of purified recycled water in the new water grid if it was only to be used as a back-up when dam levels dropped below 40 percent?

In response to these questions, 54 percent of people stated that they supported the addition of reclaimed water to the drinking water supply as a general strategy and an additional 28 percent stated that they supported the scheme as a backup measure (Galaxy Research, 2008). The remaining 18 percent opposed the use of reclaimed water for drinking water supplementation.

To fully understand community attitudes to IPR, it is necessary to consider instinctive and emotional responses that people have to human excrement and sewage issues. It has been illustrated that many people trust their own impressions of water quality (often based on cloudiness of the water) more than they trust medical and scientific evidence (Hartley, 2003). Cognitive factors such as the so-called law of contagion and the law of similarity may explain many of the less rational perceptions that people may have about water reuse (Haddad, 2004). The law of contagion suggests that once water has been in contact with contaminants, it can be psychologically very difficult for people to accept that it has been purified. The law of similarity suggests that the *appearance* of a substance’s condition or status is psychologically linked to perceptions of reality. Combined, these factors can create mental barriers to the acceptance of reuse water as a source of pure water. However, the true significance of these cognitive factors is yet to be properly established. It should also be assumed that responses to reuse are also dependent on social and cultural contexts and debate, which are current in a particular social network.

Despite the challenges, a review of research studies has revealed encouraging data about community perceptions and attitudes toward water reuse in the United States (Hartley, 2003; Ruetten et al., 2004). It is anticipated that many of the findings will also apply to other countries. The findings highlight opportunities for effective communication between water reuse organizations and their stakeholders. They include

1. The community is interested in being meaningfully involved in water reuse decisions.
2. The community is interested in finding ways to ensure independent and secure water supplies for their communities.
3. While the community is not well versed in the water cycle, they are generally aware that there are water supply problems in many parts of the country.

4. The community believes that some form of potable reuse is inevitable, given growth and water supply constraints.
5. Information sharing, educational activities, and opportunities for reflection on the concepts of water reuse can increase support.

ABBREVIATIONS

ADI	acceptable daily intake
AOP	advanced oxidation processes
AWT	advanced water treatment
BNR	biological nutrient removal
CCP	critical control point
CDPH	California Department of Public Health
CWA	Clean Water Act
DALYs	disability-adjusted life years
DBPs	disinfection by-products
DOC	dissolved organic carbon
EDC	endocrine-disrupting compound
EfOM	effluent organic matter
GAC	granular activated carbon
IMS	integrated membrane system
IPR	indirect potable reuse
LAS	linear alkylbenzene sulphonates
LOEL	lowest dose resulting in an observable effect
MCL	maximum contaminant level
MCLG	maximum contaminant level goal
MF	microfiltration
mgd	million gallons per day
ML	megaliters
NF	nanofiltration
NOEL	no observed adverse effects level
NOM	natural organic matter
ntu	nephelometric turbidity unit
PAC	powdered activated carbon
PDF	probability density function
PDT	pressure decay test
PFCs	perfluorochemicals
PFOA	perfluorooctanoic acid
PFOS	perfluorooctane sulfonate
POD	point of departure

RBF	riverbank filtration
RO	reverse osmosis
SAT	soil-aquifer treatment
SAP	science advisory panel
SDI	silt density index
SDWA	Safe Drinking Water Act
SSMP	sewer discharge management plan
TDS	total dissolved solids
TOC	total organic carbon
UF	ultrafiltration
USEPA	U.S. Environmental Protection Agency
UV	ultraviolet irradiation
WHO	World Health Organization

INTRODUCTION

Disinfection is a process designed for the deliberate reduction of the number of pathogenic microorganisms. While other water treatment processes, such as filtration or coagulation-flocculation-sedimentation, may achieve pathogen reduction, this is not generally their primary goal. A variety of chemical or physical agents may be used to carry out disinfection.

The concept of disinfection preceded the recognition of bacteria as the causative agent of disease. Averill (1832), for example, proposed chlorine disinfection of human wastes as a prophylaxis against epidemics in 1832. Chemical addition during water treatment for disinfection became accepted only after litigation on its efficacy (Race, 1918). The prophylactic benefits of water disinfection soon became apparent, particularly with respect to the reduction of typhoid and cholera.

Although significant progress is being made in controlling the classic water-borne diseases, newly recognized agents have added to the challenge. These include viruses (Melnick et al., 1978; Mosley, 1966); certain bacteria, for example, *Campylobacter* (Palmer et al., 1983), *Yersinia* (Brennhovd et al., 1992; Reasoner, 1991) or *Mycobacterium* (Geldreich, 1971; Iivanainen et al., 1993; Reasoner, 1991); and protozoans such as *Giardia* (Brown et al., 1992; Lechevallier et al., 1991; Miller, 1992; Reasoner, 1991; Renton et al., 1996; Rose et al., 1991) and *Cryptosporidium* (Bridgman et al., 1995; Centers for Disease Control and Prevention, 1995; Gallaher et al., 1989; Goldstein et al., 1996; Hayes et al., 1989; Lechevallier et al., 1991; Leland et al., 1993; MacKenzie et al., 1994; Miller, 1992; Reasoner, 1991; Richardson et al., 1991; Rose et al., 1991; Rush et al., 1990; Smith, 1992). Occasional outbreaks of hepatitis associated with drinking water have also occurred (Nasser, 1994; Rosenberg et al., 1980). In addition, new water-borne pathogens are continually being identified, *E. coli* O157:H7 and noroviruses being two examples. There has been a progression of revolutions in disinfection challenges over the history of drinking water disinfection, and what is sure is that there will continue to be more challenges (McGuire, 2006).

Many water utilities have moved to the use of multiple disinfectants (rather than simply chlorination), switched to combined residual chlorination, or abandoned chlorine/chloramines entirely. This is shown by comparing surveys taken in 1998 and 2007 by the AWWA Disinfection Committee (Table 17-1) (AWWA Disinfection Systems Committee, 2008; AWWA Water Quality Division Disinfection Systems Committee, 2000). This chapter covers the use of chlorine, as well as the major alternative chemical agents, for the purpose of disinfection. Specifically, history, chemistry, kinetics, and design implications will be presented. Chapter 18 of this book covers the application of ultraviolet light for disinfection.

TABLE 17-1 Water Utility Disinfection Practices According to 1998 and 2007 AWWA Surveys

Chemical	Percentage of utilities using	
	1998	2007
Chlorine gas	70	61
Chloramines	11	30
Sodium hypochlorite	22	31
Onsite generation of hypochlorite	2	8
Calcium hypochlorite	4	8
Chlorine dioxide	4	8
Ozone	2	9
UV	0	2

Notes:

1. Numbers sum to more than 100% because of multiple disinfectant use at a given facility.

2. Since this survey, there has been a reduction in the use of chlorine gas and an increased use of sodium hypochlorite, but quantitative survey data are not available.

HISTORY OF DISINFECTION

Chlorine

Chlorine gas was first prepared by Scheele in 1774, but chlorine was not regarded as a chemical element until 1808 (Belohlav and McBee, 1966). Early uses of chlorine include the use of Javelle water (chlorine gas dissolved in an alkaline potassium solution) in France for waste treatment in 1825 (Baker, 1926) and its use as a prophylactic agent during the European cholera epidemic of 1831 (Belohlav and McBee, 1966).

Disinfection of water by chlorine was first done in 1908 at Bubbly Creek (Chicago) and by the Jersey City Water Company. Within 2 years, chlorine was introduced as a disinfectant at New York City (Croton), Montreal, Milwaukee, Cleveland, Nashville, Baltimore, and Cincinnati, as well as at other smaller cities. Frequently, dramatic reductions in typhoid accompanied the introduction of this process (Hooker, 1913). By 1918, over 1000 cities, treating more than 1.1×10^7 m³/d (3 billion gpd) of water, were employing chlorine as a disinfectant (Race, 1918).

Chloramination, the addition of both chlorine and ammonia, either sequentially, or simultaneously, was first employed in 1917 at Ottawa, Ontario, and Denver, Colorado. Both of these early applications employed prereaction of the two chemicals prior to their addition to the full flow of water. Sometime later, preammoniation (the addition of ammonia prior to chlorine) was developed. In both cases, the process was advocated for its ability to prolong the stability of residual disinfectant during distribution and to diminish the disinfectant's propensity to produce chlorophenolic taste and odor substances. Shortages of ammonia during World War II and recognition of the superiority of free chlorine as a disinfectant reduced the popularity of the chloramination process. Concerns for organic by-products of chlorination, for example, trihalomethanes and haloacetic acids, however, have increased the popularity of chloramination (Wolfe et al., 1984), although chloramines have been found to produce other classes of by-products (Mitch et al., 2003).

Chlorine Dioxide

Chlorine dioxide was first produced from the reaction of potassium chlorate and hydrochloric acid by Davy in 1811 (Miller et al., 1978). However, not until the industrial scale preparation of sodium chlorite, from which chlorine dioxide can more readily be generated, did its widespread use occur (Rapson, 1966).

Chlorine dioxide has been used widely as a bleaching agent in pulp and paper manufacture (Rapson, 1966). Despite early investigations on the use of chlorine dioxide as an oxidant and disinfectant (Aston and Synan, 1948), however, its ascendancy in both water and wastewater treatment has been slow, with no evidence of its use even in the early 1970s. (Morris, 1971).

In 1998, 8.1 percent of medium and large utilities reported using chlorine dioxide as a disinfectant (perhaps intermittently or in combination with other disinfectants), up from 4.5 percent in 1986 (AWWA Water Quality Division Disinfection Systems Committee, 2000). The increase in use has occurred because of the potency of ClO₂ as a disinfectant combined with the lack of formation of organo-chlorine disinfection by-products produced by pure chlorine dioxide.

Ozone

Ozone was discovered in 1783 by Van Marum, and named by Schonbein in 1840. In 1857, the first electric discharge ozone generation device was constructed by Siemens, with the

first commercial application of this device occurring in 1893 (Water Pollution Control Federation, 1984).

Ozone was first applied as a potable water disinfectant in 1893 at Oudshoorn, Netherlands. In 1906, Nice, France, installed ozone as a treatment process, and this plant represents the oldest ozonation installation in continual operation (Rice et al., 1981). In the United States, ozone was first employed for taste and odor control at the New York City Jerome Park Reservoir in 1906. In 1998, 5.6 percent of medium or large utilities reported using ozone as a disinfectant, up from 0.37 percent in 1989 (AWWA Water Quality Division Disinfection Systems Committee, 2000).

UV Radiation

The biocidal effects of ultraviolet radiation (UV) have been known since it was established that short-wavelength UV was responsible for microbial decay often associated with sunlight (Downes and Blount, 1877). By the early 1940s, design guidelines for UV disinfection were proposed (Huff et al., 1965). UV has been accepted for treating potable water on passenger ships (Huff et al., 1965). Until recently, however, it has met with little enthusiasm in public water supply applications because of the lack of a residual following application. With findings that UV is highly effective against protozoan pathogens, a strong interest in the use of UV as a primary disinfectant in water treatment has occurred (Hijnen et al., 2006). This is seen in the recent (2007) AWWA Survey (Table 17-1).

Other Agents

A variety of other agents may be used to effect inactivation of microorganisms. These include heat, extremes in pH, metals (silver, copper), surfactants, permanganate, and electron beam irradiation. Heat is useful only in emergencies, as in boil-water orders, and is uneconomical. An alkaline pH (during high lime softening) may provide some microbial inactivation, but is not usually sufficient as a sole disinfectant. Potassium permanganate has been reported to achieve some disinfecting effects; however, its efficacy has not been well characterized. High-energy electrons for disinfection of wastewaters and sludges have also been studied (Farooq et al., 1993); however, their feasibility in drinking water is uncertain. In this chapter, therefore, primary consideration is given to chlorine compounds, including chlorine dioxide. In water treatment (as discussed in Chaps. 7 and 18), combinations of ultraviolet radiation and oxidizing agents (typically ozone or hydrogen peroxide) are used in advanced oxidation processes. While the free radicals generated in such processes may be effective at reducing concentrations of certain organic compounds, these free radicals are not highly effective disinfectants, however the individual processes (UV radiation, ozonation) used in such processes by themselves may provide inactivation. More detailed discussions of ozone and UV appear in Chaps. 7 and 18, respectively.

REGULATORY ISSUES FOR DISINFECTION

Amendments to the Safe Drinking Water Act require that all surface water suppliers in the United States filter and/or disinfect to protect the health of their customers. The filtration and disinfection treatment requirements for public water systems using surface water sources or groundwater under the direct influence of surface water are included in what is called the Surface Water Treatment Rule (USEPA, 1991). See Chap. 1 for additional information.

The Surface Water Treatment Rule (SWTR) requires that all surface water treatment facilities (except those meeting specific exemption criteria) provide filtration and disinfection that achieves at least (1) a 99.9 percent (3-log) removal-inactivation of *Giardia lamblia* cysts and (2) a 99.99 percent (4-log) removal-inactivation of enteric viruses. The SWTR credits a treatment plant having effective conventional treatment including filtration with achieving 2.5-log removal of *Giardia* and a 2-log removal of viruses. Disinfection is required for the remainder of the removal-inactivation.

The amount of disinfection credit to be awarded is determined with the $C \times T_{10}$ concept is defined as the residual disinfectant concentration (C , mg/L) multiplied by the contact time (T_{10} , min) for the fastest 10 percent of the flow; T_{10} can be estimated from the mean hydraulic residence time between the point of disinfectant application and the point of residual measurement and a baffling factor (varying between 0.1 and 1) describing the hydraulic characteristics of the contactor. The SWTR Guidance Manual (USEPA, 1991) provides tables of $C \times T_{10}$ values for several disinfectants achieving particular degrees of inactivation of *Giardia* and viruses. A large safety factor was incorporated into the $C \times T_{10}$ values included in the Guidance Manual tables. In addition to relying on the $C \times T_{10}$ tables to calculate disinfection credit, the SWTR allows utilities to demonstrate the ability of their disinfection systems to inactivate microorganisms by conducting pilot-scale studies, which may be prohibitively expensive for smaller operations. The SWTR was revised to take into account knowledge developed since the mid 1980s, including the need to achieve inactivation of *Cryptosporidium*. This resulted in the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) in 2006. A more complete discussion of regulatory requirements is included in Chap. 1.

Along with disinfection requirements, explicit regulations have been imposed on disinfection by-products since 1974, first with respect to trihalomethanes and more recently with respect to haloacetic acids, bromate, and other possible by-products. The combination of the requirement to achieve disinfection along with the requirement to minimize disinfection by-products has led to an increasing spectrum of options being considered. For more information on either by-product or disinfection regulations, Chaps. 1 and 19 should be consulted.

DISINFECTANTS AND THEORY OF DISINFECTION

Basic Chemistry

Chlorine and Chlorine Compounds. Chlorine may be used as a disinfectant in the form of compressed gas under pressure which is dissolved in water at the point of application, solutions of sodium hypochlorite, or solid calcium hypochlorite. The three forms are chemically equivalent because of the rapid equilibrium that exists between dissolved molecular gas and the dissociation products of hypochlorite compounds.

Molecular chlorine (Cl_2) is a dense gas that, when subject to pressures in excess of its vapor pressure, condenses into a liquid with the release of heat and with a reduction in specific volume of approximately 450-fold. Hence, commercial shipments of chlorine are made in pressurized tanks to reduce shipment volume. When chlorine is to be dispensed as a gas, supplying thermal energy to vaporize the compressed liquid chlorine is necessary. Due to safety and security concerns, the prevalence of use of gaseous chlorine has been decreasing.

The relative amount of chlorine present in chlorine gas, or hypochlorite salts, is expressed in terms of available chlorine. The concentration of hypochlorite (or any other oxidizing disinfectant) may be expressed as available chlorine by determining the electrochemical

equivalent amount of Cl_2 to that compound. By Eq. 17-1, 1 mole of molecular chlorine is capable of reacting with two electrons to form inert chloride.

From Eq. 17-2, 1 mole of hypochlorite (OCl^-) may react with two electrons to form chloride.

Hence, 1 mole of hypochlorite is electrochemically equivalent to 1 mole of molecular chlorine and may be said to contain 70.91 g of available chlorine (identical to the molecular weight of Cl_2).

Calcium hypochlorite ($\text{Ca}(\text{OCl})_2$) and sodium hypochlorite (NaOCl) contain 2 moles and 1 mole of hypochlorite per mole of chemical, respectively, and, as a result, 141.8 g and 70.91 g of available chlorine per mole, respectively. The molecular weights of $\text{Ca}(\text{OCl})_2$ and NaOCl are, respectively, 143 and 74.5, so that pure preparations of the two compounds contain 99.2 and 95.8 weight percent of available chlorine; hence, they are effective means of supplying chlorine for disinfection purposes. Calcium hypochlorite is available commercially as a dry solid. In this form, it is subject to a loss in strength of approximately 0.013 percent per day (Laubusch, 1963). Calcium hypochlorite is also available in a tablet form, for use in automatic feed equipment at low-flow treatment plants. Sodium hypochlorite is available in 1 to 16 weight percent solutions. Higher concentration solutions are not practical because chemical stability rapidly diminishes with increasing strength. At 20°C to 25°C , the half-life of sodium hypochlorite solutions varies between 60 and 1700 days, respectively, for solutions of 18 and 3 percent available chlorine (Baker, 1969; Laubusch, 1963).

It is noted that the loss of strength in sodium hypochlorite solutions may also result in the formation of by-products that may be undesirable. Thermodynamically, the autodecomposition of hypochlorite to chlorate is highly favored by the following overall process (Bolyard et al., 1992):

Measurements of sodium hypochlorite disinfectant solutions at water utilities have revealed that the mass concentration of chlorate is from 1.7 to 220 percent of the mass concentration of free available chlorine (Bolyard et al., 1993; Bolyard et al., 1992). The concentration of chlorate present in these stock solutions is kinetically controlled and may be related to the solution strength, age, temperature, pH, and presence of metal catalysts (Gordon et al., 1995; Gordon et al., 1993).

When a chlorine-containing compound is added to water containing insignificant quantities of Kjeldahl nitrogen, organic material, and other chlorine-demanding substances, a rapid equilibrium is established among the various chemical species in solution. The term *free available chlorine* is used to refer to the sum of the concentrations of molecular chlorine (Cl_2), hypochlorous acid (HOCl), and hypochlorite ion (OCl^-), each expressed as available chlorine.

The dissolution of gaseous chlorine to form dissolved molecular chlorine is expressible as a phase equilibrium, and is called *Henry's law*.

In Eq. 17-4, quantities within square brackets represent molar concentrations, P_{Cl_2} is the gas phase partial pressure of chlorine in atmospheres, and H^* is the Henry's law constant, estimated from the following equation (Downs and Adams, 1973):

$$H^* = 4.805 \times 10^{-6} \exp(2818.48/T) \text{ (mol/L - atm)} \quad (17-5)$$

where T is the temperature in Kelvins ($\text{K} = ^\circ\text{C} + 273$).

Dissolved aqueous chlorine reacts with water to form hypochlorous acid, chloride ions, and protons (Downs and Adams, 1973) as indicated by Eq. 17-6.

This reaction typically reaches completion in 100 msec (Aieta and Roberts, 1985) and involves elementary reactions between dissolved molecular chlorine and hydroxyl ions. The extent of chlorine hydrolysis, or disproportionation (because the oxidation state of chlorine changes from 0 on the left to +1 and -1 on the right), as described by Eq. 17-6, decreases with decreasing pH and increasing salinity; hence, the solubility of gaseous chlorine can be increased by the addition of alkali or by the use of fresh, rather than brackish, water.

Hypochlorous acid is a weak acid and may dissociate according to the following reaction:

The pK_a of hypochlorous acid at 20°C is approximately 7.6. Morris (1966) has provided a correlating equation for K_a as a function of temperature.

$$\ln(K_a) = 23.184 - 0.0583 T - 6908/T \quad (17-8)$$

Figure 17-1 illustrates the effect of pH on the distribution of free chlorine between OCl^- and HOCl . At a pH < the pK_a , HOCl is the dominant species, while for $\text{pH} > \text{pK}_a$, OCl^- is the dominant species.

FIGURE 17-1 Effect of pH on relative amount of hypochlorous acid and hypochlorite ion at 20°C.

One practical consequence of the reactions described by Eqs. 17-4 to 17-8 is that the chlorine vapor pressure over a solution depends on solution pH, decreasing as pH increases (because of the increased formation of nonvolatile hypochlorite acid). Therefore, the addition of an alkaline material such as lime or sodium bicarbonate will reduce the volatility of chlorine from accidental spills or leaks and minimize danger to exposed personnel.

The acid-base properties of gaseous chlorine, or the hypochlorite salts, will also result in a loss or gain, respectively, of alkalinity, and also a reduction or increase, respectively, in pH. For each mole of free chlorine (i.e., 1 mole of Cl_2 or of NaOCl or 1/2 mole of $\text{Ca}(\text{OCl})_2$), there will be a change of one equivalent of alkalinity (increase for sodium and calcium hypochlorite and decrease for chlorine gas).

Example 17-1 The solution produced by a gas chlorinator contains 3500 mg/L available chlorine at a pH of 3. What is the equilibrium vapor pressure of this solution at 20°C (given that the value of the hydrolysis constant, K_H , is 1.49×10^4 at this temperature)?

Solution

1. The pH is sufficiently low so that the dissociation of hypochlorous acid to form hypochlorite can be ignored (Fig. 17-1). Therefore, a balance over chlorine species yields

$$[\text{Cl}_2] + [\text{HOCl}] = (3500 \times 10^{-3})/71$$

The factor of 71 reflects the fact that one mole of either dissolved chlorine or hypochlorous acid contains 71 g of available chlorine.

2. The hydrolysis equilibrium constant can be used to develop an additional equation.

$$1.49 \times 10^4 = [\text{H}^+][\text{Cl}^-][\text{HOCl}]/[\text{Cl}_2]$$

or, because the pH is given,

$$1.49 \times 10^7 = [\text{Cl}^-][\text{HOCl}]/[\text{Cl}_2]$$

3. Because chlorine gas was used to generate the dissolved free chlorine, the disproportionation reaction requires that for each mole of HOCl produced 1 mole of Cl^- must have been produced. If the initial concentration of chloride (in the feed water to the chlorinator) was minimal, then a third equation results.

$$[\text{Cl}^-] = [\text{HOCl}]$$

4. These three equations can be manipulated to produce a quadratic equation in the unknown $[\text{Cl}_2]^{1/2}$:

$$[\text{Cl}_2] + 3860[\text{Cl}_2]^{1/2} - 0.049 = 0$$

The single positive root is the only physically meaningful one; hence,

$$[\text{Cl}_2]^{1/2} = 1.27 \times 10^{-5}$$

or

$$[\text{Cl}_2] = 1.6 \times 10^{-10}$$

5. The Henry's law constant can be computed from Eq. 17-5 as 0.072 moles/L-atm, and therefore the partial pressure of chlorine gas is found.

$$\begin{aligned} P_{\text{Cl}_2} &= 1.6 \times 10^{-10}/0.072 = 2.23 \times 10^{-9} \text{ atm} \\ &= (2.23 \text{ ppb}) \end{aligned}$$

The OSHA permissible exposure limit (PEL) is reported as 1 ppm (ACGIH, 1994). Therefore, this level is of no apparent health concern to the workers. ▲

Chlorine Dioxide. Chlorine dioxide (ClO_2) is a neutral compound of chlorine in the +IV oxidation state. It has a boiling point of 11°C at atmospheric pressure. The liquid is denser than water and the gas is denser than air (Noack and Doeff, 1979). Unlike Cl_2 , chlorine dioxide does not hydrolyze in water and remains as a dissolved gas.

Chemically, chlorine dioxide is a stable free radical that, at high concentrations, reacts violently with reducing agents. It is explosive, with the lower explosive limit in air variously reported as 10 percent (Masschelein, 1979b) or 39 percent (Noack and Doeff, 1979). As a result, virtually all applications of chlorine dioxide require the synthesis of the gaseous compound in a dilute stream (either gaseous or liquid) on location as needed.

The solubility of gaseous chlorine dioxide in water may be described by Henry's law, and a fit of the available solubility data (Battino, 1984) results in the following relationship for the Henry's law constant (in units of atm^{-1}):

$$\begin{aligned}\ln(H) &= \text{mole fraction dissolved } \text{ClO}_2(\text{aq})/P_{\text{ClO}_2} \\ &= 58.84621 + (47.9133/T) - 11.0593 \ln(T)\end{aligned}\quad (17-9)$$

Under alkaline conditions, the following disproportionation into chlorite (ClO_2^-) and chlorate (ClO_3^-) occurs (Gordon et al., 1972):

In the absence of catalysis by carbonate, the reaction (Eq. 17-10) is governed by parallel first- and second-order kinetics (Gordon et al., 1972; Granstrom and Lee, 1957). The half-life of aqueous chlorine dioxide solutions decreases substantially with increasing concentration and with $\text{pH} > 9$. Even at neutral pH values, however, in the absence of carbonate at room temperature, the half-life of chlorine dioxide solutions of 0.01, 0.001, and 0.0001 mol/L is 0.5, 4, and 14 h, respectively. Hence, the storage of stock solutions of chlorine dioxide for even a few hours is impractical. For research purposes, acidified solutions in laboratory pure water may be held under refrigeration without appreciable loss for substantially longer (possibly up to months).

The simple disproportionation reaction to chlorate and chlorite is insufficient to explain the decay of chlorine dioxide in water free of extraneous reductants. Equation 17-10 predicts that the molar ratio of chlorate to chlorite formed should be 1:1. Medir and Giral (1982), however, found that the molar ratio of chlorate:chlorite:chloride:oxygen produced was 5:3:1:75, and that the addition of chloride enhanced the rate of decomposition and resulted in the predicted 1:1 molar ratio of chlorite:chlorate. Thus, the oxidation of chloride by chlorate and the possible formation of intermediate free chlorine may be of significance in the decay of chlorine dioxide in demand-free systems (Gordon et al., 1972), conceivably in some circumstances in water distribution.

The concentration of chlorine dioxide in solution is generally expressed in terms of g/L as chlorine by multiplying the molarity of chlorine dioxide by the number of electrons transferred per mole of chlorine dioxide reacted and then multiplying this by 35.5 g Cl_2 per electron mole. Conventionally, the five-electron reduction (Eq. 17-11) is used to carry out this conversion.

Note, however, that the typical reaction of chlorine dioxide in water, being reduced to chlorite, is a one-electron reduction as follows:

Hence, according to Eq. 17-11, 1 mole of chlorine dioxide contains 67.5 g of mass, and is equivalent to 177.5 ($= 5 \times 35.5$) g Cl_2 . Therefore, 1 g of chlorine dioxide contains 2.63 g

as chlorine. In examining any study on chlorine dioxide, due care with regard to units of expression of disinfectant concentration is warranted.

Ozone. Ozone is a colorless gas, produced from the action of electric fields on oxygen. It is highly unstable in the gas phase; in clean vessels at room temperature the half-life in air is 20 to 100 hours (Manley and Niegowski, 1967). Hence it must be produced on a continuous basis. Details of the chemistry and production of ozone are discussed in Chap. 7.

Disinfectant Demand Reactions

Chlorine

Reactions with Ammonia. In the presence of certain dissolved constituents in water, each of the disinfectants may react and transform to less biocidal chemical forms. In the case of chlorine, these principally involve reactions with ammonia and amino nitrogen compounds. This typically occurs in drinking water treatment when ammonia is added along with, immediately before, or after the addition of chlorine or hypochlorites. In the presence of ammonia nitrogen ion, free chlorine reacts in a stepwise manner to form chloramines (Jafvert and Valentine, 1992). This process is depicted in Eqs. 17-13 through 17-15.

These compounds, monochloramine (NH_2Cl), dichloramine (NHCl_2), and trichloramine (NCl_3), each contribute to the total (or combined) chlorine residual in a water. The terms *total available chlorine* or *total oxidants* refer, respectively, to the sum of free chlorine compounds and reactive chloramines, or the total oxidating agents. Under normal conditions of water treatment, if any excess ammonia is present, at equilibrium the amount of free chlorine is much less than 1 percent of total residual chlorine. Each chlorine atom associated with a chloramine molecule is capable of undergoing a two-electron reduction to chloride; hence, each mole of monochloramine contains 71 g available chlorine; each mole of dichloramine contains 2×71 or 142 g; and each mole of trichloramine contains 3×71 , or 223, g of available chlorine. Inasmuch as the molecular weights of mono-, di-, and trichloramine are 51.6, 86, and 110.5, respectively, the chloramines contain, respectively, 1.38, 1.65, and 2.02 g of available chlorine per gram. The efficiency of the various combined chlorine forms as disinfectants differs, however, and thus, the concentration of available chlorine does not completely characterize process performance. On an approximate basis, for example, for coliforms, the biocidal potency of $\text{HOCl}:\text{OCl}:\text{NH}_2\text{Cl}:\text{NHCl}_2$ is approximately 1:0.0125:0.005:0.0166, and for viruses and cysts, the combined chlorine forms are considerably less effective (Chang, 1971). As the reaction in Eq. 17-13 indicates, the formation of monochloramine is accompanied by the loss of a proton, because chlorination reduces the affinity of the nitrogen moiety for protons (Weil and Morris, 1949a).

The significance of chlorine speciation on disinfection efficiency was graphically demonstrated by Weber as shown in Fig. 17-2 (Weber et al., 1940). As the dose of chlorine is increased, the total chlorine residual (i.e., remaining in the system after 30 min) increases until it reaches a dose of approximately 50 mg/L, whereupon residual chlorine decreases to a very low value, and subsequently increases linearly with dose indefinitely. The “hump-and-dip” behavior is paralleled by the sensitivity of microorganisms to the available chlorine residual indicated by the time required for 99 percent inactivation of test bacteria. At the three points indicated, the total available chlorine is approximately identical at 22 to 24 mg/L yet a

FIGURE 17-2 Effect of increased chlorine dosage on residual chlorine and germicidal efficiency; pH 7.0, 20°C, NH_3 10 mg/L. (Adapted from Weber *et al.*, Journal AWWA, Vol. 32, No. 11 (November 1940) by permission.)

32-fold difference in microbial sensitivity occurred. It should be noted that there is substantial impact of the breakpoint curve on the formation of disinfection by-products, which is discussed in Chap. 19.

The explanation for this behavior is the breakpoint reaction between free chlorine and ammonia (Fig. 17-3). At doses below the “hump” in the chlorine residual curve (zone 1), only combined chlorine is detectable. At doses between the “hump” and the “dip” in the curve, an oxidative destruction of combined residual chlorine accompanied by the loss of nitrogen occurs (zone 2) (Taras, 1950). One possible reaction during breakpoint is

This reaction also may be used as a means to remove ammonia nitrogen from water or wastewaters (Pressley *et al.*, 1972). Finally, after the ammonia nitrogen has been completely oxidized, the residual remaining consists almost exclusively of free chlorine (zone 3). The minimum in the chlorine residual versus dose curve (in this case $\text{Cl}_2:\text{NH}_4^+ \text{-N}$ weight ratio of 7.6/1) is called the *breakpoint* and denotes the amount of chlorine that must be added to a water before a stable free residual can be obtained. If it is desired to maintain a free residual following disinfection, the dose must be at least as large as that required to achieve breakpoint.

In their investigations of the chlorination of drinking water, Griffin and Chamberlin (1941a and b) observed that

1. The classical “hump-and-dip” curve is only seen at pH between 6.5 and 8.5.
2. The molar ratio between chlorine and ammonia nitrogen dose at the breakpoint under ideal conditions is 2:1 corresponding to a mass dose ratio ($\text{Cl}_2:\text{NH}_4^+ \text{-N}$) of 10:1.
3. In practice, mass dose ratios of 15:1 may be needed to reach breakpoint.

FIGURE 17-3 Schematic idealization of breakpoint curve. (Modified after White, 1978)

More recent investigators have reported breakpoint in waters with lower chlorine demand that may occur at mass dose ratios as low as 7.6:1.

The breakpoint reaction may also affect the pH of a water. If sodium hypochlorite is used as the source of active chlorine, as breakpoint occurs, the pH decreases caused by an apparent release of protons during the breakpoint process (Eq. 17-16). If gaseous chlorine is used, this effect is reinforced by the release of protons by hydrolysis of gaseous chlorine according to the reactions in Eqs. 17-6 and 17-7 (Mc Kee, 1960).

The oxidation of ammonia nitrogen by chlorine to gaseous nitrogen at the breakpoint would theoretically require 1.5 mole of chlorine (Cl_2) per mole of nitrogen oxidized according to the reaction in Eq. 17-16. The observed stoichiometric molar ratio between chlorine added and ammonia nitrogen consumed at breakpoint is typically about 1.6-1.7:1, suggesting that more oxidized nitrogen compounds are produced at breakpoint than N_2 gas. Experimental evidence (Saunier and Selleck, 1979) indicates that the principal additional oxidized product may be nitrate formed via the reaction in Eq. 17-17.

Depending on the relative amount of nitrate formed in comparison to nitrogen at breakpoint, between 1.5 and 4.0 mole of available chlorine may be required, which is consistent with the available data.

Below the breakpoint, inorganic chloramines decompose by direct reactions with several compounds. For example, monochloramine may react with bromide ions to form monobromamine (Trofe, 1980). If trichloramine is formed, as would be the case for applied chlorine dosages in excess of that required for breakpoint, it may decompose either directly to form nitrogen gas and hypochlorous acid or by reaction with ammonia to form monochloramine and dichloramine (Saguinsin and Morris, 1975). In distilled water, the half-life of monochloramine was approximately 100 hours (Kinman and Layton, 1976). Even in

this simple circumstance, however, the decomposition products have not been completely characterized. Valentine et al. (1986) found that the decomposition of pure solutions of monochloramine produces an unidentified product that absorbs UV light at 243 nm and is capable of being oxidized or reduced.

Where the pH is below 9.0 (so that the dissociation of ammonium ion is negligible), the amount of combined chlorine in dichloramine relative to monochloramine after the reactions in Eqs. 17-13 and 17-14 have attained equilibrium, is given by the following relationship (McKee, 1960)

$$A = -1 + \left(\frac{BZ}{1 - \sqrt{1 - BZ(2 - Z)}} \right) \quad (17-18)$$

where A is the ratio of available chlorine in the form of dichloramine to available chlorine in the form of monochloramine, Z is the ratio of moles of chlorine (as Cl_2) added per mole of ammonia nitrogen present, and B is defined by Eq. 17-19.

$$B = 1 - 4 K_{eq} [\text{H}^+] \quad (17-19)$$

The equilibrium constant in Eq. 17-19 refers to the direct interconversion between dichloramine and monochloramine as follows:

At 25°C, K_{eq} has a value of 6.7×10^5 L/mol (Gray et al., 1978). From these relationships, determination of the equilibrium ratio of dichloramine to monochloramine as a function of pH and applied chlorine dose ratio is possible (assuming no dissipative reactions other than those involving the inorganic chloramines). As pH decreases and the Cl:N dose ratio increases, the relative amount of dichloramine also increases (Fig. 17-4). As the Cl:N molar dose ratio increases, the relative amount of dichloramine also increases. As the Cl:N molar dose ratio increases beyond unity, the amount of dichloramine relative to monochloramine rapidly increases as well. For the conversion from dichloramine to trichloramine, the equilibrium constant given at 0.5M ionic strength and 25°C indicates that the amount of trichloramine to be found in equilibrium with di- and monochloramine at molar dosage ratios of up to 2.0 is negligible (Gray et al., 1978). This agrees with experimental measurement of the individual combined chlorine species as a function of approach to breakpoint (White, 1999).

These findings, coupled with the routine observation of the breakpoint at molar dosages at or below 2:1 (weight ratios Cl_2 :N below 10:1), indicate that trichloramine is not an important species in the breakpoint reaction. Rather, the breakpoint reaction leading to oxidation of ammonia nitrogen and reduction of combined chlorine is initiated with the formation of dichloramine.

The kinetics of formation of chloramine species has been investigated by various researchers since initial attempts by Weil and Morris (1949b). The formation of monochloramine is a first-order rate process with respect to both hypochlorous acid and unionized ammonia. However, determining whether this or a process involving hypochlorite ions reacting with ammonium cations is the actual mechanism of reaction is not possible solely through kinetic arguments. If the neutral species are selected as the reactants, then the rate of formation of monochloramine (r) may be described by (Morris and Isaac, 1983).

$$r \text{ (mol/L-s)} = 6.6 \times 10^8 \exp(-1510/T) [\text{HOCl}][\text{NH}_3] \quad (17-21)$$

FIGURE 17-4 Effect of pH and $\text{Cl}_2:\text{NH}_4^+$ molar ratio on dichloramine-to-monochloramine ratio (25°C).

Because hypochlorous acid dissociates into hypochlorite with a pK_a of approximately 7.6 and ammonia is able to associate with a proton to form the ammonium cation, with the pK_a for the latter of approximately 9.3, for a constant chlorine:nitrogen dose ratio, the maximum rate of monochloramine formation occurs at a pH where the product $\text{HOCl} \times \text{NH}_3$ is maximized, which is at the midpoint of the two pK values, or 8.4. At this optimum pH and the usual temperatures encountered in practice, the formation of monochloramine attains equilibrium in seconds to 1 min; however, at either a higher or lower pH, the speed of the reaction slows.

A number of the other reactions in the chlorine-ammonia system may be kinetically limited. Recently, these have been reviewed, and Table 17-2 is a compilation of the known reaction kinetics involving chlorine, ammonia, and intermediate species.

The reaction of NH_2Cl with HOCl to form NHCl_2 is catalyzed by a number of acidic species that may be present in water (Valentine and Jafvert, 1988). Possibly, a number of the other reactions in Table 17-2 can also be catalyzed in a similar manner; however, insufficient data are available to evaluate this possibility.

TABLE 17-2 Summary of Chlorine Reaction Kinetics

Reaction	Forward rate expression	Reverse rate expression
$\text{NH}_3 + \text{HOCl} \rightleftharpoons \text{NH}_2\text{Cl} + \text{H}_2\text{O}$	$6.6 \cdot 10^8 \exp\left(-\frac{1510}{T}\right)$	$1.38 \cdot 10^8 \exp\left(-\frac{8800}{T}\right)$
$\text{NH}_2\text{Cl} + \text{HOCl} \rightleftharpoons \text{NHCl}_2 + \text{H}_2\text{O}$	$3 \cdot 10^5 \exp\left(-\frac{2010}{T}\right)$	$7.6 \times 10^{-7} \text{ L/mol}\cdot\text{s}^\dagger$
$\text{NHCl}_2 + \text{HOCl} \rightleftharpoons \text{NCl}_3 + \text{H}_2\text{O}$	$2 \cdot 10^5 \exp\left(-\frac{3420}{T}\right)$	$5.1 \cdot 10^3 \exp\left(-\frac{5530}{T}\right)$
$2\text{NH}_2\text{Cl} \rightleftharpoons \text{NHCl}_2 + \text{NH}_3$	$80 \exp\left(-\frac{2160}{T}\right)$	$24.0 \text{ L/mol}\cdot\text{s}^*(*)$

Notes: Rates are in units of L/mol·s.

Concentrations are in mol/L.

Reactions are elementary and water is at unit activity

[†]This is the rate constant at 25°C.

Source: (Morris and Isaac, 1983).

When free chlorine is contacted with a water containing ammonia, the initial velocity of monochloramine formation is substantially greater than the velocity of the subsequent formation of dichloramine. Hence, relative to equilibrium levels, an initial accumulation of monochloramine will occur if large dose ratios (>5:1 Cl₂:N on a mass basis) are employed, until the dichloramine formation process can be driven (Palin, 1983).

The kinetic evolution of the chlorine-ammonia speciation process in batch systems is described by a series of coupled ordinary differential equations. While these are highly nonlinear, various authors have applied numerical integration techniques for their solution and, below the breakpoint, have found reasonable concordance between model predictions and experimental measurements (Haag and Lietzke, 1980; Isaac et al., 1985; Saunier and Selleck, 1979; Valentine and Jafvert, 1988).

The breakpoint process involves a complex series of elementary reactions, of which Eqs. (17-16) and (17-17) are the net results. Saunier and Selleck (1979) proposed that hydroxylamine (NH₂OH) and NOH may be intermediates in this reaction. Sufficient evaluation of their proposed kinetic scheme for the breakpoint process, however, has not yet been achieved to justify its use for design applications.

Example 17-2 A water supply is to be postammoniated. If the water has a pH of 7.0, a free chlorine residual of 1.0 mg/L, and a temperature of 25°C, how much ammonia should be added such that the ratio of dichloramine to monochloramine is 0.1 (assume that, on the addition of ammonia, none of the residual dissipates)?

Solution

1. From Eqs. 17-18 and 17-19, the following is determined:

$$B = 1 - 4 K_{eq} (10^{-7}) = 1 - 4 (6.7 \times 10^5)(10^{-7}) \\ = 0.732$$

From Eq. 17-16, noting that the problem condition specifies A = 0.1, the following equation is to be solved:

$$0.1 = -1 + \frac{0.732 Z}{1 - \sqrt{1 - 0.732(2 - Z)Z}}$$

This can be rearranged into a quadratic equation

$$-0.289Z^2 + 0.134Z = 0$$

- The single nonzero root gives $Z = 0.463$, which is molar ratio of chlorine (as Cl^2) to ammonia nitrogen. Because chlorine has a molecular weight of 71, 1 mg/L of free chlorine has a molarity of 1.43×10^{-5} (i.e., 1/71,000). Therefore, 3.09×10^{-5} molarity of ammonia is required, or (multiplying by the atomic weight of nitrogen, 14) a concentration of 0.43 mg/L as N of ammonia must be added. ▲

Reactions with Organic Matter. Morris (1967) has determined that organic amines react with free chlorine to form organic monochloramines. The rate laws for these reactions follow patterns similar to the inorganic monochloramine formation process, except that the rate constants are generally less. In addition, the rate constants for this process correlate to the relative basicity of the amine reactant. Organic chloramines may also be formed by the direct reaction between monochloramine and the organic amine, and this is apparently the most significant mechanism of organic N-chloramine formation at higher concentrations such as might exist at the point of application of chlorine to a water (Isaac and Morris, 1980). Some solutions of amino acids and some proteins yield breakpoint curves resembling those of ammonia solutions (Baker, 1947; Wright, 1936). However, with the chlorination of organic amines, formation of other intermediates, for example, the toxic cyanogen chloride, can occur (Shang et al., 2000).

Free chlorine reacts with organic constituents to produce chlorinated organic by-products. Murphy et al. (1975) noted that phenols, amines, aldehydes, ketones, and pyrrole groups are readily susceptible to chlorination. Granstrom and Lee (1957) found that phenol could be chlorinated by free chlorine to form chlorophenols of various degrees of substitution. The kinetics of this process depend on both phenolate ions and hypochlorous acid. If excess ammonia was present, however, the formation of chlorophenols was substantially inhibited.

DeLaat et al. (1982) determined that polyhydric phenols are substantially more reactive than simple ketones in the production of chloroform and that the rates of these processes are first order with respect to the phenol concentration and the free chlorine concentration. More significantly, the reactivity of these compounds was observed to be greater than the reactivity of ammonia with hypochlorous acid. Therefore, even if subbreakpoint chlorination is practiced, some chloroform (typically in small amounts) may be formed rapidly prior to the conversion of free to combined chlorine. Chapter 19 presents additional discussion of the formation of trihalomethanes and other disinfection by-products that can arise from reactions with natural organic matter.

The reactivity of the chlorine species with compounds responsible for some tastes and odors depends on the predominant form of chlorine present. In field tests, Krasner et al. (1986) determined that free chlorine, but not combined chlorine, could remove tastes and odors associated with organic sulfur compounds. However, many taste and odor compounds are not amenable to removal by chlorine oxidation.

Reactions with Other Inorganic Compounds. The rates of reaction between free chlorine residuals and other inorganic compounds likely to be present in water are summarized in Table 17-3 (Wojtowicz, 1979). These reactions are generally first order in each of the oxidizing agent (hypochlorous acid or hypochlorite anion) and the reducing agent.

Nitrites present in partially nitrified waters react with free chlorine via a complex, pH-dependent mechanism (Cachaza, 1976). While combined chlorine residuals were generally thought to be unreactive with nitrite, Valentine (1985) has found that the rate of decay of monochloramine in the presence of nitrite was far greater than would be predicted on the basis of the reaction of the equilibrium free chlorine; this implicates a direct reaction between NH_2Cl and NO_2^- .

TABLE 17-3 Summary of Kinetics of HOCl and OCl⁻ Reduction by Miscellaneous Reducing Agents

Oxidizing agent	Reducing agent	Oxidation product	Log <i>k</i> , L/mol-s, 25°C
OCl ⁻	IO ⁻	IO ₄ ⁻	-5.04
OCl ⁻	OCl	ClO ₂ ⁻	-7.63
OCl ⁻	ClO ₂ ⁻	ClO ₃ ⁻	-5.48
OCl ⁻	SO ₃	SO ₄ ⁻²	3.93
HOCl	NO ₂ ⁻	NO ₃ ⁻	0.82
HOCl	HCOO ⁻	H ₂ CO	-1.38
HOCl	Br ⁻	BrO ⁻	3.47
HOCl	OCN ⁻	HCO ₃ ⁻ , N ₂	-0.55
HOCl	HC ₂ O ₄ ⁻	CO ₂	1.20
HOCl	I ⁻	IO ⁻	8.52

Overall Chlorine Demand Kinetics. Chlorine demand is defined as the difference between the applied chlorine dose and the chlorine residual measured after a particular reaction or contact time (Fig. 17-3). The rate of exertion of chlorine demand in complex aqueous solutions has been the subject of numerous studies. The most systematic work has been that of Taras (1950), who chlorinated pure solutions of various organic compounds and found that chlorine demand kinetics could be described by a power function (Eq. 17-22).

$$D = kt^n \quad (17-22)$$

where *t* is the time in hours, *D* is the chlorine demand, and *k* and *n* are empirical constants. In subsequent work (Feben and Taras, 1950; Feben and Taras, 1951), it was found that chlorine demand exertion of waters blended with wastewater could be correlated to Eq. 17-22 with the value of *n* correlated to the 1 hour chlorine demand.

Haas and Karra (1984c) developed Eq. 17-23 to describe chlorine demand exertion kinetics.

$$D = C_0 \{1 - [x \exp(-k_1 t) + (1-x) \exp(-k_2 t)]\} \quad (17-23)$$

In Eq. 17-23, *x* is an empirical parameter, typically 0.4 to 0.6, and *k*₁ and *k*₂ are rate constants, typically 1.0 min⁻¹ and 0.003 min⁻¹, respectively, and *C*₀ is the chlorine dosage in mg/L.

Dugan et al. (1995) found that a Monod (Langmuir Hinshelwood) kinetic model could describe free chlorine decay in drinking water in the absence of ammonia, although the mechanism for this process was not presented. It describes chlorine decay as a reaction with *total organic carbon (TOC)* in water according to the following differential equation:

$$\frac{dC}{dt} = \frac{k(\text{TOC})C}{K(\text{TOC}) + C} \quad (17-24)$$

where TOC (assumed constant) is in mg/L as carbon, *C* is the free chlorine concentration in mg Cl₂/L, and both *k* and *K* are functions of TOC. Equation 17-24 can be integrated to the following implicit equation for chlorine concentration at time *t* (*C*_{*t*}):

$$C_t = K(\text{TOC}) \ln \left(\frac{C_0}{C_t} \right) - k(\text{TOC})t + C_0 \quad (17-25)$$

Furthermore, k and K were correlated with the initial chlorine dose (C_0) and TOC concentration. By conducting tests on a variety of waters, the constants were found to be given by the following equations (it should be noted that the pH and temperature were fixed at 8 and 20°C and the waters were of relatively low ionic strength, so that the applicability of these relationships under other conditions is unclear).

$$K = -0.85 \left(\frac{C_0}{\text{TOC}} \right)$$

$$k = 0.03 - 0.006 \left(\frac{C_0}{\text{TOC}} \right)$$
(17-26)

Chlorine Dioxide. The chlorine dioxide demand in natural waters appears to be associated as much with constituents in the water (e.g., TOC) as with the water itself. This results in interconversions to chlorite and chloride, as outlined (Eqs. (17-10) and (17-11)). At mg/L concentrations, ammonia nitrogen, peptone, urea, and glucose have insignificant chlorine dioxide demand in 1 hour (Ingols and Ridenour, 1948; Sikorowska, 1961). However, a variety of inorganic and biological materials will react (Werderhoff and Singer, 1987).

Masschelein (1979a) concluded that only the following organic-ClO₂ reactions are of significance to water applications:

1. Oxidation of tertiary amines to secondary amines and aldehydes
2. Oxidation of ketones, aldehydes, and (to a lesser extent) alcohols to acids
3. Oxidation of phenols
4. Oxidation of sulfhydryl-containing amino acids

Wajon et al. (1982) found a reaction stoichiometry of 2 mol of chlorine dioxide consumed per mole of phenol (or hydroquinone) consumed. Products formed included chlorophenols, aliphatic organic acids, benzoquinone, and (in the case of phenol) hydroquinone. The mechanism appeared to include the possible formation of hypochlorous acid as an active intermediate, and the rate of this process was found to be base catalysed and first order in each of the reactants.

In general, chlorine dioxide itself has been found to produce fewer organic by-products with naturally occurring dissolved organic material although some nonpurgeable organic halogenated compounds are formed (Rav-Acha, 1984; Richardson et al., 1994). Therefore, unless chlorine dioxide is generated in a manner in which highly pure ClO₂ is produced, chlorine may be present as an impurity, and then, the reactions of such a stream may also include those discussed regarding chlorine reactions. The inorganic by-products of chlorine dioxide decay consist of chloride (typically trace), chlorate (typically 30 percent of the applied dose), and chlorite (typically 70 percent of the applied dose); specific ratios may depend on the precise application conditions (Noack and Doeff, 1981; Werderhoff and Singer, 1987). A more detailed discussion on by-products can be found in Chap. 19.

Ozone. On addition to water, ozone reacts with hydroxide ions to form hydroxyl radicals and organic radicals. These radicals cause increased decomposition of ozone, and also are responsible for nonselective (compared to the direct ozone reaction) oxidation of a variety of organic materials. Carbonate, and possibly other ions, may act as radical scavengers and slow this process (Hoigne and Bader, 1975; Hoigne and Bader, 1976).

Gulrol and Singer (1982) determined that ozone decomposition kinetics in various aqueous solutions are second order in ozone concentration and base promoted. Some systematic difference between various buffer systems employed does occur, with borate giving higher

decomposition rates than phosphate and with phosphate at higher ionic strength giving lower decomposition rates than phosphate at lower ionic strength (1 M vs. 0.1 M). This effect was suggested as being caused by phosphate being a radical scavenger (and radical decomposition being important at higher pH values). As with any rate process, ozone decay is more rapid at higher temperatures.

As a result of these decomposition processes, the half-life of ozone in water, even in the absence of other reactive constituents, is quite short, on the order of seconds to minutes. Water chemistry may exert a strong influence on the rate and extent of ozone demand in a given application. Reactions of ozone in aqueous solution are discussed further in Chap. 7. Formation of disinfection by-products with ozone is discussed in Chap. 19.

Demand of UV. For UV disinfection, the applied dose may be described in terms of the emitted lamp power in the germicidal range per unit volume of fluid under irradiation, for example, W/m^3 . This can also be expressed as an integral over the disinfection reactor volume of the surface intensity (e.g., in W/m^2) (Severin et al., 1983b; Severin et al., 1984b).

With UV-light disinfection systems, the equivalent of demand results from dissolved and suspended materials, such as proteins, humic material, and iron compounds that absorb radiation and thus shield microorganisms. It has become increasingly practicable to use intensity monitoring within the reactor itself to monitor and correct for such effects (Larason and Ohno, 2006; Sommer et al., 2008).

Details of UV performance characteristics and modeling are discussed in Chap. 18.

ASSESSMENT OF MICROBIAL QUALITY (INDICATORS)

The microbial quality of a source water, or the efficacy of a treatment system for removing microorganisms, can be assessed either by direct monitoring of pathogens or by the use of an indicator system. Because pathogens are a highly diverse group, generally requiring a highly specialized (and often insensitive and expensive) analytical technique for each pathogen, the use of indicator organisms is a more widespread and practical strategy.

An indicator group of organisms is used to assess either source water contamination or degree of treatment; however, often the same indicator group is used to assess both properties. This poses severe constraints on the group of indicator organisms chosen. Criteria from Bonde (1966) for an ideal indicator remain valid, that is, that an ideal indicator must

1. Be present whenever the pathogens concerned are present
2. Be present only when the presence of pathogens is an imminent danger (i.e., they must not be able to proliferate to any greater extent in the aqueous environment)
3. Occur in much greater numbers than pathogens
4. Be more resistant to disinfectants and to the aqueous environment than pathogens
5. Grow readily on relatively simple media
6. Yield characteristic and simple reactions enabling, as far as possible, an unambiguous identification of the group
7. Be randomly distributed in the sample to be examined, or it should be possible to obtain a uniform distribution by simple homogenization procedures
8. Grow widely independent of other organisms present when inoculated in artificial media (i.e., the indicator bacteria should not be seriously inhibited in their growth by the presence of other bacteria)

The use of coliforms as indicator organisms stems from the pioneering work of Phelps (1909). The basic rationale was that coliforms and enteric bacterial pathogens originate from a common source, namely, human fecal contamination. Subsequent work by Butterfield and others (Butterfield and Wattie, 1946; Butterfield et al., 1943; Kabler, 1951; Wattie and Butterfield, 1944) confirmed that these organisms were at least as resistant to free or combined chlorine as enteric bacterial pathogens.

The coliform group is a heterogeneous conglomerate of microorganisms, including forms native to mammalian gastrointestinal tracts, as well as a number of exclusively soil forms. The common *fermentation tube* (FT) and *membrane filter* (MF) procedures are subtly different in the organisms they enumerate. Classically, total coliforms have been defined as gram-negative, non spore-forming bacteria that ferment lactose at 35°C to 37°C, with the production of acid and gas” (APHA et al., 1989). The FT procedure, however, ignores anaerogenic and lactose-negative coliforms, and the MF procedure ignores nonlactose fermenting strains (Clark and Pagel, 1977).

Furthermore, interferences can selectively reduce coliforms as measured by one or the other method. Allen et al. (1977), for example, found that high concentrations (> 500 to 1000/mL) of standard plate count (SPC) organisms appeared to reduce the recovery of coliforms by the MF technique when compared to the FT technique.

The fecal coliform group of organisms is that subset of coliforms that are capable of growing at elevated temperature (44.5°C). The original rationale for development of this test was to provide a more selective indicator group, excluding mesophilic coliforms indigenous, primarily, to soils. Total coliforms, however, continue to be the basic U.S. microbiological standard for drinking water because their absence ensures the absence of fecal coliforms and so is a conservative standard. However, there are continuing developments in the direct measurement of *E. coli* as an indicator group.

While coliforms, either fecal or total, may be reasonably good indicators of fecal contamination of a water supply, as early as 1922 (Anonymous, 1922) reservations were expressed about the relative resistance of coliforms to chlorine vis a vis pathogenic bacteria, and so the adequacy of the coliform test as an indicator of disinfection efficiency. It has been found that coliforms are more sensitive to disinfection by one or more forms of chlorine than various human enteric viruses (Grabow et al., 1983; Kelly and Sanderson, 1958) and the protozoan pathogens *Naegleria* (Rubin et al., 1983), *Giardia* (Jarroll et al., 1981; Korich et al., 1990; Leahy, 1985; Rice et al., 1982), and *Cryptosporidium* (Korich et al., 1990). In addition, viruses (Scarpino et al., 1977) and protozoan cysts (Leahy, 1985) have been found to be more resistant to ClO₂ inactivation than coliforms. Farooq (1976) has determined that coliforms are more resistant to ozone than viruses. Human enteric viruses have been isolated in full-scale water treatment plants practicing conventional treatment and meeting turbidity and coliform standards in the presence of free residual chlorine (Payment et al., 1985; Rose et al., 1986).

As a result of the problems with the coliform group of organisms, a number of workers have investigated alternative indicator systems with greater resistance to disinfectants than coliforms. Among the most successful of these are the acid-fast bacteria and yeasts studied by Engelbrecht and associates (Engelbrecht et al., 1979; Engelbrecht et al., 1977; Haas et al., 1983a; Haas et al., 1983b; Haas et al., 1985a; Haas et al., 1985b). In addition, work using endotoxins (Haas et al., 1983c), *Clostridia* (Cabelli, 1977; Payment and Franco, 1993), and bacteriophage (Abad et al., 1994; Grabow, 1968; Grabow and et al., 1983; Payment and Franco, 1993) has been carried out. In addition, to some degree, heterotrophic plate count (HPC) organisms may provide a conservative indicator of treatment efficiency. Indigenous aerobic spores have also been shown to be useful particularly in assessing performance of processes in which removal occurs via physical mechanisms (Rice et al., 1996). However, quantitative correlations between removal/inactivation of indicator organisms and pathogens in water treatment, including disinfection, remain elusive (Costan-Longares et al., 2008).

Therefore in U.S. practice, design, operation and regulation of water treatment remains based on total coliform, supplemented with the direct pathogen removal requirements associated with the enhanced surface water treatment rule.

Pathogens of Concern

A variety of pathogenic organisms capable of transmission by the fecal-oral route may be found in raw wastewaters. Water-borne outbreaks of shigellosis, salmonellosis, and various viral agents have been reported; in many cases these have been associated with sewage-contaminated water supplies (Blostein, 1991; Drenchen and Bert, 1994; Herwaldt et al., 1992; Levine et al., 1990; Reeve et al., 1989). Among the bacteria, *Salmonella*, *Shigella*, and *Vibrio cholerae* organisms are the classical agents of concern (Mosley, 1966). In more recent times, concern has expanded to other agents that have been found in wastewater—viruses and protozoa.

Among the viruses, enteroviruses (ECHO virus, Coxsackievirus), rotavirus, reovirus, adenovirus, and parvovirus have been isolated from wastewater (Melnick et al., 1978). New viruses that are suspected of water-borne transmission continue to be identified. Among the more important of these newly identified agents may be the Norwalk virus (Norovirus) and Calicivirus.

Over the past 20 years, significant concerns have increased over the risk from pathogenic protozoa in drinking water, particularly *Giardia* and *Cryptosporidium* (Gallaher et al., 1989; Goldstein et al., 1996; Lechevallier et al., 1991; Leland et al., 1993; Richardson et al., 1991; Rose et al., 1991; Smith, 1992). Under the USEPA Candidate Contaminant Rule, there is the periodic reassessment of additional microorganisms to consider. This process is discussed in Chap. 1.

DISINFECTION KINETICS

The information needed for the design of a disinfection system includes knowledge of the rate of inactivation of the target, or indicator, organism(s) by the disinfectant. In particular, the effect of disinfectant concentration on the rate of this process determines the most efficient combination of contact time and dose to employ.

Chick's Law and Elaborations

The major precepts of disinfection kinetics were enunciated by Chick (1908), who recognized the close similarity of microbial inactivation by chemical disinfectants to chemical reactions. A good overview of the principles of kinetic modeling of disinfection has been presented by Gyurek and Finch (1998). Disinfection is modeled as a bimolecular chemical reaction, with the reactants being the microorganism and the disinfectant, and can be characterized by a rate law as are chemical reactions.

$$r = -kN \quad (17-27)$$

In Eq. 17-27, r is the inactivation rate (organisms killed/volume-time) and N is the concentration of viable organisms. In a batch system, this results in an exponential decay in organisms, because the rate of inactivation equals dN/dt , assuming that the rate constant k is actually constant (e.g., the disinfectant concentration, temperature, and pH are constant).

Watson (1908) proposed Eq. 17-28 to relate the rate constant of inactivation k to the disinfectant concentration C .

$$k = k' C^n \quad (17-28)$$

In Eq. 17-28, n is termed the coefficient of dilution, and k' is presumed independent of disinfectant concentration, and, by virtue of Eq. 17-27, microorganism concentration. From the Chick-Watson law, when C , n , and k' are constant (i.e., no demand, constant concentration), Eq. (17-28), the rate law, may be integrated so that in a thoroughly mixed batch system,

$$\ln(N/N_0) = k' C^n t \quad (17-29)$$

In Eq. 17-29, N and N_0 are, respectively, the concentrations of viable microorganisms at time t and at time zero. When disinfectant composition changes with time or when another configuration than a batch (or plug flow; see Chap. 4 for an explanation that batch and plug flow reactors yield the same performance) system is used, the appropriate rate laws characterizing disinfectant transformation (Haas and Karra, 1984b) along with the applicable mass balances must be used to obtain the relationship between microbial inactivation and concentration and time.

Inactivation of microorganisms in batch experiments, even when disinfectant concentration is kept constant, does not always follow the exponential decay pattern predicted by Eq. 17-29. Indeed, two common types of deviations are noted (Fig. 17-5). In addition to the

FIGURE 17-5 Chick's law and its deviations.

linear Chick's law decay, the presence of "shoulders," or time lags, until the onset of disinfection is often observed. Also, some microorganisms and disinfectants exhibit a "tailing" wherein the rate of inactivation progressively decreases. In some cases, a combination of both of these behaviors is seen.

Even if deviations from Chick-Watson behavior are observed, plotting combinations of disinfectant concentration and time to produce a fixed percent inactivation is generally possible. Such plots tend to follow the relationship $C_m = \text{constant}$, where the constant is a function of the type of organism, pH, temperature, type of disinfectant, and extent of inactivation. Such plots are linear on a log-log scale. If the value of n is greater than 1, a proportionate change in disinfectant concentration produces a greater effect than a proportionate change in time. In many cases (Hoff, 1986), the Chick-Watson law n value is close to 1.0, and hence a fixed value of the product of concentration and time ($C \times T$) results in a fixed degree of inactivation (at a given temperature, pH, etc.).

In the chemical disinfection of a water, the disinfectant residual may change with time, and, particularly when organic or ammonia nitrogen is present, during the initial moments of contact the chemical form(s) of halogens such as chlorine undergo rapid transformations from the free to the combined forms. Because C would thus not be a constant, typically disinfection results obtained in batch systems exhibit "tailing," the degree of which may depend on the demand and the concentration of reactive constituents (such as ammonia and organic nitrogen compounds) in the system (Jafvert and Valentine, 1992; Olivieri et al., 1971). Determination of the disinfectant residual (and its chemical forms) is more critical than the disinfectant dose in these systems.

For chlorine disinfection, for example, by knowing the rate laws for inactivation by individual separate species and the dynamics of chlorine species interconversions, as described previously, an overall model for chlorine inactivation can be formulated (Haas and Karra, 1984b). In doing this computation, the individual rates are usually assumed to be additive (Fair et al., 1948), although this assumption has not yet been experimentally verified.

"Shoulder" inactivation curves may be explained by a multitarget model (assuming that multiple locations within an organism need to be deactivated before death occurs) (Hiatt, 1964), by a series event model (assuming that a location with an organism must be subject to multiple sequential reactions before death occurs) (Severin et al., 1984a), or by a diffusional model (assuming that transport of disinfectant serves to retard the rate of inactivation) (Haas, 1980). Tailing inactivation curves may be explained either by a vitalistic hypothesis in which individuals in a population are nonidentical, and their inherent resistance is distributed in a permanent (time-independent) manner or by a mechanistic concept (Cerf, 1977). In the latter case, four particular mechanisms have been advanced leading to tailing.

1. Conversion to resistant form during inactivation (hardening)
2. Existence of genetic variants of differing sensitivity
3. Protection of a subpopulation or variations in received dose of disinfectant
4. Clumping of a subpopulation

The hardening process and resultant tailing have received wide attention following discoveries of apparent hardening in the formaldehyde inactivation of poliovirus prepared for the Salk vaccine (Nathanson and Langmuir, 1963). Gard (1960) proposed an empirical rate law for this behavior, which has been used by Selleck et al. (1978) in the analysis of wastewater chlorination kinetics. Tailing behavior has been found for viral and coliform inactivation by ozone (Katzenelson et al., 1974) and for coliform inactivation by free chlorine (Haas and Morrison, 1981; Olivieri et al., 1971).

Hom's Law

Hom (1972) developed a flexible but highly empirical kinetic formulation for the inactivation rate based on modifying Eqs. 17-27 and 17-28 to the following form:

$$r = -k''mNt^{m-1}C^n \quad (17-30)$$

The parameter m quantifies nonlinearity from the Chick-Watson behavior with time (if $m = 1$, Eq. 17-30 becomes identical to the combination of Eqs. 17-28 and 17-29. Eq. 17-30 is difficult to use as a rate model since it contains time as an explicit variable. A formulation leading to the classical Hom integrated relationship can be written as (Haas and Joffe 1994)

$$r = -mN(k''C^n) \left[\ln \left(\frac{N}{N_0} \right) \right]^{(1-1/m)} \quad (17-31)$$

On integration, if C is constant, this results in the following relationship:

$$\ln \left(\frac{N}{N_0} \right) = -k''C^n t^m \quad (17-32)$$

Depending upon the value of m , both shoulders and tailing may be depicted by Eq. 17-32. In early work, Fair et al. (1948) used a model of the form of Eq. 17-32 with $m = 2$ to analyze *E. coli* inactivation by free and combined chlorine.

Example 17-3 A certain water supply has experienced regrowth of HPC organisms during distribution. To maintain adequate system water quality, a decision has been made to keep the concentration of HPC organisms below 10/mL at the entry point to the distribution system (i.e., following disinfection). Disinfection using free residual chlorine is practiced. As part of the laboratory investigation to develop design criteria for this system, the inactivation of the HPC organisms is determined in batch reactors (beakers). The pH and temperature are held constant at the expected final water conditions. Using water with an initial HPC of 1000/mL, the following data are taken:

Cl ₂ residual, mg/L	Contact time, min	HPC remaining, #/mL
0.5	10	40
0.5	20	4
0.5	30	1
1.0	5	35
1.0	10	4
1.0	15	1
1.5	2	98
1.5	5	10
1.5	10	1

From this information, determine the best fit using the Hom inactivation model, and compute the necessary chlorine residual that will achieve HPC < 10/mL (from an initial concentration of 1000/mL) at a contact time of 10 minutes.

Solution

1. This problem can be solved using a maximum likelihood technique to fit the Hom model to the data. Regression methods, however, can be used in two different

ways—multiple linear regression, and nonlinear regression (Haas and Heller, 1989; Haas et al., 1988). In a batch system, without chlorine demand, the Hom model is that of Eq. 17-32.

Equation 17-32 can be rearranged as

$$\ln \left[-\ln \left(\frac{N}{N_0} \right) \right] = \ln(k'') + n \cdot \ln(C) + m \cdot \ln(t)$$

2. A multiple linear regression using $\ln \left[-\ln \left(\frac{N}{N_0} \right) \right]$ as the dependent variable and $\ln(C)$ and $\ln(t)$ as the independent variables produces an intercept (equal to $\ln(k'')$) and slopes equal to n and m . This computation can be handled on common spreadsheet programs, as well as statistical packages. Transformation of the data given produces the following values of the dependent and independent variables:

$\ln \left[-\ln \left(\frac{N}{N_0} \right) \right]$	$\ln(t)$	$\ln(C)$
1.169	2.303	-0.693
1.709	2.996	-0.693
1.933	3.401	-0.693
1.210	1.609	0
1.709	2.303	0
1.933	2.708	0
0.843	0.693	0.405
1.527	1.609	0.405
1.933	2.303	0.405

The results are

$$k'' = 1.11$$

$$n = 0.68$$

$$m = 0.70$$

$$\text{Correlation coefficient} = 0.997$$

3. The final estimation equation then becomes

$$\ln \left(\frac{N}{N_0} \right) = -1.11 C^{0.68} t^{0.7}$$

4. Inserting the design specifications gives the following results:

$$\ln \left(\frac{10}{1000} \right) = -1.11 C^{0.68} t^{0.7}$$

$$C^{0.68} = 0.83$$

$$C = 0.77 \frac{\text{mg}}{\text{L}}$$

Hence, if a 10 minute contact time is accepted as a worst-case condition and good contactor hydraulics are assumed, the maximum chlorine residual required to achieve the design inactivation is 0.77 mg/L. From this information, and the chlorine demand of the water, the capacity of a chlorine feed system can be computed. ▲

Power Law Models

Another class of models can be obtained by assuming that inactivation is other than first order in surviving microbial concentrations. Depending on the order chosen, either tailing or shoulders can be produced. For example, Roy et al. (1979, 1981, 1981), using continuous flow stirred tank reactor (CFSTR; see Chap. 4 for the hydraulic characterization of CFSTRs) studies on inactivation of Poliovirus I with ozone in demand-free systems, developed the following rate law:

$$r = -kCN^{0.69} \quad (17-33)$$

A similar model was used by Benarde et al. (1967) to analyze *E. coli* inactivation by chlorine dioxide and for analysis of various organisms in ozone contacting (Zhou and Smith, 1994; Zhou and Smith, 1995).

The model of Roy, which is power law in N , and the Hom model can be combined into a generalized formulation for the reaction rate and for the survival ratio (under demand-free conditions) as shown in Eq. 17-34. This was first developed by Anotai (1996) and written in more convenient form by Gyurek and Finch (1998).

$$r = -kmN^x t^{m-1} C^n$$

$$\ln\left(\frac{N}{N_0}\right) = \left(\frac{1}{x-1}\right) \ln[1 + N_0^{x-1}(x-1)kC^n t^m] \quad (17-34)$$

This relationship, having four parameters (x, k, n, m) is highly flexible. In addition to describing inactivation curves with shoulders and tailing off, it is capable of describing inactivation curves with inflection points, such as the S curve and inverted S curve in Fig. 17-5. In contrast to the Chick, Chick-Watson, and Hom models, the Hom power law (and power law) models predict inactivation to be a function of initial microorganism concentration (N_0) as long as $x \neq 0$. This dependency has been observed experimentally (Haas and Kaymak, 2003; Haas and Kaymak, 2008).

Models Accounting for Disinfectant Decay

If the disinfectant concentration is not constant, then the rate laws for inactivation must be combined with those for disinfectant demand. For example, in the case of the Hom model with first-order decay in a batch system, the following approach has been developed (Haas and Joffe, 1994). The time course of disinfectant concentration is given by

$$C = C_0 \exp(-k^* t) \quad (17-35)$$

where C_0 is the initial concentration and k^* is the demand constant. This equation is substituted into the Hom rate expression and then into a batch mass balance to yield

$$\frac{dN}{dt} = -mN[k(C_0 \exp(-k^* t))^n]^{1/m} \left[-\ln\left(\frac{N}{N_0}\right) \right]^{(1-1/m)} \quad (17-36)$$

This equation has an analytical solution in terms of an incomplete gamma function, which under conditions generally present in disinfection can be approximated as (Haas and Joffe, 1994) by

$$\ln\left(\frac{N}{N_0}\right) = -kC_0^n t^m \left[\frac{1 - \exp\left(\frac{-nk^* t}{m}\right)}{\frac{nk^* t}{m}} \right]^m \quad (17-37)$$

For other disinfection decay rate laws, the solution may be obtained by numerical integration (Finch et al., 1993).

Impact of Temperature and Other Water Chemistry Factors

Disinfection, like all other rate processes, is temperature dependent. This dependency may be quantified by the Arrhenius relationship.

$$k = k_0 \exp(-E_a/RT) \quad (17-38)$$

where k is a rate constant characterizing the reaction (such as the Chick-Watson k' value), T is the absolute temperature, R is the ideal gas constant, k_0 is called the *frequency factor*, and E_a , with units of energy/mole, is the activation energy. E_a is always positive, and as it increases, the effect of temperature becomes more pronounced. The values of E_a and k_0 may be determined from rates of inactivation obtained as a function of temperature. As E_a increases, the effect of temperature on the rate increases. For example, E_a of 10 kcal/mol doubles the rate between 10°C and 20°C. In contrast, activation energies for breaking hydrogen bonds are 3 to 7 kcal/mol (Bailey and Ollis, 1986). Activation energies less than this range suggest physical (e.g., transport) limitations rather than chemical reactions.

It should be noted that, like pH, other water chemistry factors can influence the kinetics of disinfection, although the mechanism for many of these effects are unknown. This has been shown to be the case for chlorine and chloramines (Haas et al., 1996) and ozone (Finch et al., 2001). While generic kinetics (e.g., the $C \times T$ tables in Tables 17-7 and 17-8) have been published, these generally utilize laboratory buffered water, and a prudent designer particularly for a large system would consider doing testing to verify inactivation rates under water quality conditions particular to the situation.

MODE OF ACTION OF DISINFECTANTS

Chlorine

Since Nissen (1890), free chlorine at low pH has been known to be more biocidal than free chlorine at high pH. Holwerda (1928) proposed that hypochlorous acid was the specific agent responsible for inactivation, and thus the pH effect. Fair et al. (1948) determined that the pH dependency of free chlorine potency correlated quantitatively with the dissociation constant of hypochlorous acid. Chang (1944) determined that, at low pH, the association of chlorine molecules with cysts of *Entamoeba histolytica* was greater than at high pH. Friberg (1957; Friberg and Hammarstrom, 1956), and Haas and Engelbrecht (1980a), using radioactive free chlorine, found that similar results with respect to bacteria and that the microbial binding of chlorine could be described by typical chemical isotherms. With respect to viruses, this association of chlorine parallels the biocidal efficacy of hypochlorous acid, hypochlorite, and monochloramine (Dennis et al., 1979a; Dennis et al., 1979b; Olivieri et al., 1980).

Once taken into the environment of the living organism, chlorine may enter into a number of reactions with critical components causing inactivation. In bacteria, respiratory, transport, and nucleic acid activity are all adversely affected (Haas and Engelbrecht, 1980a and b; Venkobachar et al., 1975; Venkobachar et al., 1977). In bacteriophage f2, the mode of inactivation appears to be disruption of the viral nucleic acid (Dennis et al., 1979a). With poliovirus, however, the protein coat, and not the nucleic acid, appears to be the critical site for inactivation by free chlorine (Fujioka et al., 1985; Tenno et al., 1980).

The rate of inactivation of bacteria by monochloramine is greater than could be attributed to the equilibrium-free chlorine present in solution. This argues strongly for a direct inactivation reaction of combined chlorine (Haas and Karra, 1984a). Although organic chloramines are generally measured as combined or total chlorine by conventional methods, they are of substantially lower effectiveness as disinfectants than inorganic chloramines (Feng, 1966; Wolfe and Olson, 1985).

In general, the rate of inactivation of microorganisms by various disinfectants increases with increasing temperature. This may be characterized by an activation energy, a Q_{10} (factor of increase for every 10°C temperature increase) or a temperature multiplier (the latter two methods being an approximation of an Arrhenius approach).

Surprisingly, Scarpino et al. (1972) reported that viruses were more sensitive to free chlorine at high pH than at low pH. A variety of subsequent authors confirmed these findings with viruses and with bacteria (Berg et al., 1989; Haas, 1981; Haas et al., 1986, 1990). Hypochlorite can form neutral ion pairs with sodium, potassium, and lithium, and (particularly at ionic strengths approaching 0.1 M) these can increase disinfection efficiency by free chlorine at high pH (above 8.0) (Haas et al., 1986). Calcium enhancement of chlorine inactivation of coliforms has also been reported (Haas and Anotai, 1996).

Chlorine Dioxide

The dependence of inactivation efficiency on pH is weaker for chlorine dioxide than for chlorine and more inconsistent. Benarde et al. (1965), working with *E. coli*, and Scarpino et al. (1979), working with Poliovirus I, found that the degree of inactivation by chlorine dioxide increases as pH increases. However, for amoebic cysts, as pH increases, the efficiency of inactivation by chlorine dioxide decreases (Chen et al., 1985). Barbeau et al. (2005) found that the efficiency of chlorine dioxide against bacteria spores and bacteriophage was also greater at pH 8.5 than at pH 6.5, and it was hypothesized that some inactivation processes are catalyzed by the presence of hydroxide ion.

The physiological mode of inactivation of bacteria by chlorine dioxide has been attributed to a disruption of cell envelope permeability (Berg et al., 1986). In the case of viruses, chlorine dioxide preferentially inactivated capsid functions, rather than nucleic acids (Noss et al., 1985; Olivieri et al., 1985).

Benarde et al. (1967) computed the activation energy for the inactivation of *E. coli* by chlorine dioxide at pH 6.5 as 12 kcal/M. An identical number was computed for the disinfection of Poliovirus Type I by chlorine dioxide at pH 7 (Scarpino et al., 1979).

Ozone

Understanding of the mode of inactivation of microorganisms by ozone remains hindered by difficulties in measuring low concentrations of dissolved ozone. The effect of pH on ozone inactivation of microorganisms appears to be predominantly associated with changing the stability of residual ozone, although additional work is needed. Farooq (1976) found little effect of pH on the ability of dissolved ozone residuals to inactivate acid-fast bacteria. Roy (1979) found a slight diminution of the virucidal efficacy of ozone residuals as pH decreased; however, Vaughn, as cited in Hoff (Hoff, 1986; Hoff and Akin, 1986), noted the opposite effect. The principal action of ozone as a disinfectant occurs from the dissolved ozone, rather than physical contact with ozone gas bubbles (Dahi and Lund, 1980; Farooq, 1976). The disparate conclusions of the early studies may have been due to difficulties with measuring ozone residuals. In the USEPA *ct* tables, the efficacy of ozone residuals are regarded as being independent of pH.

Bacterial cells lacking certain DNA polymerase gene activity were found to be more sensitive to inactivation by ozone than wild-type strains, strongly implicating physico-chemical damage to DNA as a mechanism of inactivation by ozone (Hamelin and Chung, 1978). For poliovirus, the primary mode of inactivation by ozone also appears to be nucleic acid damage (Roy et al., 1981).

Energies for ozone inactivation of *Giardia* and *Naegleria* cysts were reported by Wickramanayake et al. (1985). At pH 7, the activation energies were 9.7 and 16.7 kcal/M. For Poliovirus Type I, Roy et al. (1981) estimated an activation energy of 3.6 kcal/M at pH 7.2. If the latter value is correct, its low value suggests that ozone inactivates a virus by a diffusion process, rather than a reaction controlled one.

UV Radiation

The application of UV radiation is covered in detail in Chap. 18. In this section, broad aspects of UV are summarized in a parallel fashion to chemical disinfectants.

The mode of inactivation of microorganisms by UV radiation is quite well characterized. Specific deleterious changes in nucleic acid arise on exposure to UV radiation (Jagger, 1967). These may be repaired by light-activated as well as dark repair enzymes in vegetative microorganisms. The phenomenon of photoreactivation of UV disinfected microorganisms has been demonstrated in municipal effluents (Scheible and Bassell, 1981). However, the operation of these repair processes in microorganisms discharged to actual distribution systems or receiving waters is not clear (Bohrerova and Linden, 2007). Pathogenic protozoan cysts and oocysts do not appear capable of UV photoreactivation.

Severin (1983a) showed that the series event model for inactivation (in which it is assumed that a sequential set of processes must occur to achieve kill) describes the kinetics of UV disinfection quite well. Kinetic parameters for inactivation are shown in Table 17-4.

TABLE 17-4 Kinetics of UV Inactivation

	k (cm ² /(mW-s))	Number of events	Activation energy (kcal/mole)
<i>E. coli</i>	1.538	9	0.554
<i>Candida parapsilosis</i>	0.891	15	0.562
φ2 virus	0.0724	1	1.023

Source: Severin et al., 1983a.

Activation energies for UV inactivation using this model were lower than for chemical disinfection (indicating the relative insensitivity to temperature) (Severin et al., 1983a). These are considerably less than the activation energies for chemical disinfectants in accord with the apparent (purely physical) mechanism of UV inactivation. This also indicates, as a practical matter, that the effect of temperature on UV performance is much less than for chemical agents such as ozone or chlorine.

The pH dependency of UV inactivation has not been characterized in controlled systems. However, since the mechanism of UV inactivation appears to be purely photochemical, it is not anticipated that pH would dramatically alter the efficiency of UV disinfection. However, insofar as pH may affect the light absorption characteristics of humic materials, an indirect effect of pH (by changing the extent of demand) on inactivation efficiency may exist.

Influence of Physical Factors on Disinfection Efficiency

The apparent increase in microbial resistance by clumping has already been discussed. Microorganisms can also be partially protected against the action of disinfectants by adsorption to or enmeshment in nonviable solid particles present in water. Stagg et al. (1978) and Hejkal et al. (1979) found that fecal material protected poliovirus against inactivation by combined chlorine. Boardman and Sproul (1977) found that kaolinite, alum flocs, and lime sludge increased the resistance of Poliovirus Type 1 to free chlorine in demand-free systems. For chlorine dioxide, bentonite turbidity protects poliovirus against the action of chlorine dioxide (Brigano and et al., 1978). Although there was some protection from ozone inactivation afforded to coliform bacteria and viruses by fecal matter and by cell debris, at ozone doses usually employed in disinfection, it was still possible to achieve more than 99.9 percent inactivation within 30 sec (Sproul 1978).

The particular conditions wherein particles can protect viruses from disinfection have been recently reviewed (Templeton et al., 2008).

Influence of Physiological Factors on Disinfection Efficiency

The physiological state of microorganisms, especially vegetative bacteria, may influence their susceptibility to disinfectants. Milbauer and Grossowicz (1959) found that coliforms grown under minimal conditions were more resistant than cells grown under enriched conditions. Similarly, Berg et al. (1985) found that chemostat-grown cells produced at high growth rates were more sensitive to disinfectants than cells harvested from low growth rates. A simple subculturing of aquatic strains of *Flavobacterium* has been found to increase sensitivity to chlorine disinfection (Wolfe and Olson, 1985).

Postexposure conditions can also influence apparent microbial response to disinfectants (Milbauer and Grossowicz, 1959). In three New England water treatment plants and distribution systems sampled for total coliforms using both standard MF techniques and media to recover sublethally injured organisms (m-T7 agar medium) from 8 to 38 times as many coliforms were recovered on the latter medium than on the former medium (McFeters et al., 1986). This sublethal injury does not adversely affect pathogenicity to mice (Singh et al., 1986).

With viruses, the phenomenon of multiplicity reactivation can occur when individual viruses, inactivated by different specific events, are combined in a single host cell to produce a competent and infectious unit. This has been demonstrated to occur in enteric viruses inactivated by chlorine (Young and Sharp, 1979).

The survivors from disinfection can exhibit inheritable increased resistance to subsequent exposure. This was first demonstrated for poliovirus exposed to chlorine (Bates et al., 1978). However, demonstration in bacteria has not been consistent (Haas and Morrison, 1981; Leyval, 1984). Subculturing of survivors from iodine disinfection of *Burkholderia (Pseudomonas) cepacia* have been found to have increased resistance to iodination, although expression of this increased resistance could be modulated by environmental conditions (Pyle et al., 1994).

DISINFECTANT RESIDUALS FOR POSTTREATMENT PROTECTION

One factor that is important in evaluating the relative merits of alternative disinfectants is their ability to maintain microbial quality in a water distribution system. With respect to chlorine, it has been suggested that free chlorine residuals may serve to protect the distribution system against regrowth, or at least to serve as a sentinel for the presence of

contamination (Snead et al., 1980). However, other studies have noted the lack of correlation between distribution system water quality and the form or concentration of chlorine residual (Haas et al., 1983a). Similarly, Lechevallier (1990) has reported that microbial slimes grown in tap water may be more sensitive to inactivation by combined chlorine than by free chlorine transported by the overlying water. It must be recognized that, regardless of the disinfectant chosen, the water distribution system can never be regarded as biologically sterile. As shown by Means et al. (1986a), shifts in the dominant form of disinfectant (e.g., from free chlorine to monochloramine) can result in shifts in the taxonomic distribution of microorganisms that inhabit the distribution system.

It must be noted that there are differences between the distribution system in the United States and many distribution systems in Europe (Haas, 1999; Hydes, 1999; Trussell, 1999). In the United States, most utilities strive to maintain minimum chlorine residuals in the distribution system (and there is a strong incentive to do so under regulatory requirements), with minimum residuals generally exceeding 0.2 mg/L total chlorine. In a number of countries in Europe and elsewhere the philosophical approach to maintaining distribution system water quality relies on nutrient control (principally, degradable organic matter) rather than on disinfectant residuals.

While chlorine dioxide has somewhat greater decay than chlorine in distribution, it has been found to be as or more effective than free chlorine (Gagnon et al., 2004). With respect to both ozone and UV, their absence of a residual may necessitate the addition of a second disinfectant if a residual in the distribution system is desired. Further discussion on this point is in Chap. 21.

DESIGN AND APPLICATION OF TECHNOLOGIES

With the increasing and conflicting objectives that must be met by disinfection processes, water utilities are moving toward the use of multiple disinfectants. In general, disinfectants may be applied at three locations within treatment. When applied prior to coagulation, it is generally termed preoxidation or predisinfection. While some inactivation may occur due to predisinfection, generally this is minor due to substantial disinfectant demand. Primary disinfection occurs when disinfectant is applied after clarification by sedimentation or dissolved air flotation, either before or after filtration, and with contact time prior to distribution. The majority of inactivation by disinfection processes is expected to occur due to this application. If another application occurs following primary disinfection (or if ammonia is added to convert a free residual to a combined residual), this is termed *secondary disinfection*. When secondary disinfection is used, this disinfectant is applied just before entry into the distribution system. Generally the objective of secondary disinfection is to allow the maintenance of an active disinfectant residual into the distribution system.

Chlorination

As noted previously, chlorine may be obtained for disinfection in three forms, gaseous Cl_2 , liquid NaOCl , and solid $\text{Ca}(\text{OCl})_2$, as well as generated on-site. Generally, on a per-unit mass basis of active chlorine, the least expensive form with large use rates is liquified chlorine gas. The use of liquified chlorine gas carries with it certain risks associated with accidental leakage of the gas. As a result, a number of utilities have elected to use the somewhat more expensive sodium hypochlorite, NaOCl , as a source of disinfectant.

The intrinsic hazards associated with gaseous chlorine at wastewater (and drinking water) disinfection facilities has long been recognized (White, 1999). It is increasingly

recognized that storage of large amounts of gaseous chlorine could present a potential target for malicious activity such as by terrorists (Copeland, 2007). As a result, particularly since 2001, water and wastewater utilities have switched from gaseous chlorine to sodium hypochlorite (Jones et al., 2007; U.S. Government Accountability Office, 2007).

The use of sodium hypochlorite solutions as sources of chlorine for water disinfection is not without its own risks. As a strong oxidant, the solutions must be stored and transported in chemically resistant tanks and pipeline systems, and organic matter must be prevented from entering the tanks. Tanks must be vented since the solutions will decompose on a constant basis. Finally, sodium hypochlorite solutions are corrosive and present potential worker safety hazards in the event of a spill or tank breach.

On addition to water, chlorine gas reduces the pH and alkalinity, while sodium hypochlorite raises the pH and alkalinity. In poorly buffered water, when gaseous chlorine is used, the addition of a pH-buffering chemical may be necessary to control the distribution system water aggressiveness.

Chlorine and hypochlorites have been produced from the electrolysis of brines and saline solutions since the early twentieth century (Rideal, 1908). This remains an attractive option for remote treatment plants near an inexpensive source of brine. The basic principle is the use of a dc electric field to effect the oxidation of chloride ion with the simultaneous and physically separated reduction usually of water to gaseous hydrogen.

In practice, it is necessary to operate electrolytic chlorine generating units at voltages as high as 3.85 volts in order to provide reasonable rates of generation. At these high voltages, however, additional oxidations such as formation of chlorate, ohmic heating, and incomplete separation of hydrogen from oxidized products with subsequent dissipative reaction combine to produce system inefficiencies. Current on-site hypochlorite generators have salt efficiencies of 3 kg NaCl/kg (3 lb/lb) free chlorine and power efficiencies of 0.91 kw-hr/kg (2 kw-h/lb) free chlorine (Garibi, 2007).

Chlorine can be applied at a variety of points within treatment. Table 17-5, from the 1989 AWWA Committee Survey illustrates the frequency with which chlorine is applied at various locations. The most recent survey does not contain data on details of points of application (AWWA Disinfection Systems Committee, 2008); however, it is likely that chlorination before sedimentation has decreased in prevalence.

TABLE 17-5 Points of Application of Chlorine or Hypochlorite

Point of application	Frequency of plants (<i>N</i> = 268)
Before coagulation	18.66%
After coagulation	5.97%
After sedimentation and before filtration	31.34%
After filtration	47.01%
Within the distribution system	15.67%

Notes: Percentages sum to more than 100% due to multiple points of application at a given facility.

Source Water Chlorination/Preoxidation. Prechlorination, the addition of chlorine at an early point within a treatment plant, is designed to minimize operational problems associated with biological slime formation on filters, pipes, and tanks, and also to release potential taste and odor problems from such slimes. In addition, prechlorination can be used for the oxidation of hydrogen sulfide or reduced iron and manganese. Probably the most

common point of addition of chlorine for prechlorination is the rapid-mix basin (where coagulant is added). However, with present concerns for minimizing the formation of chlorine by-products, the use of prechlorination is being supplanted by the use of other chemical oxidants (e.g., chlorine dioxide, permanganate) for the control of biological fouling, odor, or amount of iron or manganese.

Postchlorination. Postchlorination, or *terminal disinfection*, is the primary application for microbial reduction. It has been most common to add chlorine for these purposes either immediately before the clearwell or immediately before the granular media filter. In the latter case, the filter itself provides a contact time for disinfection.

In general, the use of specific contact chambers subsequent to the addition of chlorine to a water has been uncommon. Instead, the clearwell, or finished water reservoir, serves the dual function of providing contact to ensure adequate time for microbial inactivation prior to distribution. The distribution system itself, from the entry point until the first consumers tap, provides additional contact time. Many times, however, the water treatment plant itself is the first point of water consumption. Table 17-6 summarizes distributions of first contact times.

TABLE 17-6 Residual and Contact Time to First Customer: 1989 AWWA Disinfection Committee Survey of Utilities (N = 178)

Residual (mg/L)	Contact time to first customer (min)						Total
	0	1-9	10-29	30-60	75-240	>240	
0-.35	4.49%	0.56%	0.56%	0.56%	1.12%	0.56%	7.87%
.4-.95	10.1%	3.93%	3.93%	3.93%	3.37%	2.81%	28.09%
1-1.5	14.6%	5.62%	2.25%	4.49%	1.69%	5.62%	34.27%
1.6-2	3.93%	1.69%	1.69%	3.93%	3.37%	1.69%	16.29%
>2	6.74%	0.56%	0.56%	0.56%	2.81%	2.25%	13.48%
Total	39.9%	12.4%	8.99%	13.5%	12.4%	12.9%	100%

The hydraulic characteristics of most finished water reservoirs, however, are not compatible with the ideal characteristics of chlorine contact chambers. The latter are most desirably plug flow, whereas the former most usually have a large degree of dispersion. Chapter 4 has a detailed discussion of ideal and non-ideal reactors (contact chambers) and how they may be characterized.

Superchlorination/Dechlorination. In the process of superchlorination/dechlorination, which has generally been employed when it is desired to treat a poor-quality water (with high ammonia-nitrogen concentrations, or perhaps with severe taste and odor problems), chlorine is added beyond the breakpoint. This process has become infrequent due to concerns with by-product formation. In this process, the ammonia-nitrogen present is oxidized. Generally, the residual chlorine obtained at this point is higher than may be desired for distribution. The chlorine residual may be decreased by the application of a dechlorinating agent (sulfur compounds or activated carbon).

Chloramination. Chloramination, the simultaneous application of chlorine and ammonia, or the application of ammonia prior to or after the application of chlorine, resulting in a stable combined residual, has been a long-standing practice at many utilities, with Denver using it since 1914 (Trussell and Kreft, 1984). Typical dose ratios are 5 to 7:1 on a Cl₂ to

ammonia-nitrogen weight basis. With increasing concerns for disinfection by-products, the use of chloramination has been increasing as well.

A major concern that has been identified in chloramination arises during the transition from free chlorination to chloramination (Means et al., 1986a). Before and after data on distribution system water quality were collected at the Metropolitan Water District of Southern California when the distribution system was changed from free chlorine residual to combined (monochloramine) chlorine residual. There was no effect on coliform counts; however, the plate counts on m-R2A medium increased dramatically (with some increase also observed using pour plates/TGEA medium). In one of the reservoirs, a precipitous drop in chlorine residual occurred following the switchover, associated with nitrification in the reservoir and growth of microorganisms. This was postulated to occur as a reaction between nitrites and monochloramine. The occurrence of postchloramination nitrification may also result in problems with pH control and corrosion control.

Influence of Relative Point of Addition of Chlorine and Ammonia. Details of chloramination practice can dramatically influence process performance. Options as to pre- versus postammoniation, or pH, in particular, must be considered.

Prereacted chloramine residuals are more effective bactericides (*E. coli*, demand free batch tests) at pH 6 than at pH 8, and at high Cl₂:N ratios (5:1) rather than low ratios (down to 2:1). Concurrent addition of ammonia and chlorine was as effective as preammoniation (and at pH 6 was nearly as effective as free residual chlorination). Both simultaneous addition and preammoniation were more effective than prereaction of the chlorine, except at pH 8, where all three modes behaved in a similar manner (Ward et al., 1984).

In pilot plant studies, Means et al. (1986b) found that concurrent and sequential methods (chlorine at rapid mix and ammonia at end of flocculation tank) gave better performance at removing m-SPC bacteria than preammoniation (but poorer than free chlorination). Concurrent addition gave about as low a total trihalomethane value as preammoniation, and lower than the use of free chlorine alone.

In the presence of concentrations of organic nitrogen similar to ammonia, prereacted chloramines may give better performance than dynamically formed chloramines from preammoniation due to the favorable competition for chlorine by many organic nitrogen compounds (and their low biocidal potency) relative to inorganic nitrogen (Wolfe and Olson, 1985). However, such waters will likely produce high concentrations of N-Nitrosodimethylamine (NDMA), an emerging disinfection by-product (Mitch et al., 2003).

Contact Tank Hydraulics Characterizing and Improving. Any mixing—deviations from ideal plug flow behavior—reduces the disinfection efficiency of chlorine contactors. In serpentine contactors, the degree of mixing (i.e., the dispersion) can be estimated from the geometry of the tank, in particular the length-to-width ratio (Stover et al., 1986).

When a finished water reservoir is used as a contact tank, severe mixing, and other deviations from ideal flow (due for example to density, and temperature differences and wind) may occur (Boulos et al., 1996; Grayman et al., 1996). Various types of baffles may be used to counteract these tendencies (Grayman et al., 1996). In addition, both hydraulic scale models and computational fluid dynamic (CFD) models may be useful in assessing potential improvements in flow patterns from alternative baffling arrangements (Boulos et al., 1996; Grayman et al., 1996; Stefan et al., 1990). Similarly, chlorine contact chambers may be upgraded in terms of hydraulic performance by installation of baffles (Bishop et al., 1993).

Chlorine Dioxide

It is necessary to generate chlorine dioxide on a continuous basis for use as a disinfectant. Although a few European potable water treatment plants have been reported to use the

acid-chlorite generation process (Miller et al., 1978), the most common synthesis route for disinfectant ClO_2 generation is the chlorine-chlorite process.

Chemistry of Generation. For practical purposes in water treatment, chlorine dioxide is generated exclusively from chlorite in as much as the reductive processes using chlorate as a starting material are capital intensive and competitive only at larger capacities (Masschelein, 1979b).

In the acid-chlorite process, sodium chlorite and hydrochloric acid react according to Eq. 17-39.

The resulting chlorine dioxide may be evolved as a gas or removed in solution. Mechanistically, this process occurs by a series of coupled reactions, some of which may involve the in situ formation of chlorine, the catalysis by chloride, and the oxidation of chlorite by chlorine (Gordon et al., 1972; Masschelein, 1979a; Noack and Doeff, 1979). In addition, the yield of the reaction as well as the rate of the process is improved by low pH values in which both gaseous chlorine and chlorous acid formation are favored. Under these favorable conditions, the reaction proceeds in the order of minutes; however, to achieve these conditions, excess hydrochloric acid is required.

During the acid-chlorite reaction, the following side reactions result in chlorine production:

if equal weights of the reactants are added, than close to 100 percent of the conversion of chlorite may occur; this means a final pH below 0.5 (Masschelein, 1979b).

Alternatively, chlorine dioxide may be produced by the oxidation of chlorite with chlorine gas according to the reaction in Eq. 17-43.

As in the previous case, decreases in pH accelerate the rate of this process, as do excess amounts of chlorine gas. However, if chlorine gas is used in stoichiometric excess, the resultant product may contain a mixture of unconsumed chlorine as well as chlorine dioxide. The excess unreacted chlorine may result in the formation of undesirable disinfection by-products such as the trihalomethanes.

The rate of the direct reaction between dissolved Cl_2 and chlorite has been measured (Aieta and Roberts, 1985), with a forward second-order rate constant given by the following:

$$k_f = 1.31 \times 10^{11} \exp\left(\frac{-4800}{T}\right) \text{ L/M-s} \quad (17-44)$$

In the chlorine-chlorite process, sodium chlorite is supplied as either a solid powder or a concentrated solution. A solution of chlorine gas in water is produced by a chlorinator-ejector system, of similar design to that used in chlorination. The chlorine-water solution and a solution of sodium chlorite are simultaneously fed into a reactor vessel packed with Raschig rings to promote mixing (Miller et al., 1978). From Eq. 17-42, 1 mole of chlorine is required for moles of sodium chlorite, or 0.78 parts of Cl_2 per part of NaClO_2 by weight; however, for this reaction to proceed to completion, it is necessary to reduce the pH below

that provided by the typically acidic chlorine-water solution produced by an ejector. At 1:1 feed ratios by weight, only 60 percent of the chlorite typically reacts (Miller et al., 1978). To provide greater yields, several options exist. First, it is possible to produce chlorine-water solutions in excess of 3500 mg/L using pressurized injection of gas. In this case, however, there will be an excess of unreacted chlorine in the product solution, and the resultant disinfectant will consist of a mixture of chlorine and chlorine dioxide. The second option consists of acid addition to the chlorine and chlorite solution. For example, the addition of 0.1 mole of HCl per mole of chlorite enabled the production of a disinfectant solution of 95 percent purity in terms of chlorine dioxide, and achieved a 90 percent conversion of chlorite to chlorine dioxide (Jordan 1980). A third process, developed by CIFEC (Paris, FR), involves recirculation of the chlorinator-ejector discharge water back to the ejector inlet to produce a strong (5000–6000 mg/L) chlorine solution, typically at pH below 3.0, and in this manner to increase the efficiency of chlorite conversion (Miller et al., 1978). It has been reported that this last option is capable of producing 95 to 99 percent pure solutions of chlorine dioxide. The intricacies of chlorine dioxide reactions and by-products necessitate careful process monitoring during operation of the generator (Lauer et al., 1986).

Example 17-4 A water utility has chlorination capacity of 907 tonne/day (1000 tons/day) and is considering a switchover to chlorine dioxide to be generated using the chlorine-chlorite process. If the existing chlorination equipment is to be used, what is the maximum production capacity of chlorine dioxide, and how much sodium chlorite must be used under these conditions? Assume ideal stoichiometry and no excess chlorite or chlorine requirements.

Solution From Eq. 17-43, 2 moles of sodium chlorite (NaClO_2) react with 1 mole of chlorine to produce 2 moles of chlorine dioxide. Because chlorine has a molecular weight of 70, the current chlorinators have a capacity of $454,000/70 = 6486$ moles/day of chlorine. Therefore, 12,972 moles/day of sodium chlorite are required, and the result would be an equal number of moles of chlorine dioxide. The molecular weights are 67 for ClO_2 and 89 for NaClO_2 .

Therefore, the sodium chlorite required is $12,971(89) = 1.15 \times 10^6$ g/day (2540 lb/day). The chlorine dioxide produced would be $12,971(67) = 0.87 \times 10^6$ g/day (1914 lb/day). ▲

Application of Chlorine Dioxide. The use of chlorine dioxide is limited by two factors. First, the maximum residual which does not cause adverse taste and odor problems is 0.4–0.5 mg/l as ClO_2 (Masschelein, 1979b). Second, the chlorite produced by the reduction of chlorine dioxide has been found to cause certain types of anemia. Health effects from disinfectants and disinfection by-products are reviewed in Chap. 2. Therefore the maximum chlorine dioxide residual is limited by a maximum residual disinfectant level (MRDL) of 0.8 mg/L as ClO_2 (Chap. 1).

Insofar as chlorine dioxide is produced free of chlorine (in the acid-chlorite process, or in optimized chlorine-chlorite processes), the reactions with organic material to produce chlorinated by-products appear less significant than with chlorine (Aieta and Berg, 1986; Lykins and Griese 1986). Pure chlorine dioxide would not be expected to produce THMs or HAAs. Additional discussion of by-products can be found in Chap. 19.

Ozonation

The generation and application of ozone is presented in Chap. 7.

The role of hydraulics in ozone contactors has two influences on performance. It influences ozone transfer efficiency, and by virtue of the influence of dispersion on performance, it influences the effectiveness with which a given combination of residual and time

can be effective. The complex interactions involved are illustrated in several papers (Lev and Regli, 1992; Martin et al., 1992; Roustan et al., 1991). The designer is faced with a trade-off in which multiple stages, each approximating a completely mixed system, are used to transfer ozone. As the number of stages increase, the overall system hydraulics and performance improves (see Chap. 4), and also potentially the transfer efficiency may improve. The improvement in residence time distribution and transfer efficiency may be sufficient to reduce the size of reactor required, thus offsetting the increase in complexity of the internal reactor design.

UV Radiation

The application and design of UV systems is considered in Chap. 18.

The role of hydraulics in UV disinfection has two effects on performance. In addition to a negative influence of mixing, due to dispersion as noted, the movement of microorganisms relative to lamp surfaces may dramatically influence the integrated exposure to radiation during contacting. The effect of turbulence to decrease the potential for stratification (defined as travel of a given microorganism at a fixed distance from lamp surfaces) is desirable to increase UV disinfection efficiency (Haas and Sakellaropoulos, 1979).

There is an interaction between the residence time distribution and the distribution of intensities of exposure which microorganisms experience in transiting a UV disinfection unit. The use of CFD models may assist in providing a more precise prediction of the effect of flow rate and water quality parameters (absorbancy) on the inactivation expected in full-scale UV units (Chiu et al., 1999; Lyn et al., 1999).

From Kinetics to Process Design

In general, microbial inactivation kinetics has been determined in batch systems. Real contactors, however, are continuous and may have non-ideal flow patterns with mixing and short-circuiting. If the residence time distribution of a continuous flow reactor is known, for example, from tracer experiments, then it is possible to develop reasonable estimates of inactivation efficiency in these systems (Haas, 1988; Haas et al., 1995; Lawler and Singer, 1993; Stover et al., 1986; Trussell and Chao, 1977). There are several design approaches, the use of a $C \times T$ concept (as embodied in regulations), the integration of residence time and kinetics (termed the *integrated disinfection design framework* (IDDF)), and the direct solution of the coupled fluid transport and kinetic relations using CFD (see Chap. 4 for discussion of CFD).

The residence time distribution is determined from a pulse or step tracer experiment. In a pulse experiment, a virtually instantaneous slug of tracer is introduced, while in a step experiment a virtually instantaneous step change in concentration is effected. Experimental aspects of these experiments in disinfection systems have been described by a number of authors (Bishop et al., 1993; Boulos et al., 1996; Teefy and Singer, 1990). From this experiment, descriptive characteristics of the residence time distribution may be obtained, such as the mean residence time and dispersion; in addition the cumulative residence time distribution (F curve) and its density function (E curve) is also directly obtained. The E curve, written as a function of time $E(t)$, is the probability density function that gives the fraction of the fluid elements leaving the reactor that were in the reactor a period of time between t and $t + dt$. The tracer tests, tracer curves, and data analysis are discussed in detail in Chap. 4.

Two commonly used analytical forms for residence time distribution (though they may not always be appropriate) are the axial dispersion and the tanks-in-series models (Haas et al., 1997; Nauman and Buffham, 1983). These are given respectively by

Tanks in series model

$$E(t) = \frac{1}{t \Gamma(N_{CFSTR})} \left(\frac{N_{CFSTR} t}{\bar{t}} \right)^{N_{CFSTR}} \exp\left(-\frac{N_{CFSTR} t}{\bar{t}}\right) \quad (17-45)$$

Axial dispersion model

$$E(t) = \sqrt{\frac{\bar{t}}{2\pi t^3 v}} \exp\left[-\frac{(t-\bar{t})^2}{2\bar{t}t v}\right] \quad (17-46)$$

where N_{CFSTR} is the number of equal volume tanks in series and v is the dimensionless variance, which is related to the Peclet number by Eq. 17-47. The Peclet number (Pe) is defined as $Pe = v_z D/L$ where v_z is the axial velocity, D is the dispersion coefficient, and L is the flow path length. The reciprocal of the Pe number is referred to as the *dimensionless dispersion number*; see Chap. 4.

$$v = \frac{2}{Pe} - \frac{2}{Pe^2} (1 - \exp(-Pe)) \quad (17-47)$$

The axial dispersion model also has the integrated solution that gives F , the cumulative fraction of fluid that spends a residence time $\leq t$ in the system as

$$F(t) = \Phi\left[\left(\frac{t}{\bar{t}} - 1\right)\sqrt{\frac{\bar{t}}{t v}}\right] + \exp\left(\frac{2}{v}\right)\Phi\left[-\left(\frac{t}{\bar{t}} + 1\right)\sqrt{\frac{\bar{t}}{t v}}\right] \quad (17-48)$$

where $\Phi(z)$ is the standard normal probability integral (i.e., area under the normal distribution from negative infinity to z).

Use of the Integrated Disinfection Design Framework (IDDF). Using the E curve and the batch kinetic rate expression, the composition of the effluent can be obtained. The approach assumes a completely segregated system (Danckwerts, 1958; Levenspiel, 1972) and estimates the survival ratio in a disinfection reactor by the following equation:

$$\ln\left(\frac{N}{N_0}\right)_{\text{continuous}} = \int_0^{\infty} S(t)E(t)dt \quad (17-49)$$

where $\ln(N/N_0)_{\text{continuous}}$ = predicted continuous survival ratio

$S(t)$ = predicted batch survival at time t , given influent concentration as initial condition (N/N_0)

$E(t)$ = normalized density function for the residence time distribution

The complete segregation model is one extreme of micromixedness behavior. In this model, all fluid (and particles) entering remain in the vicinity of the material with which they entered until the last possible time (given by the residence time distribution) before their exit. This (complete segregation model) underlies the approach used by USEPA in the $C \times T$ tables, and therefore there is a systematic bias to greater predicted inactivation than other micromixedness reactor properties (Craik, 2005; Haas, 1988).

Application of this method is illustrated by the following example.

Example 17-5 Batch studies of inactivation of *Giardia* in water by chlorine have shown the applicability of the Hom model with first-order decay. The kinetic parameters are $k^* = 0.03$, $k = 0.1$, $m = 1.2$, and $n = 0.9$. A contactor is to be designed with a mean residence time of 30 minute and a Peclet number of 50. If a chlorine dose of 2 mg/L is to be used, what is the anticipated survival ratio?

Solution

1. First, from Eq. 17-47, the dimensionless variance is computed as

$$v = \frac{2}{50} - \frac{2}{50^2}(1 - e^{-50}) = 0.0392$$

2. Now, the trapezoidal rule (Chapra and Canale, 1988) can be used to evaluate the integral as shown in the following table:

Time (min)	$S(t)$	$E(t)$	$S(t) \times E(t)$	Trapezoid area
0	1	0	0	
5	0.3000	8.189E-24 [†]	2.457E-24	6.141E-24
10	0.0750	1.435E-08	1.076E-09	2.690E-09
15	0.0192	3.228E-04	6.206E-06	1.552E-05
20	0.0053	0.0147	7.808E-05	2.107E-04
25	0.0016	0.0577	9.234E-05	4.261E-04
30	5.308E-04	0.0672	3.565E-05	3.200E-04
35	1.934E-04	0.0393	7.609E-06	1.081E-04
40	7.713E-05	0.0151	1.162E-06	2.193E-05
45	3.349E-05	0.0044	1.461E-07	3.271E-06
50	1.574E-05	0.0010	1.637E-08	4.062E-07
55	7.954E-06	2.158E-04	1.716E-09	4.522E-08
60	4.299E-06	4.035E-05	1.735E-10	4.724E-09

[†]E in the columns means 10; e.g., E-24 means 10⁻²⁴.

Time intervals are selected on the basis that the finer the time spacing, the more precise is the evaluation of the integral. More sophisticated integration approaches, such as Simpson's rule, or higher-order methods may also be chosen to improve precision (Chapra and Canale, 1988). The second and third columns are the computed values of the survival (S) and residence time density function (E) at the particular time (t). The fourth column is the product of S and E . The final column represents the contribution of the rectangle to the area. If t_0 and t_1 represent the prior row and the current row, then the values in the final column are given by

$$\left[\frac{S(t_0)E(t_0) + S(t_1)E(t_1)}{2} \right] (t_1 - t_0)$$

The sum of the final column is 0.0011061, indicating that there is just under three logs removal, that is, 0.11 percent survival. Note that times beyond 60 minute were not examined, since at these higher times, as shown in the right-hand column the contribution to the integral is very small. ▲

The $C \times T$ Approach in Regulation. Under the Surface Water Treatment Rule, the adequacy of disinfection is judged using the product of the final residual concentration of disinfectant (in mg/L) and the contact time in minutes ($C \times T$). This is meant to be a simpler computational method than the IDDF described previously. The contact time is evaluated as that which is exceeded by 90 percent of the fluid (this is designated as the t_{10} , denoting that 10 percent of the fluid has a smaller residence time in the system; see Chap. 4 for further information. The t_{10} for disinfection systems may be evaluated from tracer studies or by the use of default multipliers of the theoretical hydraulic residence time (V/Q). Critical values

of the $C \times T$ to achieve varying levels of disinfection of *Giardia* and viruses, incorporating a margin of safety, have been published under USEPA guidance documents (Malcolm Pirnie and HDR Engineering, 1991; United States Environmental Protection Agency, 1991). For ozone, chlorine dioxide, and chloramines, they are indicated in Table 17-7. In the case of

TABLE 17-7 CT Values for 99.9 Percent Reduction of *Giardia lamblia* with Ozone, Chlorine Dioxide, and Chloramines

Disinfectant	pH	Temperature (°C)					
		1	5	10	15	20	25
Ozone	6–9	2.9	1.9	1.4	0.95	0.72	0.48
Chlorine dioxide	6–9	63	26	23	19	15	11
Chloramines	6–9	3800	2200	1850	1500	1100	750

Source: Malcolm Pirnie and HDR Engineering, 1991.

free chlorine the $C \times T$ values are functions of temperature, pH, and concentration (under the regulations, measured at the end of the contact chamber). Space does not permit a recapitulation of the full $C \times T$ tables for free chlorine; the values at a few conditions are given in Table 17-8.

TABLE 17-8 CT Values for 99.9 Percent Reduction of *Giardia lamblia* with Free Chlorine Under Selected Conditions

Temperature (°C)	5	5	20
pH	7	9	7
C (mg/L)			
0.4	139	279	52
0.6	143	291	54
0.8	146	301	55
1	149	312	56
1.2	152	320	57
1.4	155	329	58
1.6	158	337	59
1.8	162	345	61
2	165	353	62
2.2	169	361	63
2.4	172	368	65
2.6	175	375	66
2.8	178	382	67
3	182	389	68

Source: Malcolm Pirnie and HDR Engineering, 1991.

The use of the $C \times T$ approach is illustrated in the following example.

Example 17-6 The disinfection contactor described in Example 17-5 is to be used to achieve 3-log inactivation of *Giardia*. Compute the required residual necessary to achieve this result from the $C \times T$ tables if the pH is 7 and the temperature is 20°C.

Solution

1. First, the t_{10} must be computed. Since the contactor is an axial dispersion contactor, Eq. 17-48 can be used. We therefore need to solve the following equation for the time at which 10 percent of the fluid has exited:

$$0.1 = \Phi \left[\frac{(t_{10} - 1)}{30} \sqrt{\frac{30}{t_{10}(0.0392)}} \right] + \exp \left(\frac{2}{0.03392} \right) \Phi - \left[\frac{(t_{10} + 1)}{30} \sqrt{\frac{30}{t_{10}(0.0392)}} \right]$$

This equation must be solved by trial and error; however, this can readily be done on a spreadsheet such as Microsoft Excel (in which the cumulative normal distribution function is available). Doing this, it is found that $t_{10} = 25.3$ minute.

2. We now need to examine the last column of Table 17-8 to determine what chlorine residual would satisfy the requirement at this t_{10} . The following table illustrates the computation:

C	CT	$t = (CT/C)$
2.4	65	27.08
2.6	66	25.38
2.8	67	23.93

3. Finally, an inverse interpolation is needed to obtain the C that yields the desired t . Therefore, the final residual chlorine should exceed 2.61 mg/L. ▲

Computational Fluid Dynamic Design. Computational fluid dynamic (CFD) methods directly simulate the motion of liquids and potentially the reactions of materials within the fluids. They are computer-intensive methods and are increasingly being used for process design, particularly for the design of large systems. A more detailed explanation of CFD techniques is given in Chap. 4.

The simplest application of CFD techniques in disinfection systems is to simulate the flow patterns in a contactor (not considering reactions) (Hannoun et al., 1998; Henry and Freeman, 1995). This can be used either to estimate a t_{10} (for application in CT-based design) or to generate the residence time distribution for use in an IDDF approach. This avoids the need to perform tracer tests and can be used before a system is constructed.

The decay rate of disinfectant can be incorporated into a CFD model, and then an average integrated ct can be computed by mathematical simulation. This results in a direct integration of residual and time that can be compared with ct tables. The method has been illustrated by Do-Quang et al. (2000).

If experiments are done to elucidate the inactivation kinetics (e.g., Hom, Chick-Watson, etc.) as well as the disinfectant decay rates, then both of these phenomena can be incorporated into a CFD simulation to directly estimate the inactivation ratio of a microorganism in a contactor. This has been illustrated both in the case of homogenous chlorine contactors (Greene et al., 2004; Greene et al., 2006) and with multiphase ozone contactors (where both the gas and liquid phases must be simulated along with the two phase mass transfer) (Bartrand, 2007; Bartrand et al., 2009).

RELATIVE COMPARISONS

The dominant disinfection technology in the United States remains free residual chlorination. However, chloramination, chlorination with partial dechlorination, and chlorine

TABLE 17-9 Applicability of Alternative Disinfection Techniques

Consideration	Cl ₂ [†]	O ₃	ClO ₂	UV
Equipment reliability	Good	Fair to good	Good	Fair to good
Relative complexity of technology	Simple	Complex	Moderate	Moderate
Safety concerns	Yes	Moderate	Yes	Moderate

[†]Includes hypochlorites as well as chlorine gas.

dioxide treatment are viable alternative primary disinfectants. In addition, ozone, or possibly UV, when supplemented with a chemical which can produce a lasting residual in the distribution system have application.

Table 17-9 summarizes important aspects of the major technologies and their technical pros and cons.

ABBREVIATIONS

CFD	computational fluid dynamics
CFSTR	continuous flow stirred tank reactor
$C \times T$	product of contact time and residual
HAA	haloacetic acids
HPC	heterotrophic plate count
IDDF	integrated disinfection design framework
LT2ESWTR	Long Term 2 Enhanced Surface Water Treatment Rule
MRDL	maximum residual disinfectant level
NDMA	N-nitrosodimethylamine
PEL	permissible exposure limit
SWTR	Surface Water Treatment Rule
OSHA	Occupational Safety and Health Administration
THM	trihalomethane
TOC	total organic compounds
USEPA	U.S. Environmental Protection Agency
UV	ultraviolet

NOTATION FOR EQUATIONS

C	concentration, M/L^3
C_0	initial concentration, M/L^3
CT	concentration-time product, MT/L^3
$E(t)$	residence time distribution density function, $1/T$
E_a	activation energy
$F(t)$	residence time distribution cumulative function, dimensionless
H	Henry's law constant, L^2/T^2
k'	Chick-Watson rate constant, $(M/L^3)^{-n}/T$
k''	Hom rate constant, $(M/L^3)^{-n}T^{-m}$
n	Chick-Watson coefficient of dilution, dimensionless
N	microorganism concentration, $\#/L^3$
N_{CFSTR}	number of CFSTRs in tanks in series model, dimensionless
Pe	Peclet number, dimensionless
T	temperature
t	time, T
t_{10}	time of passage for fastest 10% of fluid, T
\bar{t}	mean residence time, T
P	pressure
r	reaction rate, M/L^3T , or for microbial inactivation, $\#/L^3T$
R	ideal gas law constant
$\Gamma(x)$	gamma function
v	dispersion number, dimensionless
$\Phi(t)$	cumulative standard normal integral, dimensionless

INTRODUCTION TO ULTRAVIOLET LIGHT PROCESSES

Ultraviolet (UV) light has long been an important tool in biological and chemical research. UV research has developed into the fields of photobiology and photochemistry and has increased our understanding of biological and chemical processes in the environment. The

*Presently with Hazen and Sawyer, Fairfax, Virginia, United States.

effects of UV light on the survival and mutation of microorganisms have been studied for over a century. The first recorded discovery of the bactericidal effects of sunlight was made in England by Downes and Blunt (1877). In 1901, Peter Cooper Hewitt invented the mercury vapor arc lamp, which, when coupled with a quartz sleeve in 1906, allowed the production of UV lamps and stimulated research into the bactericidal properties of UV light. The first recorded use of UV light for disinfection of water was in Marseilles, France, in 1910, where disinfection of 36 m³/h (9500 gph) of pathogen-spiked water was achieved in a few seconds using a Westinghouse Cooper Hewitt mercury lamp in fused quartz. The use of UV light for the disinfection of water on ships began in 1916, a practice that continues to this day. Baker (1948) reported, based on personal contacts, that UV disinfection facilities in the United States, supplied by the R.U.V. Co., Inc., of New York, were installed in Henderson, Ky., operating from 1916 to 1923; Berea, Ohio, operating from 1923 to 1936; Horton, Kan., beginning in 1923 (end date unknown); and Perrysburg, Ohio, operating from 1928 to 1939. These facilities were abandoned owing to the cost of operation compared with other water disinfection techniques, problems with electrical supply reliability, and the belief among state officials that chlorine was a more effective technology. The R.U.V. Co. also noted that the small size of quartz lamps limited the applications for municipal systems. The use of UV light for disinfection of water gradually grew out of favor in the 1920s owing to the increasing use of chlorination, the difficulties with reliability and maintenance of UV systems, and the comparatively higher costs associated with the UV technology available at that time.

Despite the decline of UV light for applications in water disinfection, an intense interest in the effects of UV light on biological and chemical processes was sparked. In 1929, Gates reported the inactivation efficacy of individual wavelengths of monochromatic UV light, developing the first germicidal action spectrum (Gates, 1929). This work and the work of subsequent researchers demonstrated the similarity between the absorbance spectrum of DNA and the germicidal action spectrum, suggesting that the target of action of UV light leading to inactivation was the nucleic acids. The wavelengths that were determined to be germicidally effective were found to be those in the far UV range of 200 to 300 nm. Within this range, the most effective germicidal wavelengths were between 250 and 270 nm. Although not as germicidally efficient as the far UV range, near UV light (300–390 nm) also was found to produce essentially all the biological effects produced by far UV light, as well as other sublethal physiologic effects that may interfere with proper cellular functions and contribute to eventual inactivation (Jagger, 1983).

Although chlorination was a proven effective disinfectant, concerns in the 1970s surrounding the toxicity of chlorine residuals to the aquatic biota in receiving waters and the discovery of the potential carcinogenic and mutagenic properties of chlorinated organic compounds formed during disinfection of water and wastewater led to the investigation of alternative disinfectants. Advances in ballast and electronics technology in the 1970s and 1980s, along with the desire to find new disinfection technologies, helped the resurgence of UV light treatment as a viable technology for disinfection. Since that time, UV disinfection has grown into a major commercial industry and increasingly has been the subject of academic and industrial research.

UV light has developed a large market share in wastewater disinfection applications, where it has been shown to be competitive with chlorination in terms of disinfection efficacy and economics (Darby et al., 1995). The use of UV light for wastewater disinfection took root for a variety of reasons: Its small footprint, lack of a need for a large contact basin, elimination of the need for dechlorination before discharge into a natural water body, and ease of use. However, until the late 1990s, about 20 years after adoption for use in wastewater in North America, UV light had not found widespread acceptance for disinfection of potable water (Wolfe, 1990; USEPA, 1996). It was at this time that Bolton and colleagues (1998) and Clancy and colleagues (1998, 2000) discovered that UV treatment was effective in inactivating the chlorine-resistant protozoan pathogen *Cryptosporidium*. This discovery

led to a rapid rise in interest for implementation of UV technologies as a primary disinfectant for drinking water, especially in the wake of recent regulations.

Regulation (see Chap. 1 for coverage of regulations) of the water industry in the form of the Ground Water Rule (GWR), the Enhanced Surface Water Treatment Rule (ESWTR), the Information Collection Rule (ICR), the Disinfection/Disinfectant By-Products Rule (D/DBPR), the Uniform Fire Protection Code (UFP), and the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) has motivated the water industry to examine disinfection as it is currently practiced with increasing scrutiny. Among the challenges facing this industry are control of disinfection by-products, inactivation or removal of persistent pathogens such as protozoan cysts and some viruses, and limiting bacterial regrowth in distribution systems (USEPA, 2006b). One response to these challenges has been the investigation of alternative disinfectants. UV light is one of a number of disinfection alternatives available. Depending on the type of UV technology applied, UV can meet the needs of the water industry regarding disinfection by-product formation control and inactivation of persistent pathogens. Because UV light does not provide a residual disinfectant concentration for control of regrowth, a chemical disinfectant may be needed when biofilm formation in the distribution system is of concern or regulations demand that a residual be supplied. A summary of the main differences between UV light and chlorine disinfection processes is presented in Table 18-1. The advantages and disadvantages of using UV for disinfection of water are summarized in Table 18-2.

TABLE 18-1 Comparison of UV and Chlorine Disinfection

Parameter	UV Light	Chlorine
Action	Physical	Chemical
Mechanism	DNA damage	Oxidation
Resulting cell structure	Intact	Damaged
Reactivation	Photo/dark	Resuscitation
Design dose	Fixed/semivariable	Adjustable
Calculated dose	$I \times T$	$C \times T$
Exposure time	Seconds	Minutes
Residual	None	Varies with chlorine demand
Demand	Absorbance	Organics/inorganics
	Attenuation	Sunlight

TABLE 18-2 UV Treatment for the Disinfection of Drinking Water Supplies

Advantages

- ⇒ Effective against bacteria, viruses, and protozoa
- ⇒ Germicidal effectiveness for standard bacterial and viral indicator organisms is representative of actual pathogen inactivation
- ⇒ No known toxic by-products formed
- ⇒ Low operation and maintenance costs
- ⇒ Small footprint
- ⇒ Short contact times

Disadvantages

- ⇒ No residual disinfectant
- ⇒ Limited effectiveness against adenoviruses
- ⇒ Complexity measuring germicidally effective UV dose
- ⇒ Potential for bacterial reactivation
- ⇒ Lamp fouling

Now that UV light is an accepted technology for drinking water disinfection, the use of UV treatment for applications involving chemical contaminants in water is also growing. UV processes can be effective for degrading organic pollutants via direct UV photolysis or via generation of hydroxyl radicals in advanced oxidation processes (AOPs) such as UV combined with hydrogen peroxide. Therefore, this chapter covers applications of UV light for water treatment both for the disinfection of pathogenic microorganisms and for the destruction of chemical contaminants. The scope of the chapter includes the fundamentals of UV light applications, the science behind UV disinfection processes and inactivation of pathogens, practical aspects of UV disinfection, the use of UV for destruction of contaminants via both photolysis and oxidation pathways, and theory and practice of UV-based oxidation processes.

FUNDAMENTALS OF UV LIGHT

Electromagnetic Spectrum and UV Classification

The electromagnetic spectrum covers a very wide range of energies from radio waves through visible and UV light down through gamma rays (Fig. 18-1). The UV part of that

FIGURE 18-1 The location of the UV wavelength region within the electromagnetic spectrum. (Source: USEPA, 2006a.)

spectrum extends from 100 to 400 nm. The UV spectrum is divided into four ranges: vacuum UV (100–200 nm), UV-C (200–280 nm), UV-B (280–315 nm), and UV-A (315–400 nm). UV light below 200 nm exists only in a vacuum because these wavelengths are readily absorbed by chemical constituents (principally O_2) in air. The UV-C range is considered to be the most germicidally active UV range because these wavelengths are strongly absorbed by nucleic acids. The UV-B portion of the spectrum can be thought of as the sun-burning wavelengths because it contains wavelengths from sunlight that reach the earth's surface (wavelengths > 300 nm) and can damage exposed skin. The UV-A range is often dubbed the sun-tanning portion of the UV spectrum.

UV Lamp Types

UV light typically is delivered to water using UV lamps, which are constructed out of quartz to allow transmission of UV light. Several different types of UV lamps are available

commercially. The most common are the continuous-wave mercury vapor-based lamps including low-pressure (LP) and medium-pressure (MP) UV lamps, but nonmercury UV lamps are also being developed, including pulsed UV sources, excimer sources, and UV light-emitting diodes.

Mercury-Based Lamps. The first UV disinfection systems to be developed commercially employed LP mercury vapor lamps. Initially, these lamps were suspended above a thin liquid film to achieve disinfection. Current designs allow for lamps to be submerged in the water, configured parallel or perpendicular (horizontal or vertical) to the flow path. Approximately 85 percent of the UV light emitted by LP lamps is monochromatic at 253.7 nm. LP UV systems can be divided into low output (LPLO) and high output (LPHO). LPLO lamps typically are used for low flow applications, where the number of lamps can be kept to a minimum and also where UV transmittance and turbidity are not limiting factors in the water quality. LPHO lamps contain solid spots of a mercury amalgam attached to the inside of the lamp's quartz tube. These amalgams are a mercury alloy with an element such as gallium or indium. This mercury amalgam helps to control the mercury vapor pressure, allowing a characteristic LP output at 253.7 nm to be emitted at a higher intensity than is possible without the amalgam. LP UV light from either LPLO or LPHO sources has been proven effective for the inactivation of bacteria, viruses, and protozoa (Hijnen et al., 2006).

Medium-pressure (MP) mercury vapor lamps have grown in use as UV disinfection is applied to systems with large flows and more diverse water quality. MP UV lamps have a polychromatic emission with a germicidal efficiency of approximately 10 to 20 percent. Thus MP lamps are less germicidally efficient than LP lamps; however, because the UV output is much greater, they emit approximately 10 to 50 times the germicidal UV output of LPLO lamps and 4 to 10 times the germicidal output of LPHO lamps. The higher UV output translates into a relatively smaller footprint for a disinfection system, significantly fewer lamps for the equivalent effect, and potentially lower operation and maintenance costs. Most MP UV systems have contact times on the order of 0.5 to 5 seconds. MP UV systems, inherently containing the same wavelength as LP UV along with other wavelengths across the germicidal range, are likewise effective for inactivating bacteria, viruses, and protozoa. Table 18-3 provides a summary of the principal characteristics of typical LP and MP mercury vapor lamps. The emission spectra of LP and MP UV lamps are presented in Fig. 18-2.

TABLE 18-3 Characteristics of Typical Low and Medium-Pressure Mercury Vapor Lamps

Characteristic	Low pressure	Medium pressure
Emission	Monochromatic (85% at 253.7 nm)	Polychromatic (185–1367 nm)
Mercury vapor pressure (torr)	10^{-3} to 10^{-2}	10^2 to 10^4
Operating temperature (°C)	40 to 60	500 to 800
Arc length (cm)	40 to 150	5 to 150
Lifetime (hours)	8000 to 12,000	4000 to 8000
Light intensity (relative)	Low/Medium	High

Note: 100 torr = 13.3 kPa.

The use of mercury-based UV sources in water treatment has led to an investigation of the possibility of mercury release owing to lamp breakage. This issue is addressed in detail in the *UV Disinfection Guidance Manual* (USEPA 2006a). UV lamps can break within a UV disinfection system if overheated owing to loss of water, overtightening during installation,

FIGURE 18-2 The absorbance spectra of DNA overlaid with the UV lamp output from LP and MP UV sources. (Courtesy of Bolton Photosciences, Inc.)

if some foreign debris strikes the lamp envelope, malfunction of the lamp wiper mechanism, or some extreme pressure event such as water hammer. Proper engineering of the UV system would avoid these types of occurrences, but design considerations for possible mercury containment should be reviewed. UV lamps also may break off-line during lamp handling and bulb changes, and in this case, operator safety precautions and procedures should be followed.

Emerging Lamps. Because of a general concern for use of mercury in the water environment, a number of new mercury-free UV lamps have been developed in recent years. The most prevalent nonmercury UV lamp is the pulsed-UV xenon arc lamp, or flashlamp (Dunn et al., 1995; Bank et al., 1990; Bohrerova et al., 2008). These lamps are characterized as high-intensity broadband sources, with an emission spectrum from the far UV through the infrared. They have seen commercial use in packaging disinfection and UV curing; however, they are not very efficient in their germicidal UV output compared with mercury-based lamps. Commercialization of these lamps into UV disinfection systems has not yet been successful. Surface-discharge lamps also emit pulsed UV light but operate on the principle of plasma emitting from a dielectric (Schaefer et al., 2007) and have improved efficiencies over flashlamps. Excimer lamps are UV sources that can be tuned to emit specific wavelengths (Oppenländer, 2007; Naunovic et al., 2008). UV light-emitting diodes have been developed recently and now can produce emissions down to below 250 nm. However, these UV LEDs are low intensity, are currently expensive to produce, and do not yet have the lifetime needed for municipal applications (Gaska, 2007; Bettles et al., 2007; Chatterley and Linden, 2010). All these sources, by their characteristic wavelength emission in the germicidal UV range, are effective for inactivation of pathogenic microorganisms.

UV Dose Theoretical Considerations

The accurate measurement of UV dose (or UV fluence) both at the bench scale and in field-scale systems is essential to the development of reproducible data regarding the UV dose response of microorganisms and the degradation of contaminants. Because UV light cannot be seen or captured to measure off-site, special methods have been developed to measure UV fluence.

Measurement of UV Energy. A number of techniques have been developed to measure UV irradiance or UV fluence, including physical, chemical, and biological approaches.

Physical Techniques. Physical methods are techniques involving radiometers equipped with detectors calibrated to narrow- or broadband spectral responses. Radiometer detectors can accurately measure only the irradiance incident and near-normal to the plane of the detector; therefore, these systems are applied principally to laboratory-scale UV exposure experiments, where the UV light can be collimated effectively. Radiometers measure the incident intensity on the surface of the detector; therefore, corrections for absorption in and the depth of the liquid samples must be made to provide a measure of the average irradiance in a batch sample. Radiometry has been employed routinely in full-scale reactors, where UV sensors monitor the constancy of the UV output and indicate when the irradiance has decreased owing to lamp fouling, water quality changes, or aging of the lamps.

Chemical Techniques. Chemical actinometry is the measurement of the quantity of UV light exposure by the change produced in a chemical. Some common actinometers in use for measurement of UV irradiance include potassium ferrioxalate, potassium iodide/iodate, and uridine. Each has its benefits and challenges for use with monochromatic and polychromatic UV sources (Jin et al., 2006). Ideal actinometers for measuring polychromatic germicidal UV light would have the following characteristics (von Sonntag and Schuchmann, 1992): (1) They would absorb only germicidal UV light, (2) they would have an absorbance spectrum similar to that of DNA, (3) they would have constant quantum yield throughout germicidal wavelength range, (4) they would be easy to quantify using standard laboratory equipment, and (5) they would be nontoxic in the environment. With any chemical actinometer, care must be taken when evaluating it for use with water sources of a diverse chemical nature to ensure that nonphotochemically induced degradation of the actinometer is not a factor. Similarly, actinometry with polychromatic and/or high-intensity sources must validate that the change produced in the chemical actinometer is solely attributable to the direct photon absorption process and not the result of a photochemically mediated secondary reaction.

Biological Techniques. Biological measurement of fluence has centered on the bioassay or biodosimetry technique for assessing the UV dose in a flow-through UV disinfection system. In the bioassay approach, a UV dose-response curve is established for a given organism under controlled conditions where the UV dose can be determined accurately. A culture of the same organism then is released into a more complex system and the log inactivation determined. This log inactivation value then is used along with the initial UV dose-response curve to estimate what the UV dose must have been to achieve the resulting inactivation response. Because it is a biologically based test, the method provides a measure of the effective germicidal UV dose—the UV dose necessary for a desired germicidal effect. This method provides a single average UV dose value [called the *reduction equivalent dose* (RED)] to the UV disinfection system. Sommer and Cabaj (1993) identified four criteria for selection of a bioassay test organism, including (1) steady inactivation over a wide UV dose range, (2) simple and sufficient culturability, (3) nonpathogenic, and (4) temporal stability with regard to UV susceptibility. In addition, techniques used in culturing the organisms may play a role in the subsequent UV susceptibility. Organisms that have been used for bioassays include *Bacillus subtilis* spores (Qualls and Johnson, 1983) and the MS2 coliphage (Braunstein et al., 1996). This method is described further in the section on calculation of UV dose at the field scale.

Calculating the Average UV Irradiance. The attenuation of UV light in water can be described using an adaptation of the Beer-Lambert law, derived as follows. *Spectrophotometric absorbance* is defined as

$$A = \log \left(\frac{I_0}{I} \right) \quad (18-1)$$

or as the familiar Beer-Lambert law:

$$A = \frac{\epsilon}{C} \quad (18-2)$$

where A = absorbance, or optical density of solution, as read from the spectrophotometric output

I_0 = irradiance entering the solution in the spectrophotometer cuvette

I = irradiance exiting the solution in the spectrophotometer cuvette

ϵ = molar absorption coefficient ($M^{-1} \text{ cm}^{-1}$)

l = solution path length (cm) (see next equation)

C = molar concentration of dissolved constituent (M or mol/L)

When analyzing a complex soluble-particulate mixture such as water, the molar concentration value C is ambiguous, which makes it difficult to determine a value for the molar absorption coefficient ϵ . However, both the solution absorbance A and the path length l are well defined, such that the absorption coefficient is

$$a_{10} = \frac{A}{l} = \epsilon c \quad (18-3)$$

Rewriting Eq. 18-1 in terms of this absorption coefficient, we get

$$I = I_0 10^{-a_{10} l} \quad (18-4)$$

or

$$I = I_0 e^{-\alpha_e l} \quad (18-5)$$

where $\alpha_e = a_{10} \ln(10)$.

Equation 18-5 was used by Morowitz (1950) to model extinction of light in a stirred sample and UV attenuation coefficients in water. The percent UV transmittance (UVT) of a water is calculated using Eq. 18-6:

$$\% \text{UVT} = 100 \times 10^{-A}$$

Calculation of UV Dose: Bench Scale. Bench-scale UV testing typically is carried out in an apparatus referred to as a *collimated beam* (Fig. 18-3). When considering the calculation of UV

FIGURE 18-3 Collimated-beam apparatus for bench-scale UV exposure experiments. (Reprinted with permission from ASCE Journal of Environmental Engineering [Bolton and Linden, 2003].)

dose as the product of irradiance and exposure time ($D = I \times T$), both the irradiance and the exposure time are complex entities that need further definition and evaluation. The UV irradiance is a function of two primary factors: the nature of the UV source (e.g., mono/polychromatic, pulsed/continuous wave, low/medium pressure, lamp age, and geometry/spacing/configuration) and the nature of the path to the target (e.g., water quality). The exposure time is a simple measurement on the bench scale using a timer to monitor the time but is much more complex at the reactor scale, as discussed below. Bolton and Linden (2003) detail the specific procedures for proper calculation of the average UV irradiance in the water exposed to UV light in a collimated-beam apparatus. For LP UV systems, the UV dose is calculated as the product of average irradiance in the water at 253.7 nm and the exposure time in seconds. For MP UV sources, because the UV output is polychromatic and each wavelength output has a unique absorbance and germicidal effectiveness depending on the water quality and the target organism of interest, measuring the germicidal UV irradiance is more complex. Methods based on chemical actinometry, mathematical models, and a bioassay have been evaluated for polychromatic sources (Jin et al., 2006).

Calculation of UV Dose: Reactor Scale. The *UV Disinfection Guidance Manual* (USEPA, 2006a) provides detailed procedures for determining and validating the UV fluence (UV dose) in a UV disinfection system. The cornerstone of this method is the bioassay or biodosimetry, as described earlier. Figure 18-4 describes the biodosimetry test procedure.

FIGURE 18-5 Examples of UV reactors: (a) closed channel; (b) open channel. (Source: USEPA, 2006a.)

The biosimetry method ascribes a single UV dose value (the RED) to a UV disinfection reactor under a given set of flow, water quality, and lamp output conditions. Although this may be helpful for assessing the general trends of a UV system and setting operating parameters, the actual behavior of the UV system is not well characterized using this method. Mathematical models have been proposed to characterize the light distribution and flow conditions of a UV reactor system (Jacob and Dranoff, 1970; Chiu et al., 1999; Bolton, 2001; Lyn and Blatchley, 2005; Ducoste et al., 2005). By using irradiance distribution models coupled with computational fluid dynamics analyses of the system hydraulics, a clearer picture of the range of delivered doses provided in a UV reactor can be obtained. Based on modeling efforts, it has been determined that UV disinfection systems, much like other disinfection processes, do not provide a single uniform UV dose during water treatment, but a distribution of UV doses is delivered that depends on UV reactor characteristics (i.e., lamp orientation, baffles, up and down stream piping). Recently, an experimental method employing chemical actinometry embedded in or on microspheres has been used to verify the UV dose distribution concept and validate mathematical models that have predicted this UV dose distribution (e.g., Bohrerova et al., 2005; Blatchley et al., 2008).

Full-Scale UV Reactor Configurations

UV disinfection and oxidation reactors for drinking water treatment are most often pressurized vessels in-line with the existing piping system of the treatment plant. UV lamps in these systems may be oriented parallel or perpendicular to the flow. In some cases, an open-channel system may be desired, which is more common in wastewater UV disinfection systems. Examples of closed-vessel pressured and open-channel systems are presented in Fig. 18-5.

UV DISINFECTION

Disinfection of water can be achieved using a photochemical-based process such as UV light, as described below, or chemical methods such as chlorine or ozone, which are described in Chap. 17.

Fundamentals of UV Disinfection

UV light is a nonchemical means of disinfecting water. Essentially, UV light transmitted into a water column is absorbed by the nucleic acids of a microorganism. The energy from the photons absorbed by the organism causes damage to the genome, rendering the microbes unable to replicate. An organism that cannot replicate cannot cause an infection. Because a UV-inactivated organism is not completely destroyed, the UV damage may undergo some repair, which in cases of insufficient UV exposure may lead to reactivation.

Microbial Inactivation Mechanisms. UV light can damage the nucleic acids of a target pathogen as the photon energy is absorbed by the biological target. The absorbance spectrum of the combined nucleic acids of DNA is presented in Fig. 18-2. The primary mechanism of UV inactivation is the formation of dimers on adjacent pyrimidine bases on a DNA strand. These damage sites typically occur between adjacent thymine bases. The formation of the dimer interferes with replication of the cellular DNA (or RNA), rendering the organisms unable to replicate. An organism that cannot replicate cannot cause an infection, although it still may be metabolically active. An example of this type of nucleic acid damage is illustrated in Fig. 18-6. Other cellular damage that can occur from UV light absorption includes single- and double-strand DNA breaks, DNA-DNA cross-links, protein-DNA cross-links, pyrimidine hydrates, and pyrimidine(6-4) pyrimidine photoproducts. A review of the biological effects of UV light treatment can be found in Harm (1980).

FIGURE 18-6 DNA double helix with thymine dimer formed from UV exposure. (Courtesy of International Water-Guard Industries, Inc., www.water.aero/disinfection.html.)

Repair of UV-Induced Damage. UV light absorption causes damage mainly to the nucleic acids but does not destroy the integrity of the microorganism; therefore, some types of DNA damage can be repaired by the organism, and its ability to replicate can be restored. DNA repair generally is divided into two types: light repair and dark repair. Light repair, also called *photoreactivation*, uses an enzyme called *photolyase* that attaches to nucleic acid dimers and, when exposed to light in the UVA and visible spectra (available in sunlight or daylight lamps), repairs the damage and restores the nucleic acid integrity. Dark repair occurs without any light energy and typically includes excision repair, recombinatorial repair, and inducible error-prone repair. A review of nucleic acid repair processes is covered by Harm (1980). Repair typically is minimized or negligible when an adequate UV dose is delivered. A UV dose of 40 mJ/cm² typically is enough to eliminate the possibility of a repair process occurring that would affect the inactivation of a pathogen (Hoyer, 1998). For

drinking water applications, it is not likely that the UV-disinfected water will be exposed to visible light for periods of time that would lead to light repair, and a secondary disinfectant can serve to minimize repair and recovery of UV-inactivated microorganisms (Mofidi and Linden, 2004).

UV Doses Required for Pathogen Inactivation. The UV dose is a product of the delivered UV irradiance and the exposure time, or $I \times T$, similar to the $C \times T$ concept, and the UV doses required for some pathogens are published in the LT2ESWTR (USEPA, 2006b). Different types of pathogens require different levels of UV dose to achieve adequate inactivation. As a benchmark, the UV doses needed to achieve 4 log inactivation (99.99 percent) for various pathogenic microorganisms are presented in Fig. 18-7 (Hijnen et al., 2006; USEPA 2006b). In general, the most UV-sensitive organisms are the protozoan pathogens, including *Cryptosporidium* and *Giardia*. Almost as sensitive are the vegetative bacteria, such as *Escherichia coli* and *Salmonella*. Viruses tend to be the least sensitive to UV, but most viruses still are easily inactivated by UV light, such as polio and hepatitis viruses. Spores are known to be more resistant than their vegetative bacterial form. Adenoviruses are thought to be the most resistant pathogens to UV light, requiring a UV dose of 186 mJ/cm² for 4 log inactivation, according to the LT2ESWTR (USEPA, 2006b; Yates et al., 2006). However, this UV dose requirement is based on LP UV light treatment, but use of MP UV has been shown to reduce the required UV dose by two- to fourfold (Malley et al., 2004; Linden et al., 2007). Interestingly, both LP and MP UV light cause identical levels of DNA damage to adenoviruses (Eischeid et al., 2009). However, after assaying the viruses in cell culture, MP UV light is more effective than LP UV light, likely owing to the suppression of any viral repair activity by the MP polychromatic light emission. The UV inactivation of adenoviruses is an area of continued research interest. A review of the UV doses required for inactivation of various pathogens is provided in Hijnen and colleagues (2006) and Chevrefil and colleagues (2006).

FIGURE 18-7 UV doses required for 4 log inactivation of various waterborne pathogens. (Source: Hijnen et al., 2006, and USEPA, 2006b.)

Characterizing UV Reactor Performance. As mentioned earlier, UV disinfection reactor performance is commonly represented by a single UV dose value (the RED) generated from a bioassay validation test (Mackey et al., 2002). However, this representation ignores the complexities of UV dose delivery in a reactor. Rather than a single UV dose provided in a disinfection reactor, UV systems actually deliver a distribution of UV doses depending on the path that a microorganism travels through the reactor, subject to the specific hydraulics and the UV irradiance field within that specific UV system. This complexity was first quantified by Chiu and colleagues (1999) and has since been studied using advanced mathematical techniques such as computational fluid dynamics (CFD) coupled with light irradiance distribution (LID) modeling (e.g., Lyn and Blatchley, 2005; Ducoste et al., 2005).

CFD Analysis and Light Distribution Modeling. The use of CFD has modernized the design and analysis of UV disinfection systems. With CFD, coupled with LID, the actual performance of a UV reactor system can be detailed. The output of these models provides specific information on the fraction of the flow treated by the UV system that received a given UV dose. By analyzing these types of data, information on design optimization and expected disinfection performance can be estimated. The dose distribution of a UV reactor as predicted by mathematical models has been validated experimentally using a technique called *microsphere actinometry* (Bohrerova et al., 2005; Blatchley et al., 2008). In this technique, small particles embedded or tethered with a UV-sensitive chemical are injected into the reactor and captured, each recording a unique UV dose as it travels through the UV system. These spheres are analyzed for their UV exposure history via their chemical change. This emerging method of reactor characterization provides detailed information on UV reactor behavior, which, when coupled with the bioassay information, provides a robust means for validating UV reactor performance.

UV Disinfection Practice

The effectiveness of chlorine disinfection is followed by monitoring the chlorine residual with a simple chemical test on a chlorinated water sample. Because UV light cannot be measured using a method parallel to this chemical analysis, UV systems have been held to high standards regarding validation of performance and development of tools to monitor operation.

Validation of UV Disinfection Systems. A table of UV doses required for various levels of inactivation of viruses, *Cryptosporidium*, and *Giardia* is published in LT2ESWTR (USEPA, 2006b). These UV doses have to be delivered within a UV disinfection system, and that system must be validated and then monitored to ensure proper disinfection. The *UV Disinfection Guidance Manual* (USEPA, 2006a) provides detailed guidance on how UV reactors should be validated. Each UV disinfection system is designed to achieve a given level of disinfection performance within an envelope of operating conditions. The validation process is a means to verify that the claims made on reactor performance by vendors, specifically in the areas of UV dose delivery and monitoring, are achieved during operation. A typical validation protocol includes (1) documentation of the UV system as received from the vendor, along with its components, (2) measurement of the UV dose delivery using a bioassay testing system, (3) correlation of the bioassay-measured UV performance with monitoring devices, and (4) assessment of the uncertainty and bias in the data analysis. A validation takes place over a range of water quality UV transmittance values, flow rates, and UV lamp intensities. The validation process generates a validation factor, much like a safety factor in design, that accounts for the data uncertainties. This factor is used to calculate the validated UV dose required to achieve a given level of disinfection credit. For example, if the UV reactor is designed to achieve 3 log inactivation of *Cryptosporidium*, the

required UV dose for that level of disinfection is 12 mJ/cm^2 , as indicated in LT2ESWTR. The UV disinfection system must demonstrate a validated UV dose equal to the design UV dose multiplied by the validation factor. Therefore, if the validation factor is determined to be 1.9, the validated UV dose must equal 12×1.9 , or 23 mJ/cm^2 . More details on how the validation factor is calculated can be found in the *UV Disinfection Guidance Manual* (USEPA 2006a).

Monitoring the UV Dose. During the validation process, data must be collected for numerous monitoring tools, typically including a UV sensor, a UV transmittance monitor, and a flowmeter. The UV sensor is a detector that is embedded in the shell of the UV reactor such that it can monitor the UV irradiance. This sensor reading then is tied to a given level of reactor performance during the validation process. For a given set of flow, UVT, and lamp output, the UV system is validated to provide the desired target (validated) UV dose, and a sensor reading is recorded. These sensor readings are documented for validated conditions over a range of flow, UVT, and UV lamp outputs under which the system is expected to operate. This sensor reading then can be used in a monitoring program during UV system operation to indicate whether the UV disinfection process is within validated conditions. In more complex monitoring scenarios, some UV reactor systems are designed to maintain validated UV dose levels by modulating UV lamp intensity using sensor readings, UVT, and flow information in real time.

Effects of Water Quality and By-Products

The transmission of UV light can be affected by various water quality constituents, both dissolved and suspended. These constituents can absorb and/or scatter UV light or shield microorganisms from lethal UV exposure. The water quality also can influence the rate of fouling onto the quartz envelope surrounding the UV lamp.

UV Absorbers, Foulants, and Particles. UV absorbers of concern are constituents that absorb germicidal UV light and lower the UV irradiance within a disinfection system. Typically, compounds containing aromatic groups are strong UV absorbers, including natural organic matter (humic and fulvic substances) and some organic chemicals (e.g., those with phenolic structures). Other important absorbers are some metals (e.g., ferric iron) and nitrate. The UV absorbance typically is monitored at a wavelength of 254 nm, although a scan of the complete germicidal wavelength range from 200 to 300 nm is more revealing for applications involving polychromatic UV lamps.

Upstream water treatment processes can have an effect on UV absorbance via addition of chemicals such as chlorine, ferric iron, and permanganate. Because iron has a very high molar UV absorbance, even very low levels ($<0.01 \text{ mg/L}$) can result in large impacts to UV systems. Residual ozone also significantly absorbs UV light. Proper upstream treatment can serve to improve the UV transmission and thus reduce the size of the UV system required. For instance, enhanced coagulation, activated carbon treatment, and ozonation all reduce the UV absorbance, improving UV disinfection performance.

Polyvalent cations such as iron, calcium, and magnesium deposited onto the quartz sleeve cause fouling and reduced UV transmittance from the lamp into the water. Therefore, water quality constituents such as alkalinity, hardness, pH, and temperature influence lamp sleeve fouling rates. The mechanism of fouling is precipitation of calcium carbonate owing to higher quartz sleeve temperatures, which decrease the solubility of calcium at the water-quartz interface. MP lamps run hotter than LP lamps and are more susceptible to this type of fouling. Other processes that contribute to fouling are gravity settling or impaction, organic fouling, and photochemical reactions (Lin et al., 1999a, 1999b; Wait et al., 2007). The rate

of fouling can vary from the time scale of hours to months. Fouling is easily managed using a regular cleaning regime tailored to the fouling rate of the system or through the use of mechanical and/or chemical quartz sleeve wipers, common to many UV systems.

In addition to dissolved constituents, particles also can interfere with UV disinfection. Organic and metallic colloids and solids that form turbidity can absorb and/or scatter UV light. Typically, below a turbidity of 10 ntu, the presence of particles does not significantly affect the operation of UV disinfection systems in terms of delivery of UV light to water in a reactor (Christensen and Linden, 2003; Passantino and Malley, 2004). Elevated levels of turbidity present in water would require higher levels of UV energy to achieve disinfection, similar to the situation with higher UV absorbance (Clancy et al., 2000). If particles shield a pathogen from UV light via particle-microbe association, then UV disinfection may be compromised (Mamane-Gravetz and Linden, 2006; Templeton et al., 2008). Particle size analysis could be used to monitor the presence of protecting particles, which would indicate upstream process (e.g., filtration) performance concerns.

UV-Induced Disinfection By-Products. Another factor in the rapidly increasing interest in UV disinfection of water is the fact that application of UV disinfection does not negatively affect the formation of halogenated disinfection by-products (DBPs) or other by-products such as bromate (Bellamy et al., 2004). Although UV light itself does not contribute to the formation of regulated DBPs such as trihalomethanes (THMs) and haloacetic acids (HAAs), UV light may influence DBP precursors at high UV doses, outside the range of disinfection practice. Small changes in natural organic matter (NOM) structure have been reported (Magnuson et al., 2002), but no effects on THMs and HAAs were noted (Liu et al., 2002). The one area of potential concern for UV-induced by-products is in the photolysis of nitrate to nitrite. Nitrate may be present in groundwaters and some surface waters and absorbs UV light below 240 nm, in the range of output for MP UV lamp sources (but not LP UV). The formation of nitrite is complex (Mack and Bolton, 1999) and may be influenced by the presence of organic matter and pH, but when nitrate is below the regulated maximum contaminant limit (MCL), there is minimal chance that nitrite formation would occur at levels above the USEPA-regulated limits, although the European Union (EU) limits, which are more strict (0.5 mg/L as NO_2^-) may be approached (Sharpless and Linden, 2001). The photolysis of nitrate also may induce the formation of nitrogenous DBPs such as chloropiridin, but not much is yet known about the formation mechanisms, and little formation is expected for UV doses at disinfection levels (Reckhow et al., 2010).

Integration of UV into a Water Treatment Plant

The placement of UV disinfection in a water treatment plant can vary and often will depend on the source water quality. In surface water plants, owing to UV transmittance and particle considerations, it is often best placed following filtration and ideally after a polishing step such as enhanced coagulation or activated carbon. In this location, the UV transmittance is maximized, optimizing UV system sizing and minimizing any issues with particles in the water. UV disinfection also can be employed at other locations within a surface water treatment plant, on the raw water, upstream of filtration, or after chlorination. Upstream of filtration, the water quality will be poorer, and therefore, the UV system required to disinfect the water may be larger. UV employed following chlorination can cause some chlorine photolysis, leading to minor dechlorination (Ormezi et al., 2005), or may under some conditions of low pH form oxidizing radicals (Watts and Linden, 2007). Ideally, UV can be used as a primary disinfectant on filtered water for the inactivation of protozoa, bacteria, and viruses, followed by application of chlorine as a postdisinfectant for maintaining a distribution system residual. For groundwaters low in NOM without reduced iron, UV

can be used without pretreatment. With reduced iron, UV should be used following oxidation and removal of iron. For unfiltered water treatment systems, UV disinfection can be employed effectively for waters meeting turbidity standards and those low in NOM. UV is an ideal disinfectant as a primary barrier for inactivation of protozoan pathogens, such as *Cryptosporidium* and *Giardia*, in unfiltered systems, as well as being effective against bacteria and most viruses.

Small Systems and Groundwater Applications. UV disinfection can be an important component for proper treatment of water produced for small community systems (Malley et al., 2001). In cases where there is insufficient contact time for proper chlorination, UV disinfection can serve as a primary disinfectant for inactivation of water borne pathogens. UV is also often used as the primary disinfectant in noncommunity supplies (i.e., households) that draw water from protected groundwater, surface water, or spring sources. When UV is used as a primary disinfectant without sufficient free chlorine application, the required UV doses will need to be high enough to meet the requirements for virus inactivation.

UV Inactivation of Viruses. Presently, UV disinfection systems cannot receive much credit for virus inactivation at UV doses typically used in disinfection practices. This is so because the U.S. Environmental Protection Agency (USEPA) regulates the UV dose required for all viruses based on the results reported for the LP UV inactivation of adenoviruses. As noted in Fig. 18-7, the UV dose needed for 4 log inactivation of other pathogenic viruses (e.g., hepatitis, polio, and rotavirus) is below the commonly applied UV dose of 40 mJ/cm² (Snicer et al., 2000), whereas that for adenoviruses is almost five times higher. The fact that water utilities interested in receiving credit for virus inactivation have to apply UV doses approximately five times higher than is typical is a major issue in practice and is due solely to the UV dose regulations being based on adenoviruses. This issue, unless overturned based on new research findings on adenovirus susceptibility to UV light, will virtually require water utilities to achieve virus disinfection credit using high doses of UV light or free chlorine or other chemical disinfectants.

Multi-Barrier Approach. UV disinfection is an important component to the multiple-barrier concept in water treatment. Water treatment processes should establish a series of barriers to stop the passage of pathogens and harmful chemical pollutants to the greatest extent practicable. These protection barriers should be at multiple levels and include source water protection as well as treatment processes. In addition to multiple layers of treatment processes, incorporating processes with differing mechanisms of action is essential. UV disinfection, a photochemical process, directly complements processes such as filtration and chlorination by providing a unique mode of action not found in other treatment processes. The application of UV in combination with free chlorine is an approach that will be increasingly necessary for water utilities to achieve disinfection of both *Cryptosporidium* and viruses (Ballester and Malley, 2004).

Unfiltered Water Supply Systems. Because of its effectiveness for inactivation of *Cryptosporidium*, UV disinfection is an essential part of the water treatment process for unfiltered systems. Since filtration is a primary barrier in the treatment of protozoan pathogens, the water systems granted waivers from filtration are required to implement additional measures to achieve disinfection or removal of these pathogens. These unfiltered supplies represent some of the largest UV disinfection systems in North America and employ multiple disinfectant barriers, including combinations of ozone, UV light, chlorine, and chloramines. These multiple barriers are in place to cover inactivation of all pathogens in the absence of a conventional water treatment train.

Examples of UV Installations

Although UV disinfection has been used extensively for wastewater disinfection and has been used in small communities and thousands of household water treatment systems in the United States, it was not until the promulgation of LT2ESWTR that the design and construction of UV systems into water treatment plants in North America accelerated. Given these new regulations that now require stricter limits on DBPs and inactivation of *Cryptosporidium* for some vulnerable water supplies, it is estimated that over 3000 UV disinfection facilities will be constructed in the United States (USEPA, 2005) to meet new drinking water regulations. A number of prominent UV installations already exist, and some of these are described below.

Fort Benton, Montana. The UV disinfection system in Ft. Benton is one of the oldest and longest-operating UV systems, serving 30,000 residents. Installed in 1987, this system uses a medium-pressure UV disinfection system to disinfect 8.3 million L/day (2.2 mgd) of water from the Platte River, which is collected through a horizontal collection well approximately 7.6 m (25 ft) under the riverbed. Other than bank filtration, there is no other treatment process employed before UV disinfection. The water is postchlorinated and distributed via pipe network to the town of Ft. Benton.

Seattle Public Utilities. The City of Seattle uses a multiple-barrier system consisting of a watershed-protected source water that is unfiltered and goes through an initial ozonation process before being disinfected by a medium-pressure UV system followed by lime addition and postchlorination. This combination provides 3 log *Cryptosporidium*, 4 log *Giardia*, and 5 log virus inactivation. The system serves 1.3 million people and was installed in 2004. It treats up to 680 million L/day (180 mgd), with the UV process being the primary barrier against bacteria and protozoa, whereas ozone and chlorine are used as a dual virus barrier.

Thornton, Colorado. The Wes Brown Water Treatment Plant is a 190 million L/day (50 mgd) facility receiving source water from the South Platte River. The treatment processes include ultrafiltration membranes for filtration coupled with UV disinfection as the primary disinfectant for *Cryptosporidium* and *Giardia* and chlorine as the main disinfectant for viruses.

New York City. The unfiltered Catskill–Delaware (CAT–DEL) source water serving the City of New York will be treated with UV disinfection using 56 low-pressure, high-output UV reactors. The UV system will treat 4.9 million L/day (1300 mgd). The city also uses postchlorination.

UV PHOTOLYSIS

A *photochemical reaction* typically is defined as a chemical reaction caused by the absorption of UV or visible electromagnetic radiation (light), with UV photolysis involving the study of photochemical transformation reactions induced by light within the UV range (200–400 nm) (Bartrop and Coyle, 1978). In contrast to UV for disinfection, where UV energy generally is visualized as a field of energy through which target microbes must pass for a definitive amount of time to achieve an effective inactivation UV dose, in UV photolysis, UV energy is visualized as discrete packets of energy, known as *photons*, that are absorbed by molecules within the water matrix and may be capable of causing photochemical change.

Photochemistry Basics

Laws of Photochemistry. *UV photolysis* is defined by two main principles. The first, known as the *Grotthuss-Draper law*, states that only energy absorbed by a molecule can bring about chemical change. The second, known as the *Stark-Einstein law*, indicates that photochemical degradation of a molecule corresponds to the absorption of a single photon (this law holds for UV light sources, with exceptions possible for extremely intense light sources, such as lasers) (Coyle, 1986). The two laws serve as the basis for photochemical study, giving rise to concepts such as the molar absorption coefficient and quantum yield.

A third principle of interest requires that the energy of an absorbed photon must be equal to or greater than the weakest bond in the molecule to induce photochemical transformation (Schwarzenbach et al., 2003). UV light (200–400 nm) absorbed by molecules is often greater than the energy required for bond dissociation. U_λ , the photon energy at wavelength λ ($\text{J} \cdot \text{Es}^{-1}$), is calculated using Eq. 18-7. Photon energy is inversely related to λ , indicating that as the wavelength gets shorter, the available photon energy is greater:

$$U_\lambda = \frac{N \cdot h \cdot c}{\lambda} = \frac{0.1196}{\lambda} \left(\frac{\text{joule}}{\text{einstein}} \right) \quad (18-7)$$

where N = Avogadro's number (6.02×10^{23} photons \cdot Es $^{-1}$), h = Planck's constant (6.6256×10^{-34} J \cdot s \cdot photon $^{-1}$), c is the speed of light (2.9979×10^8 m \cdot s $^{-1}$), and λ is the wavelength (m).

Interactions of Light and Matter. When a photon of UV energy is absorbed by a chemical entity, the result is the excitation of electrons within the chemical structure, promoting an electron from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO). Figure 18-8, adapted from Oppenländer (2003), displays a generalized

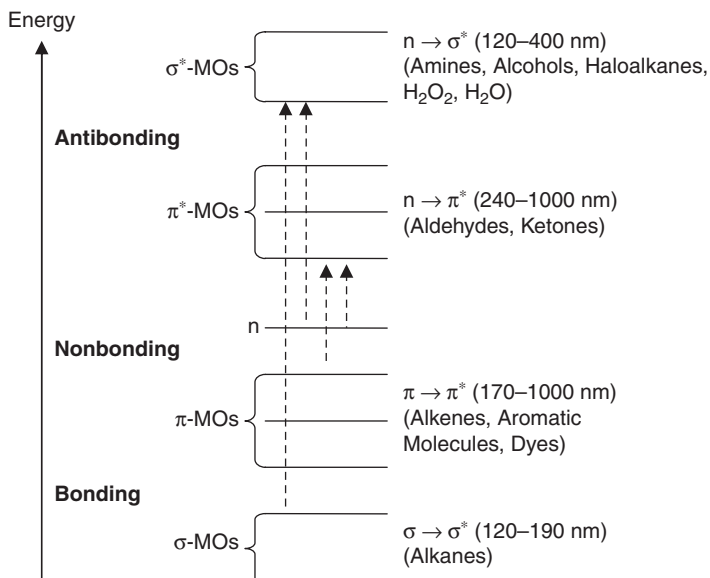

FIGURE 18-8 Molecular orbital diagram describing possible excitations caused by the absorption of a photon of UV light. (Also included are the wavelengths that have the energy to cause the electron jumps and compounds with these types of electrons.) (Source: Oppenländer, 2003; reprinted with permission from Wiley-VCH. molecular orbital diagram and shows possible electronic transitions in organic molecules, as well as associated absorption regions and examples of common chromophores.

On excitation, the molecule can follow several paths to return to the ground energy state. The Jablonski diagram (Fig. 18-9) is a convenient way to visualize the possible paths between the various electron states of a molecule. To understand Fig. 18-9, the nomenclature must be explained. S_0 indicates the unexcited ground electron state for the molecule, with S_1 and S_2 representing the first or second excited singlet states, respectively, and T_1 indicates the excited triplet state. P_1 and P_2 are photoproducts of the reaction.

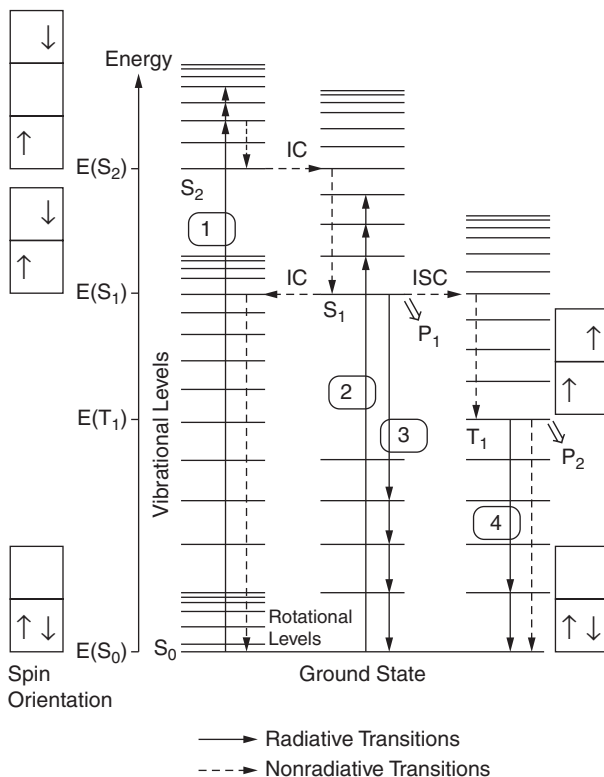

FIGURE 18-9 Modified Jablonski diagram for visualization of radiative, nonradiative, and photoproduct forming processes. (Source: Oppenlander, 2003; reprinted with permission from Wiley-VCH. Copyright © 2003.)

Depending on the photon energy, the molecule is excited from the S_0 state to either the S_1 or S_2 state. After excitation, several processes may occur, including internal conversion (IC) from the S_2 state and/or relaxation of vibrationally excited levels of the S_1 state. All subsequent processes occur from the S_1 excited state. S_1 can deactivate via IC and by vibrational relaxation to S_0 , transforming the excitation energy into vibrational energy (i.e., heat), or the S_1 deactivates by fluorescent emission. Both the S_2 and S_1 states are present for only very short lifetimes of 10^{-13} to 10^{-12} and 10^{-12} to 10^{-6} second, respectively. Because of its short lifetime, the only chemical reactions that can occur from the S_1 state involve rearrangement of the molecular structure or bond cleavage processes leading to reaction product P_1 . If special interactions

occur, the relatively long-lived triplet state (T_1) can occur via intersystem crossing (ISC) and vibrational deactivation. Once at the T_1 state, the molecule can deactivate to the S_0 state via phosphorescence emission, a much lower energy and slower energy release than fluorescence. Nearly all intermolecular photochemical reactions occur from the T_1 state, mainly owing to the comparatively long lifetime of this energy state.

Molar Absorption Coefficient. The pattern of wavelength specific UV energy absorption is defined by the molar absorption coefficient ϵ , which is a measure of the amount of UV energy transferred from an electromagnetic field to the molecular entity divided by the absorption path length and concentration. This absorption of UV energy is chemical-specific and depends heavily on moieties within the chemical. These absorptive moieties are known as *chromophores*, and this absorption is a necessary starting point for photochemical reactions. As an example, Figure 18-10 displays the molar absorption coefficients for several xenoestrogens, as well as for hydrogen peroxide, from 200 to 350 nm. The molar absorption coefficient ϵ for a particular compound can be determined by using Eq. 18-3 by measuring a_{10} for a solution containing only the compound of interest at a known concentration.

Quantum Yield. The amount of photoproducts (P_1 , P_2 , etc.) formed or the initial compound degraded via photochemical reactions as a function of the number of photons of energy absorbed is known as the *quantum yield* Φ . The quantum yield is a measure of the molecular photon efficiency of a photochemical reaction. It is defined as the number of moles of reactant removed per einstein (mole of photons) absorbed by the chemical (Bolton, 2001). There are no simple rules to predict reaction quantum yields from chemical structure, so Φ values need to be determined experimentally (Schwarzenbach et al., 2003).

FIGURE 18-10 Molar absorption spectra for bisphenol A (BPA), 17- β -estradiol (E2), 17- α -ethinyl estradiol (EE2), and hydrogen peroxide (H_2O_2) ($\times 10$).

Additionally, the wavelength dependence of Φ must be considered when using polychromatic light sources. According to Zepp (1982), quantum yield values can be assumed to be wavelength independent, at least over the wavelength range of a given absorption band, corresponding to one mode of excitation. If multiple light absorption maxima are displayed, quantum yields may have to be determined for various wavelengths to accurately predict the transformation rate of a given compound.

UV Photolysis for Treatment of Chemical Pollutants

Monochromatic UV Photolysis. In determining the efficiency of photolysis for treatment of chemical pollutants, two major chemical-specific parameters are of importance. As mentioned previously, the molar absorption coefficient (ϵ , in $M^{-1} \cdot cm^{-1}$) identifies how much UV energy at a particular wavelength a compound will absorb. In addition, the quantum yield (Φ in $mol \cdot Es^{-1}$) indicates the efficiency of the absorbed energy for causing a photochemical degradation reaction. While UV photolysis can display zero-order or pseudo-first-order reaction kinetics depending on the concentration of the pollutant and the nature of the water matrix (Bolton, 2001), most photolysis situations of interest in natural or engineered water systems are described by first-order decay kinetics, with a fluence-based rate constant, as described in Eq. 18-8. The complete derivation of the relationship can be found in Bolton and Stefan (2002). Equation 18-8 has been modified slightly from the final equation found in Bolton and Stefan (2002) to reflect a fluence-based rate constant with units of cm^2/mJ rather than m^2/J , as in the referenced text:

$$k'_1 = \frac{\Phi_{\lambda,c} \epsilon_{\lambda,c} \ln(10)}{U_{\lambda}} \quad (18-8)$$

where for micropollutant C , k'_1 is the pseudo-first-order rate constant with units of $cm^2 \cdot mJ^{-1}$, $\Phi_{\lambda,C}$ is the wavelength-specific quantum yield ($mol \cdot Es^{-1}$), $\epsilon_{\lambda,C}$ is the wavelength-specific molar absorption coefficient ($M^{-1} \cdot cm^{-1}$), and U_{λ} is the wavelength-specific photon energy ($J \cdot Es^{-1}$), as calculated in Eq. 18-7.

Table 18-4 provides several approximate molar absorption coefficients and quantum yield values for some inorganic and organic compounds at 254 nm, as reported in the

literature. Example 18-1 illustrates the potential photochemical treatment of a relatively UV-labile compound, *N*-nitrosodimethylamine (NDMA).

Example 18-1 NDMA Photolysis

Using the parameters from Table 18-4, what is the low-pressure (monochromatic, 254 nm) UV fluence required for 50 and 90 percent (1 log) NDMA photodegradation, assuming pseudo-first-order kinetics?

Solution Assuming first-order, fluence-based kinetics, the UV fluence required for removal of a fraction of contaminant *M* can be described with the following equation:

$$\ln\left(\frac{M_0}{M}\right) = k'_1 \cdot \text{UV fluence}$$

Rearranging this equation to find the UV fluence required for degradation and substitution in from Eq. 18-8 for k'_1 yields:

$$\text{UV fluence} = \frac{\ln\left(\frac{M_0}{M}\right)}{k'_1} = \frac{\ln\left(\frac{M_0}{M}\right) U_\lambda}{\ln(10)\epsilon_\lambda \Phi_\lambda}$$

To calculate UV_{254} , use Eq. 18-7:

$$\text{UV}_{254} = \frac{hc}{\lambda} = \frac{0.1196}{254 \times 10^{-9}} \left(\frac{\text{J}}{\text{Es}}\right) = 4.71 \times 10^5 \text{ J/Es}$$

From Table 18-4, there are several values for ϵ_{254} (1400, 1470, and 1650 $\text{M}^{-1} \cdot \text{cm}^{-1}$), but a consistent value and Φ_{254} ($\sim 0.3 \text{ mol} \cdot \text{Es}^{-1}$) for NDMA. Using an average value of these three published ϵ_{254} constants and calculating UV fluence for 50 percent NDMA photolysis, we get

$$\text{UV fluence} = \frac{\ln(2) \times 4.71 \times 10^5}{\ln(10) \times 1507 \times 0.3} = 313.6 \text{ mm}\cdot\text{E}\cdot\text{m}^{-2}$$

However, because of the variability in reported ϵ_{254} values observed in Table 18-4, the range of calculated UV fluence values for 50 percent photolysis of NDMA is 286 to 337 $\text{mJ} \cdot \text{cm}^{-2}$. Likewise, when calculated using the average ϵ_{254} value, one obtains a fluence value of 1041 $\text{mJ} \cdot \text{cm}^{-2}$ for 90 percent NDMA photolysis. ▲

When considering fluence-based kinetics, Eq. 18-8 indicates that UV photolysis rates for a monochromatic light source are constant, irrespective of water quality (assuming that no side reactions leading to the decay or regeneration of *C* are taking place). This observation has been substantiated for NDMA kinetics in phosphate buffer and experimental waters containing 2, 7, or 12 mg/L organic carbon (Stefan et al., 2002). No significant change was found in measured fluence-based degradation. However, this does not indicate that the amount of energy required for photodegradation is independent of water quality. As described earlier, the UV fluence is a function of the average irradiance (which is affected by the amount of energy absorbed by the water) and the exposure time. Since full-scale UV reactors typically are designed with a fairly constant exposure time, the amount of energy absorbed by the water is the parameter often adjusted to increase or decrease UV fluence. The average irradiance is determined by the amount of energy input to the system (from the

lamps) and the UV absorbance of the solution. In other words, as absorbance increases, so must the energy input from the lamps in order to maintain the same average irradiance.

Polychromatic UV Photolysis. For polychromatic UV lamp sources, such as MP mercury lamps, understanding of the photolysis mechanism is complicated by the presence of multiple emission wavelengths throughout the UV range. These wavelengths are each absorbed to a different degree by the contaminant, reflecting its molar absorption coefficient, and the possibility of different quantum yield values for various wavelengths throughout the UV range exists.

The discussion in Sharpless and Linden (2003) describes many of these complexities in the context of photolysis of NDMA. Starting with Eqs. 18-9 and 18-10, modified from Sharpless and Linden (2003), it is observed that many of the parameters describing both lamp emission and photon absorbance are wavelength-dependent:

$$-\frac{d[C]}{dt} = k'_d[C] = \left(\sum_{\lambda} k_{s,\lambda} \Phi_{\lambda,c}[C] \right) \quad (18-9)$$

where k'_d is the first-order rate constant for direct photolysis of C (s^{-1}), $k_{s,\lambda}$ is the specific rate of light absorption by compound C ($Es \cdot mol^{-1} \cdot s^{-1}$), $\Phi_{\lambda,c}$ is the wavelength-specific quantum yield of compound C ($mol \cdot Es^{-1}$), $E_{p,\lambda}^0$ is the incident photon irradiance ($10^{-3} Es \cdot cm^{-2} \cdot s^{-1}$), $\epsilon_{\lambda,c}$ is the molar absorption coefficient of C ($M^{-1} \cdot cm^{-1}$), a_{λ} is the solution absorbance coefficient (cm^{-1}), and l is the solution path length (cm). All the parameters in Eq. 18-10 are measurable.

$$k_{s,\lambda} = \frac{E_{p,\lambda}^0 \epsilon_{\lambda} (1 - 10^{-a_{\lambda}l})}{a_{\lambda}l} \quad (18-10)$$

Assuming that the quantum yield is path length independent for a range of wavelengths and that accurate measurements of the lamp emission spectrum and the wavelength-specific molar absorption coefficient are available, Eq. 18-9 can be rewritten in the form of Eq. 18-11:

$$-\frac{d[C]}{dt} = \left(\sum_{\lambda_1 \rightarrow \lambda_2} k_{s,\lambda} \Phi_{\lambda} + \sum_{\lambda_2 \rightarrow \lambda_3} k_{s,\lambda} \Phi_{\lambda} + \dots \right) [C] \quad (18-11)$$

The wavelength independence of quantum yield, at least for a range of wavelengths (i.e., from λ_1 to λ_2 or λ_2 to λ_3), has been observed for many compounds, and the general rule of thumb is that the quantum yield value will be constant over an observed UV absorbance band, as defined as the area from one UV absorbance minimum to the next UV absorbance minimum (i.e., in Fig. 18-10, an absorption band can be observed for BPA ranging from approximately 250 to 290 nm).

In the case of NDMA (Sharpless and Linden, 2003), the quantum yield is found to be constant over the entire UV wavelength range covered by the polychromatic MP UV lamp, and as a result, the observed quantum yield for NDMA is $0.3 mol \cdot Es^{-1}$ for both the monochromatic LP source and the MP sources. For atrazine photolysis, however, there are different observations (Sharpless et al., 2003). Atrazine exhibits two distinct UV absorption bands in the 200- to 400-nm range, one ranging below 250 nm and one ranging from approximately 250 to 290 nm. Using bandpass filters, Sharpless and colleagues found the quantum yield at 228 nm to be $0.066 mol \cdot Es^{-1}$, whereas at 270 nm the quantum yield was $0.038 mol \cdot Es^{-1}$. By using these constant quantum yield values for each absorbance band, the authors were able to accurately predict atrazine photolysis using the entire MP UV lamp spectrum. A photolysis study of several endocrine-disrupting compounds (EDCs) (Rosenfeldt and Linden, 2004) yielded very different observed quantum yield values for LP

UV and overall MP UV for BPA and two other hormone EDCs, 17- α -ethinyl estradiol and 17- β -estradiol), also indicating the possibility of different quantum yield values associated with each of the absorbance maxima in the 200- to 300-nm range.

If quantum yield values are measured for each of the absorption bands within the UV emission range of a particular lamp source, photolysis rates can be predicted for polychromatic lamp sources as accurately as those for monochromatic lamps through the use of Eqs. 18-10 and 18-11.

UV ADVANCED OXIDATION PROCESSES (AOPs)

The addition of hydrogen peroxide (H_2O_2) to a UV process yields an *advanced oxidation process* (AOP), where hydroxyl radicals ($\cdot\text{OH}$) are formed via the homolytic cleavage of the central HO–OH bond to initiate a propagation cycle, with the net reaction leading to water and molecular oxygen. AOPs are described by a complex chain-reaction mechanism involving the formation and rapid consumption of intermediate radical species, such as the hydroxyl radical ($\cdot\text{OH}$). Short descriptions of UV/ H_2O_2 and other AOPs are given in Chap. 7.

UV/ H_2O_2 AOP has been shown to be effective for degrading many organic and inorganic contaminants in water applications. Table 18-5 displays references for studies examining the efficiency of UV/ H_2O_2 AOP for degrading many organic contaminants of concern in water. The list was compiled with the aid of several reviews, including Ikehata and El-Din (2006), Ikehata and colleagues (2006), Gultekin and Ince (2007), and Oppenländer (2003). The extent of this list indicates the potential of the UV/ H_2O_2 AOP for degrading many organic contaminants, including emerging contaminants of concern such as pesticides, pharmaceuticals, and EDCs.

One of the major limitations of UV AOP is the inefficient absorption of UV energy by H_2O_2 ($\epsilon = 19.6 \text{ M}^{-1} \cdot \text{cm}^{-1}$ at 254 nm). The quantum yield for H_2O_2 removal associated with the photolytic decomposition of H_2O_2 to form $\cdot\text{OH}$ is relatively high ($0.5 \text{ mol} \cdot \text{Es}^{-1}$), so photons that are absorbed by the molecule efficiently initiate AOP chemistry. Additionally, the $\cdot\text{OH}$ radical is a relatively unselective oxidant that reacts equally well with many organic and inorganic species in water.

Advantages associated with the UV/ H_2O_2 AOP for water treatment over other AOP technologies include short reactor detention time leading to small reactor footprints and the fact that UV disinfection of pathogens in the water readily occurs at the elevated UV doses applied for AOP conditions, so two treatment objectives are met at once. In addition, UV/ H_2O_2 AOP provides two mechanisms for transformation of organic chemicals—direct photolysis and hydroxyl radical oxidation. Disadvantages of the process include high energy requirements associated with operating the reactors at high UV doses and the need to store and inject H_2O_2 into the water before the UV reactors at relatively high concentrations ($2\text{--}10 \text{ mg} \cdot \text{L}^{-1}$ to initiate effective AOP conditions). Another drawback of the process is based on the fact that typically only a small portion of the added H_2O_2 will degrade to $\cdot\text{OH}$ radicals during the process, leaving 80 to 90 percent of the injected H_2O_2 in the outlet stream. Processes including chemical quenching (with free chlorine, bisulfite, or enzymatic catalysts) and adsorption through granular activated carbon (GAC) or biologically active media filters are needed to remove the excess H_2O_2 before postdisinfection processes.

The UV/ H_2O_2 AOP Mechanism

A mechanism for the UV/ H_2O_2 AOP, known as the *Haber-Weiss mechanism*, is outlined in Lunak and Sedlak (1992) and described below. The initiation reaction to form hydroxyl

radical is governed by the absorption of UV energy by H_2O_2 , as well as the quantum yield of the reaction (Eq. 18-12):

As with any photochemical reaction, Eq. 18-12 is governed by the absorption of UV energy by H_2O_2 , as well as by the quantum yield for the process. The molar absorption coefficient of H_2O_2 is displayed in Fig. 18-10 and indicates that H_2O_2 does not greatly absorb UV light throughout the 200- to 300-nm range. The molar absorption coefficient for H_2O_2 at 254 nm has been reported as $19.6 \text{ M}^{-1} \cdot \text{cm}^{-1}$, which is exceptionally low for a primary absorber (Glaze et al., 1987). The energy that is absorbed by H_2O_2 initiates the reaction with a relatively high $\cdot\text{OH}$ radical quantum yield. According to the stoichiometry, the photolysis of 1 mol of H_2O_2 should produce 2 mol of hydroxyl radicals with a calculated maximum quantum yield of 1 mol H_2O_2 degraded per einstein or 2 mol $\cdot\text{OH}$ formed per einstein, but in aqueous solution, this is not the case. In water, the so-called cage effect has been postulated to explain the fact that only one hydroxyl radical is formed per einstein absorbed by H_2O_2 (Oppenländer, 2003). Equation 18-13 describes this cage effect, in which only 50 percent of the $\cdot\text{OH}$ radicals seem to be able to escape from the aqueous solvent cage.

Once initiated, a chain radical mechanism described by Eqs. 18-14 and 18-15 involving conversion of hydroxyl radical to $\text{HO}_2\cdot$ while consuming H_2O_2 occurs, propagating the radical reaction (Lunak and Sedlak 1992).

Equation 18-15 displays a slow rate constant ($3.0 \text{ M}^{-1} \cdot \text{s}^{-1}$) (Koppenol et al., 1978) when compared with Eq. 18-14 ($2.7 \times 10^7 \text{ M}^{-1} \cdot \text{s}^{-1}$) (Buxton et al., 1988) and is therefore justifiably neglected. Termination reactions outlined in Eqs. 18-16 through 18-18 act to lower the apparent quantum yield.

Of these reactions, Eq. 18-16 is entirely negligible owing to the extremely low steady state concentration of $\cdot\text{OH}$ radicals. Noticeably missing from the reaction mechanism outlined are the reactions with organic and inorganic species found in actual waters. These reactions typically are regarded as termination reactions but can in some cases propagate the $\cdot\text{OH}$ radical mechanism (NOM) or initiate new radical reaction mechanisms (e.g., carbonate species or free chlorine). The hydroxyl radical is a nonselective oxidant that displays high reaction rates with organic and inorganic species present in natural waters. Table 18-6 displays some common species present in natural water, as well as some micropollutants of concern and their rate constants with hydroxyl radical. The rates are exceptionally fast, and the oxidation reactions are nonselective, producing a variety of oxidation products.

UV/ H_2O_2 Models

Several approaches for modeling UV/ H_2O_2 AOPs exist. At the basic level, these include a simplified oxidation model, called the *steady state* $\cdot\text{OH}$ radical model and outlined in Glaze and colleagues (1995), as well as a complex set of differential equations, described in Crittenden and colleagues (1999) and in Cater and colleagues (2000). All models are based on use of Eqs. 18-12 through 18-18, as well as other termination reactions.

Steady State $\cdot\text{OH}$ Radical Model. The model presented by Glaze and colleagues (1995) is used to model micropollutant oxidation in water matrices. The model is based on the simplifying assumption that the hydroxyl radical is extremely reactive and is essentially consumed as quickly as it is produced. Using a set of equations describing production of hydroxyl radical (dominated by the initiation Eq. 18-12 in most UV/ H_2O_2 applications

but including the effects of promotion reactions) and consumption of hydroxyl radical (termination and promotion reactions) and the key assumption that hydroxyl radical concentration will achieve steady state (consumption and production are equal), the general Eq. 18-19 can be generated:

$$[\cdot\text{OH}]_{\text{ss}} = \frac{\text{rate of hydroxyl radical fotation}}{\text{rate of hydroxyl radical consumption}} \quad (18-19)$$

More specifically, the rate of hydroxyl radical formation can be described by Eq. 18-20:

$$\frac{d[\cdot\text{OH}]}{dt} = E_{p,\lambda}^{r0} \frac{(1-10^{-a_{\lambda} \cdot l})}{a_{\lambda} \cdot l} \epsilon_{\lambda, \text{H}_2\text{O}_2} [\text{H}_2\text{O}_2] \Phi_{\lambda, \text{H}_2\text{O}_2 \rightarrow \cdot\text{OH}} \quad (18-20)$$

Additionally, the rate of hydroxyl radical consumption can be described with Eq. 18-21:

$$\frac{d[\cdot\text{OH}]}{dt} = k_{\text{H}_2\text{O}_2, \cdot\text{OH}} [\cdot\text{OH}] [\text{H}_2\text{O}_2] + k_{\text{OH}, \cdot\text{OH}} [\cdot\text{OH}]^2 + k_{\text{HO}_2, \cdot\text{OH}} [\cdot\text{OH}] [\text{HO}_2 \cdot] + \sum k_{\text{S}, \cdot\text{OH}} [\cdot\text{OH}] [\text{S}] \quad (18-21)$$

where $k_{\text{S}, \cdot\text{OH}}$ is a rate constant between the hydroxyl radical and some background scavenger S (including, but not limited to, carbonate and bicarbonate species, NOM, etc.). If one assumes steady state, $d[\cdot\text{OH}]/dt = 0$, the rate of hydroxyl radical formation can be set equal to the rate of hydroxyl radical consumption, resulting in Eq. 18-22:

$$[\cdot\text{OH}]_{\text{ss}} = \frac{E_{p,\lambda}^{r0} \frac{(1-10^{-a_{\lambda} \cdot l})}{a_{\lambda} \cdot l} \epsilon_{\lambda, \text{H}_2\text{O}_2} [\text{H}_2\text{O}_2] \Phi_{\lambda, \text{H}_2\text{O}_2 \rightarrow \cdot\text{OH}} + k_{\text{HO}_2, \cdot\text{H}_2\text{O}_2} [\text{HO}_2 \cdot] [\text{H}_2\text{O}_2]}{k_{\text{H}_2\text{O}_2, \cdot\text{OH}} [\cdot\text{OH}] [\text{H}_2\text{O}_2] + k_{\text{OH}, \cdot\text{OH}} [\cdot\text{OH}]^2 + k_{\text{HO}_2, \cdot\text{OH}} [\cdot\text{OH}] [\text{HO}_2 \cdot] + \sum k_{\text{S}, \cdot\text{OH}} [\cdot\text{OH}] [\text{S}]} \quad (18-22)$$

Further assumptions are often used to negate the contributions in formation and consumption of the propagation and lesser termination reactions, so the equation is typically used in its simplified form (Eq. 18-23):

$$[\cdot\text{OH}]_{\text{ss}} = \frac{E_{p,\lambda}^{r0} \frac{(1-10^{-a_{\lambda} \cdot l})}{a_{\lambda} \cdot l} \epsilon_{\lambda, \text{H}_2\text{O}_2} [\text{H}_2\text{O}_2] \Phi_{\lambda, \text{H}_2\text{O}_2 \rightarrow \cdot\text{OH}}}{k_{\text{H}_2\text{O}_2, \cdot\text{OH}} [\cdot\text{OH}] [\text{H}_2\text{O}_2] + \sum k_{\text{S}, \cdot\text{OH}} [\cdot\text{OH}] [\text{S}]} \quad (18-23)$$

AdOx Kinetic Model for UV/H₂O₂AOP. The AdOx model simultaneously solves a series of 44 differential equations describing elementary chemical and photochemical reactions showing initiation, the chain reaction mechanism, and termination reactions and using reported reaction rates and photochemical parameters to predict contaminant destruction without the assumption of steady state hydroxyl radical concentrations (Crittenden et al., 1999). Figure 18-11 [from Crittenden et al. (1999)] directly compares the AdOx and steady state $\cdot\text{OH}$ radical models for degradation of 1,2-dibromo-3-chloropropane (DBCP) in laboratory water supplemented with inorganic carbon.

The steady state $\cdot\text{OH}$ radical model (Glaze et al., 1995) consistently underpredicts the observed DBCP degradation rate constants, whereas the AdOx model consistently provides reasonably accurate predictions for the system. The more accurate predictions are credited directly to the fact that the AdOx model does not employ the pseudo-steady state or constant-pH assumptions (Crittenden et al., 1999) that are critical to the steady state $\cdot\text{OH}$ radical model.

FIGURE 18-11 Effect of initial H_2O_2 on the pseudo-first-order rate constant for the oxidation of DBCP with UV/ H_2O_2 AOP. (Source: Reprinted with permission from Water Research [Crittenden et al., 1999].)

While these approaches perform decently in approximating chemical destruction for the UV/ H_2O_2 AOPs, they rely on published rate constants to determine the amount of $\cdot\text{OH}$ radical-mediated oxidation. Problems arise because of simplifications, such as using a universal rate constant for dissolved organic carbon as a surrogate for NOM, which are used in these models for more complex, natural water systems. Research is currently under way to address these issues, including better predictors for describing the reaction between NOM and hydroxyl radicals.

UV/ H_2O_2 AOP in Practice: Case Studies

Although there are many facilities using UV technology for mitigation of pathogenic microbial contaminants in wastewater and drinking water treatment processes, the use of UV processes for chemical contaminants is less common. However, these processes are capable of photolyzing or oxidizing a wide range of contaminants and have advantages over traditional oxidation techniques in areas of safety and reactor footprint size. For these reasons, UV-based AOP is being used or research is being performed to examine the feasibility of using this technology for indirect potable water reuse and drinking water applications. The following discussion will relate some of the full-scale uses of UV technology for the treatment of contaminants in each of these water matrices.

Indirect Potable Water Reuse Applications. The issue of potable water reuse is gaining acceptance throughout the entire United States and the rest of world, as it has already done in more arid parts of the country. Since the supply of pristine water sources is dwindling, utilities reach for new sources, including reusing water that has been treated previously, used, and passed through a wastewater treatment facility. The idea of reusing wastewater as a drinking water source is not a pleasant thought for the general public, but as demand for water increases and supplies shrink, this concept will become a reality throughout the United States. Orange County, CA, has implemented UV/ H_2O_2 AOP as part of an advanced

water purification plant designed to provide water for indirect potable reuse and is the subject of the following case study. For more information regarding water reuse, refer to Chap. 16.

Reuse Case Study: UV/H₂O₂ for Removal of NDMA in the Orange County Groundwater Replenishment System (OCWD and OCS D 2008A, 2008B). Water demands in northern and central Orange County, CA, are expected to increase nearly 20 percent by 2020. To combat this increased demand of southern California's scarce water supplies, a joint effort by the Orange County Water District (OCWD) and the Orange County Sanitation District (OCS D) created the Groundwater Replenishment System (GWRS). The GWRS is the largest potable reuse water purification project of its kind in the world and will help to increase Orange County's water independence by providing a locally controlled, drought-proof supply of safe, high-quality water.

The GWRS uses an influent of filtered secondary effluent from the neighboring OCS D treatment plant and treats it to a level exceeding all U.S. and California drinking water quality standards. The 380 million L/day (100 mgd) system consists of a three-step process known as the *Advanced Water Purification Facility (AWPF)*—microfiltration, reverse osmosis, and UV light with hydrogen peroxide. Roughly half the water from the GWRS is injected into Orange County's seawater barrier, an underground pressure ridge of water formed by injection wells along the Pacific coast. The remaining water is piped to recharge lakes in Anaheim, CA, where it will take the natural path of rainwater as it filters through clay, sand, and rock to the deep aquifers of the groundwater basin.

While microfiltration (MF) and reverse osmosis (RO) provide a physical barrier that rejects many organic compounds, *N*-nitrosodimethylamine (NDMA) is not rejected by MF and only partially removed by RO. NDMA is present as a by-product formed during the upstream wastewater treatment processes or as an industrial chemical in the production of rocket fuel and must be removed to below 10 ng/L before discharge because it is a known carcinogen. UV light is a proven technology for degrading NDMA and was included in the three-step process primarily to provide a barrier ensuring NDMA destruction. In addition, 3 mg/L H₂O₂ is added to the UV system, creating AOP conditions capable of oxidizing trace organic constituents that may be present in the water, such as 1,4-dioxane or other organic compounds.

The UV/H₂O₂ AOP system employed in the AWPF consists of three horizontally stacked chambers, each chamber made up of two reactors. Each reactor contains seventy-two 756-W low-pressure, high-output (LPHO) mercury amalgam lamps capable of emitting UVC energy at 254 nm. Each reactor consumes 18.5 kW running at 100 percent power, and power is adjusted based on water temperature, flow rate, UVT₂₅₄, lamp age, and fouling.

With an inlet total organic carbon (TOC) of less than 0.2 mg/L and an average UVT of 98.6 percent, the AWPF is an ideal situation for maximizing the efficiency of the UV/H₂O₂ AOP. Studies at the facility have shown that the system is capable of removing greater than 1.2 log NDMA and inactivating greater than 5 log MS2 with only a fraction of the total system in operation. The AWPF went on-line in January 2008, providing clean water for replenishing the diminishing groundwater basin and diverting wastewater from ocean outflow.

Drinking Water. While UV processes have been used in drinking water treatment for years throughout the world, for pathogen inactivation in drinking water (see the section on UV disinfection), using the technology for chemical oxidation has been slow to gain acceptance. This stems from the much higher UV doses required for oxidation compared with disinfection. In addition, the unselective nature of ·OH radical oxidation leads to process inefficiencies and a greater possibility of unidentified oxidation by-products.

Recently, two water treatment plants have designed processes to use UV/H₂O₂ technology to meet chemical oxidation needs within their water treatment trains. These operations

decided to install UV/H₂O₂ AOP to address targeted chemical and biological contaminants and had specific concerns related to employing other oxidation technologies.

Drinking Water UVAOP Case Study: PWN (Kruithof et al., 2004; Trojan UV, 2005a). In October 2004, the PWN Water Supply Company North Holland (PWN) officially opened its water treatment plant in Andjik, Netherlands. This was the first large-scale water treatment plant in the world designed to combine UV disinfection with UV oxidation. The plant treats more than 95 million L/day (25 mgd) of water, providing drinking water to half a million people and was designed to eliminate chemical contaminants such as pesticides, in addition to providing primary disinfection, reducing the amount of chlorine added to the water.

The system was designed in association with Trojan Technologies of Canada, with a footprint of only 49 m², significantly smaller than the requirements of many other oxidation technologies and thus reducing capital costs associated with the project. The system is designed to deliver a UV fluence of 540 mJ · cm⁻² in combination with the addition of 6 mg/L H₂O₂. At this combination, an 80 percent degradation of pesticides, EDCs, and pharmaceuticals can be achieved, primary metabolite formation was insignificant, and no bromate was formed. Bromate is of concern because ozonation technologies create bromate as a by-product, a suspected human carcinogen. Following the UV/H₂O₂ AOP in the treatment train is a GAC filter designed to remove any residual H₂O₂, assimilable organic carbon (AOC), and nitrate from the AOP-treated drinking water.

Drinking Water Case Study: Cornwall, Ontario, Canada (Cornwall, Ont., 2009; Trojan UV, 2005b, 2008). The City of Cornwall (Ontario, Canada) uses Lake St. Lawrence (St. Lawrence River) as a source water that is low in turbidity and color and uses conventional treatment with GAC adsorbers/filters. The plant is designed to treat a peak flow of up to 100 million L/day and provides drinking water for 50,000 people. In 2006, four UV units were installed after filtration to upgrade disinfection and control of seasonal algal taste and odor.

The UV system operates in two modes. In disinfection mode, which is used year round for primary disinfection, the system is designed to provide a RED of at least 40 mJ · cm⁻². This RED is achieved by operating a minimal number of lamps in each reactor (approximately half the lamps in a reactor are powered in disinfection mode) at low power of approximately 30 percent maximum. During late summer and early fall, hydrogen peroxide is injected downstream of the filter beds and upstream of the UV reactor, and the UV dose is increased to well over 100 mJ · cm⁻² to create AOP conditions. The UV dose is increased by powering on the remaining lamps in each reactor and by increasing operating power to each lamp. Peroxide is added to a concentration of at least 1 mg/L and is increased as necessary to degrade methylisoborneol (MIB) and geosmin in the water to levels below taste and odor thresholds. In addition, because the UV power is increased, UV disinfection occurs at levels greater than or equal to year-round disinfection mode. The AOP conditions used in the Cornwall system also have been shown to be effective in eliminating other algal products, including surrogates for algal toxins, at levels comparable to MIB and geosmin.

Depending on water quality, the increase in UV dose to treat taste- and odor-causing compounds requires three to six times more energy than disinfection mode, and the power-up is achieved by energizing additional lamps and reactors, which are not used during disinfection mode. In addition to the increased power usage during AOP mode, residual hydrogen peroxide must be quenched after the UV reactor. Quenching is performed by adding free chlorine at a 2.1:1 ratio and is required to ensure that residual peroxide does not interfere with the addition of residual chlorine prior to distribution.

If the system were operated continually in AOP mode, concerns regarding energy requirements and cost of hydrogen peroxide and additional chlorine would surface rapidly. However, the ability to use AOP conditions in a seasonal manner to address particular contaminants in a targeted manner and still use year-round UV primary disinfection offers a high level of water quality protection at minimized additional cost to the utility.

Alternative UV-Based AOPs

In addition to UV/H₂O₂ AOP, other UV-based AOPs have been shown to be effective for degrading organic pollutants in water. Each of these technologies works similarly to the UV/H₂O₂ AOP in that a photoinitiated reaction is used to start a radical chain reaction in which the highly reactive ·OH radical is formed and used for oxidation. Brief descriptions of two homogeneous UV-based AOPs (UV/O₃ and UV/Cl₂) and one heterogeneous AOP (UV/TiO₂) are included below to serve as an introduction to these technologies.

UV/O₃. While ozone alone is a powerful oxidant, and the addition of hydrogen peroxide in the presence of ozone is known to create ·OH radicals (see Chap. 7 for a further discussion), the photoinitiated decay of the ozone molecule also will result in hydroxyl radical-mediated advanced oxidation conditions.

Ozone is an efficient UV absorber ($\epsilon_{254} = 3300$ for O₃ versus 19.6 for H₂O₂) and has a quantum yield of 0.61 mol O₃ degraded per einstein absorbed (Wittmann et al., 2002). It must be recognized, though, that the primary photoproduct of O₃ photolysis is hydrogen peroxide (Glaze et al., 1987). This formed peroxide then either reacts directly with ozone to form hydroxyl radicals (see Chap. 7) or undergoes additional UV photolysis to form hydroxyl radicals via the Haber-Weiss mechanism described earlier. As such, the UV/O₃ AOP essentially be thought of as a method for generating in situ hydrogen peroxide via photolytic degradation of O₃ (Oppenländer, 2003).

UV/Cl₂. The photoinitiated decay of free chlorine species (HOCl and OCl⁻, depending on pH) has been shown to produce ·OH radicals. When free chlorine species absorb a photon (<511 nm), the known photoproducts are a hydroxyl radical (·OH) and chlorine radical (·Cl) (Molina et al., 1980; Nowell and Hoigne, 1992b; Oliver and Carey, 1977; Vogt and Schindler, 1991). Watts and Linden (2007) determined that the quantum yields for degradation of HOCl and OCl⁻ to ·OH and ·Cl radicals under UV conditions at 254 nm in laboratory water were both greater than 1. These reported yields, corroborated by Feng and colleagues (2007), are most likely a measure of HOCl/OCl⁻ degradation through a chain reaction with photoproducts in addition to direct photolysis rather than the true quantum yields of direct photolytic conversion.

Watts and colleagues (2007) directly compared oxidation of an ·OH radical probe compound (nitrobenzene, which displays no significant reaction with chlorine radicals) (Nowell and Hoigne, 1992b) created via UV/H₂O₂ AOP and UV/HOCl (or UV/OCl⁻) with some interesting results. The work found that at equimolar oxidant concentration in laboratory water, nitrobenzene degradation rates were approximately three times faster using the LP UV/HOCl than using LP UV/H₂O₂ AOP. However, pH adjustment had a significant impact on nitrobenzene degradation rates in the UV/Cl₂ system, whereas it had no effect on the UV/H₂O₂ system. This observation was explained by the fact that formed ·OH radicals will readily react with chlorite ion ($k_{\text{OH, OCl}^-}^- = 8.0 \times 10^9 \text{ M}^{-1} \cdot \text{s}^{-1}$), whereas it reacts much more slowly with hypochlorous acid ($k_{\text{OH, HOCl}} = 8.0 \times 10^4 \text{ M}^{-1} \cdot \text{s}^{-1}$), thus providing competition for hydroxyl radicals with the nitrobenzene as solution pH is increased above 6.0.

Similarly, results from the experiments performed in natural waters indicated that the UV/Cl₂ process still oxidized nitrobenzene at a greater rate than the UV/H₂O₂ process; however, the differences were decreased dramatically as water quality deteriorated. An operating cost analysis considering only the cost of electricity to run the UV lamps and the cost of added oxidant indicated that UV/Cl₂ was more efficient in a pH 5 postfiltration water (neglecting the cost associated with pH adjustment). However, at pH 7, UV/H₂O₂ and UV/Cl₂ operating costs were roughly equivalent, depending on oxidant concentration, and at pH 9, UV/H₂O₂ was more efficient than UV/Cl₂. Also of concern with the UV/Cl₂ process are the unknown products associated with chlorine radical chemistry in a solution with typical levels of NOM.

Heterogeneous Photocatalysis: UV/TiO₂. Carey and colleagues (1976) first reported the photodegradation of several polychlorinated biphenyls (PCBs) in water in the presence of titanium dioxide (TiO₂). Since then, many applications of the process have been reported in the literature (Legrini et al., 1993). The mechanism of the UV/TiO₂ process has been described using the bandgap model (Fox, 1983; Bard, 1982; Zafiriou et al., 1984; Childs and Ollis, 1980). The model states that excitation of a TiO₂ molecule by UV energy causes an electron-depleted valence-band hole (h⁺), as well as a reactive electron, according to Eq. 18-24:

After excitation, an electron can transfer from an adsorbed organic substrate (creating a radical organic molecule), or from an adsorbed water molecule into the electron hole (h⁺). The second transfer reaction yields an adsorbed hydroxyl radical molecule and has been identified to be of greater importance in oxidative degradation processes owing to the high concentration of water molecules adsorbed to the particle surface.

In addition, the liberated electron (e⁻) can react with oxygen in solution to form superoxide molecule, initiating a chain reaction mechanism that includes formation of the hydroxyl radical. It also has been found that the addition of hydrogen peroxide enhances the rate of photodegradation, most likely by surface-catalyzed dismutation of H₂O₂ (Legrini et al., 1993). Despite these multiple mechanisms of action, the UV/TiO₂ process is not an efficient AOP because of the low quantum yield for the generation of ·OH radicals (Sun and Bolton, 1996).

Additionally, the fact that the reaction occurs on the TiO₂ surface leads to several limitations—the compounds to be degraded must be adsorbed to the dispersed TiO₂ particles or a solid TiO₂ surface. Hydroxyl radicals formed by the second mechanism (e⁻) are constrained by the fact that the chain reaction mechanism is most likely initiated a very short distance from the particle surface. Another persistent process found in application of photocatalysis in drinking water has been the potential for irreversible fouling of the TiO₂ surfaces owing to natural organic material.

The particle nature of the process adds to inefficient UV treatment. Because the surfaces are not UV transparent, reactor geometry and particle light screening are both important factors of concern. TiO₂ molecules are excited by UV-C, UV-B, and UV-A energy, indicating that light sources other than UV-C lamps can be used to create AOP conditions. Even solar energy has been shown to be effective at creating AOP conditions via the UV/TiO₂ AOP (Bahnemann, 2004).

ABBREVIATIONS

AOC	assimilable organic carbon
AOPs	advanced oxidation processes
AWPF	advanced water purification facility
CAT-DEL	Catskill-Delaware
CFD	computational fluid dynamics
D	UV dose (mJ · cm ⁻²)
D/DBPR	Disinfection/Disinfectant By-Products Rule
DBCP	1,2-dibromo-3-chloropropane

DBPs	disinfection by-products
DNA	deoxyribonucleic acid
EDCs	endocrine-disrupting compounds
ESWTR	Enhanced Surface Water Treatment Rule
EU	European Union
GWRS	Groundwater Replenishment System
GWR	Ground Water Rule
h^+	electron hole
HAAs	haloacetic acids
HOMO	highest occupied molecular orbital
I	irradiance ($\text{mW} \cdot \text{cm}^{-2}$)
IC	internal conversion
ICR	Information Collection Rule
ISC	intersystem crossing
LEDs	light-emitting diodes
LID	light irradiance distribution
LP	low pressure
LPHO	low pressure, high output
LPLO	low pressure, low output
LT2ESWTR	Long Term 2 Enhanced Surface Water Treatment Rule
LUMO	lowest unoccupied molecular orbital
MCL	maximum contaminant level
MF	microfiltration
mgd	million gallons per day
MP	medium pressure
NDMA	<i>N</i> -nitrosodimethylamine
NOM	natural organic matter
ntu	nephelometric turbidity unit
OCSD	Orange County Sanitation District
OCWD	Orange County Water District
P_1, P_2	photoproducts
PWN	PWN Water Supply Company North Holland
RED	reduction equivalent dose
RNA	ribonucleic acid
RO	reverse osmosis
S_0	unexcited ground electron state
S_1, S_2	first or second excited singlet state
T_1	excited triplet state
THMs	trihalomethanes
TOC	total organic carbon

UFP	Uniform Fire Protection Code
USEPA	U.S. Environmental Protection Agency
UV	ultraviolet
UV-C	germicidal ultraviolet light of wavelengths 200 to 280 nm
UV-B	ultraviolet light of wavelengths 280 to 315 nm
UV-A	ultraviolet light of wavelengths 315 to 400 nm
UVT	ultraviolet transmittance

NOTATION FOR EQUATIONS

A	absorbance, or optical density of solution
a_{10}	log base 10 absorption coefficient (cm^{-1})
a_λ	solution absorbance coefficient (cm^{-1})
$c, C, \text{ or } [C]$	molar concentration of dissolved constituent (M or $\text{mol} \cdot \text{L}^{-1}$)
$E_{p,\lambda}^0$	incident photon irradiance ($10^{-3} \text{ Es} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$)
h	Planck's constant ($6.6256 \times 10^{-34} \text{ J} \cdot \text{s} \cdot \text{photon}^{-1}$)
I_0	irradiance entering the solution in the spectrophotometer cuvette
I	irradiance exiting the solution in the spectrophotometer cuvette
k'_d	first-order rate constant for direct photolysis (s^{-1})
k'_1	pseudo-first-order rate constant ($\text{m}^2 \cdot \text{J}^{-1}$)
$k_{s,\lambda}$	specific rate of light absorption ($\text{Es} \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$)
$k_{x,\text{OH}}$	second-order rate constant between compound x and $\cdot\text{OH}$
l	solution path length (cm)
N	Avogadro's number ($6.02 \times 10^{23} \text{ photons} \cdot \text{Es}^{-1}$)
U_λ	wavelength-specific photon energy ($\text{J} \cdot \text{Es}^{-1}$)
%UVT	percent UV transmittance
α_e	natural log transform of a_{10}
ϵ	molar absorption coefficient ($M^{-1} \cdot \text{cm}^{-1}$)
$\epsilon_{\lambda,c}$	wavelength-specific molar absorption coefficient for c ($M^{-1} \cdot \text{cm}^{-1}$)
λ	wavelength (m or nm)
$\Phi_{\lambda,c}$	wavelength-specific quantum yield for c ($\text{mol} \cdot \text{Es}^{-1}$)
$\Phi_{\lambda,\text{H}_2\text{O}_2 \rightarrow \cdot\text{OH}}$	wavelength-specific quantum yield for $\text{H}_2\text{O}_2 \rightarrow \cdot\text{OH}$ ($0.5 \text{ mol} \cdot \text{Es}^{-1}$)
ν	wavelength frequency (s^{-1})

INTRODUCTION

Disinfection (and oxidation) by-products (DBPs) are chemical compounds produced as an unintended consequence of disinfection or oxidation processes in drinking water treatment. Most of the compounds of greatest concern contain chlorine and bromine atoms; however, the formation of iodinated compounds also has been noted (Weinberg et al., 2002). Some of these compounds have been found to be carcinogenic or to cause adverse reproductive or developmental effects in animal studies (see Chap. 2). Others have been shown

to be mutagenic and hepatotoxic. As a result, the U.S. Environmental Protection Agency (USEPA) promulgated rules in 1979, 1998, and 2006 regulating DBP concentrations in finished drinking waters (see Chap. 1).

This chapter focuses on a group of chemical contaminants (DBPs in this case), rather than on treatment process technology. As a result, we will refer the reader to specific chapters on treatment processes as they are brought into the discussion of DBPs. In some cases we will provide supplemental information on the performance of treatment processes as they pertain specifically to the control of DBPs. The chapter opens with a summary of the types of by-products formed from each of the commonly used disinfectants, followed by a discussion of factors affecting their formation. Next, the chapter turns to DBP control, including removal of precursors, use of modified disinfection practices, and removal of DBPs after formation. The chapter concludes with a discussion of DBP concentrations and losses in distribution systems.

FORMATION OF DISINFECTION (AND OXIDATION) BY-PRODUCTS

General Considerations
