Water treatment oxidants/disinfectants derive their effectiveness from their general chemical reactivity. The same attributes that give disinfectants the ability to react with cell membranes, nuclear materials, and cellular proteins also lead to reactions with abiotic dissolved organic matter and extracellular biomolecules. Except for the occasional source with high ammonia or sulfide concentrations, most of the oxidant/disinfectant demand in raw and treated drinking water can be attributed to reactions with such dissolved organic molecules in water.

Most organic matter in surface and groundwater is of natural origin. Some of this natural organic matter (NOM) is highly reactive with a wide range of oxidants. The reaction products include reduced forms of the oxidants (e.g., chloride, hydroxide, and chlorite when using chlorine, ozone, and chlorine dioxide, respectively) and oxidized forms of the organic or inorganic reactants (e.g., bromate) (Fig. 19-1).

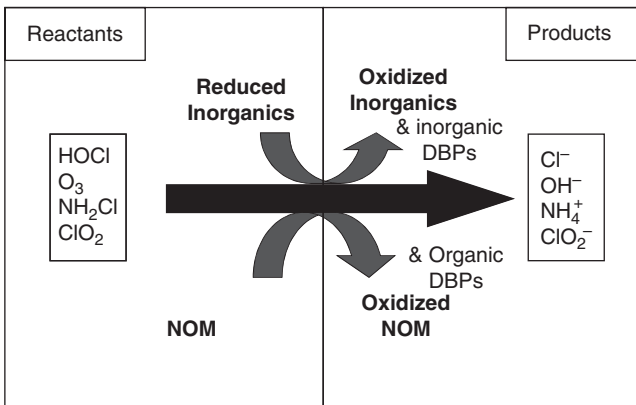

FIGURE 19-1 Schematic illustration of reactions of various oxidants with natural organic material (NOM) and reduced inorganic substances.

The sites of disinfectant (oxidant) attack on NOM are often carbon-carbon double bonds and reduced heteroatoms (e.g., N and S). The organic by-products formed are more highly oxidized, often containing more oxygen atoms. As the extent of the reaction increases, the organic matter becomes more fragmented, and the specific by-products are simpler in structure. General oxidation by-products include the C_1 – C_3 acids, diacids, aldehydes, ketones, and ketoacids (e.g., Griffini and Iozzelli, 1996). Specific examples include oxalic acid, pyruvic acid, and formaldehyde.

Several of the disinfectants are capable of producing by-products that have halogen atoms (i.e., chlorine, bromine, and iodine) incorporated into their structure. Aqueous chlorine and bromine do this to the greatest extent, followed by chloramines and ozone. In the case of ozone, high concentrations of bromide are required for substantial bromine incorporation. The organic halide by-products can be measured collectively by the total organic halide analytical method (abbreviated TOX, or more accurately, dissolved organic halide, DOX; for more on this method, see APHA et al., 2005). Because NOM contains very low levels of TOX, this analysis presents an opportunity to easily measure a large and diverse group of compounds that are indisputably DBPs. It also targets a subset of the total DBPs (i.e., just the halogenated ones) that are viewed as the compounds of greatest concern, allowing the calculation of halogen mass balances (e.g., see Singer and Chang, 1989; Shukairy et al., 2002).

Aqueous chlorine, chloramines, and ozone are all capable of oxidizing naturally occurring bromide to form active bromine (i.e., hypobromous acid (HOBr) or bromamines; see Chap. 7). The latter will react with NOM to form brominated organic compounds (e.g., bromoform and dibromoacetic acid) and, in the presence of free chlorine, mixed bromochloro-organics. The same is true with respect to the formation of iodinated DBPs in the presence of iodide, although iodinated DBPs tend to be found only in chloraminated waters (see section on chloramine by-products). These halogenated by-products all contribute to the TOX concentration of the water. Furthermore, it is possible to measure halogen-specific TOX (e.g., TOCl, TOBr, and TOI) by replacing microcoulometric detection with ion chromatography (e.g., Hua and Reckhow, 2007).

Identity of Disinfection By-Products

Since the discovery of trihalomethanes (THMs) in chlorinated drinking water in the early 1970s (Rook, 1974; Bellar et al., 1974), hundreds of specific compounds have been identified as DBPs. Many of the major groups are summarized in Table 19-1. More detailed listings of individual compounds can be found in the review by Richardson (1998).

Each of the four disinfectants presented in the table has its own unique chemistry. For example, ozone is the only disinfectant that produces measurable quantities of bromate. Nevertheless, many by-product classes and specific compounds are common to two or more of the major disinfectants. This is illustrated by the simple aliphatic carboxylic acids (e.g., acetic acid), which are universal by-products regardless of the disinfectant/oxidant. Itoh and Matsuoka (1996) found that all oxidants produce carbonyls (e.g., formaldehyde), with ozone and chlorine dioxide producing the most and chlorine and inorganic chloramines only slightly behind. Some halogenated compounds, such as dihaloacetic acids, may be produced by all four disinfectants, but the amounts produced range over several orders of magnitude, depending on the disinfectant, the disinfectant dose, and the bromide level. For this reason, an attempt has been made in the table to classify by-product abundance based on an order-of-magnitude scale (very high >100 $\mu\text{g/L}$; high = 10–100 $\mu\text{g/L}$; medium = 1–10 $\mu\text{g/L}$; low = 0.01–1 $\mu\text{g/L}$; very low < 0.01 $\mu\text{g/L}$) as assessed for an average drinking water under typical treatment conditions.

TABLE 19-1 Chemical By-Products of the Four Major Disinfectants

By-product class	Examples	Chlorine	Chloramines	Chlorine dioxide	Ozone
<i>Compounds with O–X Bonds</i>					
Oxychlorines	Chlorate, Chlorite			V.High ^{34,35}	
Oxybromines	Bromate, hypobromate				Med ^{51–53,58}
<i>Compounds with C–X Bonds</i>					
	Chloroform, bromodichloromethane, chlorodibromomethane	High	Low		
Trihalomethanes	Bromoform	Med	Low		Med ^{49,52}
	Dichloroiodomethane		Low		
Other haloalkanes	1,2-Dibromoethane, 1,2-dibromopropane	Low ^{14,15}			
Halohydrins	3-Bromo-2-methyl-2-butanol, 9-chloro-10-hydroxyl methyl stearate	(NOM ²⁰)	(Models ^{3,23})	(Models ³⁷)	Med ⁶²
Haloacids	Dichloroacetic acid, trichloroacetic acid	High	Med ^{17,18}	(NOM ²⁹)	
	Monochloroacetic acid, bromochloroacetic acid, bromodichloroacetic acid, monobromoacetic acid, dibromoacetic acid, tribromoacetic acid, diiodoacetic acid, 6,6-dichlorohexanoic acid	Med	Low		Med ⁵⁰
		Low	Low		
Haloacids (unsaturated)	3,3-Dichloropropenoic acid	(NOM ¹⁵)	(NOM ^{17,18})		
Halodiacids	2,2-Dichlorobutanedioic acid, 2,3-dichlorobutanedioic acid	(NOM ^{15,16})	(NOM ^{17,18})		
Halohydroxyacids	3,3,3-Trichloro-2-hydroxypropanoic acid, 2-chloro-4-hydroxybutanoic acid, 2,3-dichloro-3,3-dihydroxy propanoic acid, 4-chloro-4-hydroxypentenoic acid	(NOM ¹⁵)	(NOM ^{17,18})		
Haloketones	1,1,1-Trichloropropanone	Med ^{1,2,3}			
	Chloropropanone		(NOM ^{17,18})		
	Bromopropanone			Unkn ²⁸	Unkn ⁶⁰
	1,1,3,3-Tetrachloropropanone				
	1,1,1-Trichloro-2-butanone, pentachloro-3-buten-2-one	(NOM ⁴)			
Haloaldehydes	Chloral	Med			
	Chloroacetaldehyde, dichloroacetaldehyde		(NOM ^{17,18})		
	Dichloropropanal, 3-chlorobutanal, 2,3,3-trichloropropenal	(NOM ⁴)	(NOM ^{17,18})

TABLE 19-1 Chemical By-Products of the Four Major Disinfectants (*Continued*)

By-product class	Examples	Chlorine	Chloramines	Chlorine dioxide	Ozone
Ketones	Dioxopentane, 1,2-dioxobutane				Unkn ⁴¹
	Acetophenone, 4-phenyl-2-butanone				Unkn ⁴⁷
	2-Hexenal, 6-methyl-5-hepten-2-one				Low ⁶⁰
	2,3,4-Trimethylcyclopent-2-en-1-one,			Unkn ²⁸	
	2,6,6-trimethyl-2-cyclohexene-1,4-dione				
Ketoacids	Pyruvic acid, glyoxalic acid, ketomalonic acid				High
	Oxobutanoic acid, 4-oxo-2-butenic acid				Unkn ^{41,47}
	Ketosuccinic acid, ketoglutaric acid				Unkn ^{41,61}
	Dioxopropanoic acid, dioxopentanoic acid				Unkn ⁴¹
Hydroxyacids	Hydroxymalonic acid				(NOM ⁴⁴)
Hydroxy-carbonyls	Hydroxyacetaldehyde				(Models ⁵⁹)
Furans	Methylfurancarboxylic acid			(NOM ²⁹)	
Epoxides			(Models ²³)	(Models ^{31,39})	(Models ^{42,55})
Organic Peroxides					(Models)
Nitriles			(Models ^{1,19})		
Nitrosamines	Nitrosodimethylamine	V,low	Low		
Nitramines	Dimethylnitramine	(Models ⁶³)			
Hydrazines	1,1-Dimethylhydrazine		(Models)		
Miscellaneous	5-Methoxy- α -pyrone				(NOM ⁴⁴)

Notes:

1. Data marked "NOM" and "Models" are from studies using solutions of natural organic matter extracts and model compounds, respectively.

2. All other data are from treated drinking waters and unaltered natural waters. Concentrations are classified as follows: V. high (very high): >100 $\mu\text{g/L}$; High: 10–100 $\mu\text{g/L}$; Med (medium): 1–10 $\mu\text{g/L}$; Low: 0.01–1 $\mu\text{g/L}$; V. low (very low): <0.01 $\mu\text{g/L}$; Unkn (not quantified).

Many worthwhile studies have been conducted with solutions of isolated NOM (e.g., aquatic fulvic acids). Since these studies are often conducted under extreme conditions (i.e., high TOC, high chlorine dose, and sometimes high or low pH) designed to maximize DBP formation, no attempt has been made to render a judgment on the likely concentration level expected in tap water based on such studies. Also useful, but further removed from practice, are the studies using model compounds (designated "Models" in Table 19-1). Entries that are not labeled with "NOM" or "Model" refer to expected occurrence levels in typical finished drinking water.

Chlorination By-Products. The chlorination by-products include a wide range of halogenated and nonhalogenated organic compounds. Regulatory agencies have focused on the halogenated compounds, especially the THMs and haloacetic acids (HAAs) (see Chap. 1 on regulations). These are small, highly substituted end products of the reaction of chlorine with organic matter. In waters with low bromide levels, the fully chlorine-substituted forms predominate (e.g., chloroform and di- and trichloroacetic acid). Waters with high levels of bromide are likely to contain elevated levels of the bromine-containing analogues (e.g., bromoform and dibromoacetic acid) following chlorination. Waters with moderate levels of bromide will contain the mixed bromo/chloro analogues (e.g., bromodichloromethane and bromodichloroacetic acid).

Nearly all DBP studies in the 1970s focused on the THMs. Given their volatility, chemical stability, and high halogen-carbon ratio, this class of compounds could be easily analyzed with minimal analytical equipment and expertise. Consequently, the THMs were the first by-products to be found in finished drinking waters (Rook, 1974; Bellar et al., 1974), the first to be the subject of an established analytical method, and the first to be included in a large survey of public water supplies (Symons et al., 1975). In a matter of just a few years, it was recognized that the THMs were always present whenever chlorine was used as a disinfectant.

The discovery of HAAs in chlorinated waters (Miller and Uden, 1983; Christman et al., 1983) and subsequent occurrence studies trailed the THMs by several years. One early survey (Krasner et al., 1989) showed the HAAs, like the THMs, to be ubiquitous in chlorinated waters, although present at somewhat lower levels. More recent data have supported this finding. However, the lack of available standards for all the HAAs in these earlier studies may have resulted in underestimation of their concentrations (Cowman and Singer, 1996).

Many other halogenated by-products have been widely reported in chlorinated drinking waters. The most intensively studied of these nonregulated compounds are the halopropanones, the haloacetonitriles, chloropicrin, and chloral hydrate. This group owes its large industry-wide database to the analytical method that it shares with the THMs (i.e., like the THMs, they are all volatile neutral compounds that respond well to analysis by gas chromatography with electron-capture detection). The haloacetonitriles are thought to be largely derived from the chlorination of amino acids and proteinaceous material (Bieber and Trehy, 1983). Nitrogenous structures in humic substances also will form haloacetonitriles via cyano acid intermediates (Backlund et al., 1988). The halopropanones (e.g., 1,1,1-trichloropropanone) and chloral hydrate (a haloaldehyde) are halogenated analogues of some common ozonation by-products. They are commonly found at elevated concentrations in waters that had been previously ozonated (Reckhow et al., 1986; McKnight and Reckhow, 1992).

From July 1997 to December 1998, a comprehensive set of data on DBP occurrence in U.S. drinking waters was collected as part of the Information Collection Rule (ICR). All large drinking water utilities (defined as those serving populations > 100,000) provided DBP occurrence information and corresponding water quality characteristics and treatment conditions for six quarters. A total of 299 utilities participated, encompassing 500 water treatment plants. The following DBPs were measured: THMs, HAAs, haloacetonitriles (HANs), haloketones such as the chloropropanones (CPs), chloral hydrate (CH), chloropicrin

(CP), cyanogen chloride (CNCl), and TOX. Bromate, chlorite, chlorate, and aldehydes, which are oxidation by-products of ozone and chlorine dioxide (see Chap. 7 and below), also were measured in the utilities employing these oxidants. The ICR data set was generated with a high degree of quality assurance and was used to finalize the stage 1 and stage 2 DBP rules (see Chap. 1). A description of the ICR activity and its results is provided in an ICR data analysis report (McGuire et al., 2002). Figures 19-2 to 19-4 illustrate the occurrence findings from the ICR database. It should be noted that the majority of the ICR utilities had raw water sources with relatively low bromide concentrations, a characteristic shared by many high-quality surface waters, so the distribution of DBPs was skewed toward the chlorine-containing species.

About 50 percent of the TOX produced on chlorination can be attributed to the major by-products discussed earlier (Singer and Chang, 1989). The remainder is largely unknown and has been the subject of research for the past 20 years. A similar balance on mutagenic activity (Ames test) reveals that more than 50 percent of the activity can be accounted for among the known by-products. Much of the identified mutagenicity is found in a single compound given the abbreviated name MX (Backlund et al., 1988; Meier et al., 1988), a chlorinated furanone that readily undergoes ring opening. It is produced in small quantities along with several related compounds by free chlorine and chloramines. Relatively little is known about its occurrence because it is difficult to measure. Early studies showed finished water concentrations as high as 60 ng/L (Kronberg and Vartiainen, 1988). Wright and colleagues (2002) conducted a focused study of MX in U.S. finished waters and found concentrations up to 80 ng/L. Weinberg et al (2002) documented a median value of 20 ng/L and a maximum of 310 ng/L.

FIGURE 19-2 Distribution of ICR results for individual trihalomethane species. (Source: McGuire et al., 2002, Awwa Research Foundation.)

FIGURE 19-3 Distribution of ICR results for individual haloacetic acid species. Note that only six of the nine bromine- and chlorine-containing HAAs were measured by all the participating utilities. (Source: McGuire et al., 2002, Awwa Research Foundation.)

FIGURE 19-4 DBP concentrations in ICR distribution systems. (Source: McGuire et al., 2002, Awwa Research Foundation.)

Because TOX formation represents only a small fraction of the total chlorine consumed (typically < 10 percent), it can be concluded that most of the organic chlorination by-products do not contain chlorine and that most of the chlorine consumed leads to the formation of chloride. A number of these nonhalogenated by-products have been identified (Table 19-1). Most are aliphatic mono- and diacids and benzenepolycarboxylic acids. Because these compounds probably are not of health concern, they have not been studied extensively. It should be noted, however, that many of these compounds are readily biodegradable and therefore contribute to the biodegradable dissolved organic carbon (BDOC) content, sometimes measured as assimilable organic carbon (AOC). Hence, in the absence of a disinfectant residual in the distribution system, the presence of these compounds can encourage the growth of biofilms.

Chloramine By-Products. Although monochloramine and dichloramine are less reactive than free chlorine with NOM and most model compounds, inorganic chloramines can form some of the DBPs commonly associated with free chlorine. Identifiable by-products include dichloroacetic acid (DCAA), cyanogen chloride, and small amounts of chloroform and trichloroacetic acid (TCAA; see Table 19-1). While it's not clear that TCAA and the THMs are true by-products of chloramines (i.e., they may be formed owing to the presence of a small free chlorine residual), it does seem that DCAA and cyanogen chloride are true by-products (Singer et al., 1999). Cyanogen chloride concentrations generally are higher in systems using chloramines, and this is due, at least in part, to the greater stability of this compound in the presence of chloramines compared with free chlorine. Both mechanistic and occurrence studies have shown that haloacetonitriles also can be formed as true by-products of inorganic chloramines (e.g., Young et al., 1995; Weinberg et al., 2002). Backlund and colleagues (1988) found that monochloramine forms MX from humic materials, although the amount measured was less than 25 percent of that formed during chlorination.

Weinberg and colleagues (2002) found iodoacetic acid, bromiodoacetic acid, (*E*)-3,3-bromiodopropenoic acid, (*Z*)-3,3-bromiodopropenoic acid, and (*E*)-2-iodo-3-methylbutenedioic acid in a drinking water system using chloramines with no free chlorine contact time. When there is a substantial free chlorine contact time preceding ammonia addition, lower levels of iodinated organics are produced (e.g., von Gunten et al., 2006; Hua et al., 2007). This is attributed to the rapid oxidation of reactive iodine to the nonreactive iodate anion by pretreatment with free chlorine (see Chap. 7). Inorganic chloramines are not capable of this rapid oxidation, so precursor organics have a greater exposure to reactive iodine and thereby produce more iodinated organic by-products (Fig. 19-5).

FIGURE 19-5 Pathway for elevated levels of iodinated DBPs from chloramines.

Jensen and colleagues (1985) found that at high monochloramine-carbon ratios (~10 mg Cl₂/mg C), about 5 percent of the oxidant demand goes toward TOX formation. This is identical to the results for chlorine at an equally high chlorine-carbon ratio. Most of the chlorinated organic by-products remained tied up in high-molecular weight

compounds. This contrasts with free chlorine because monochloramine is a much weaker oxidant than free chlorine and is much less likely to create the smaller fragments that can be analyzed by gas chromatography.

Monochloramine is known to transfer active chlorine to the nitrogen of amines and amino acids, forming organic chloramines (Scully, 1986). This reaction also occurs with free chlorine. Model compound studies have shown that monochloramine also can add chlorine to activated aliphatic carbon-carbon double bonds (Johnson and Jensen, 1986). The adjacent carbon may become substituted with an amine group or with oxygen. Other types of reactions involve the simple addition of amine or chloramine to unsaturated organic molecules. Under certain conditions, chlorine substitution onto activated aromatic rings has been observed. For example, monochloramine will slowly form chlorophenols from phenol (Burttschell et al., 1959). Inorganic chloramines also will add chlorine to phloroacetophenone, a highly activated aromatic compound, to produce chloroform (Topudurti and Haas, 1991). However, the rate of reaction for this compound is low, and the molar yield (i.e., moles DBP formed per mole precursor) is only 3 percent compared with 400 percent for free chlorine.

In addition to chlorine transfer, inorganic chloramines also undergo addition reactions with many types of organic molecules. This results in the formation of new organic amines and organic chloramines where the nitrogen atom originates from the inorganic disinfectant. Studies designed to determine if this is a major pathway for DBP formation in drinking water have produced mixed results. Hirose and colleagues (1988) found that this was not the case when looking at cyanogen chloride (CNCl) formation from the chloramination of the amino acid leucine. Their findings are supported by Krasner and colleagues (1989). On the other hand, chloramination of formaldehyde does produce CNCl, a clear indication of the ammoniation reaction (Pedersen et al., 1999). Using ^{15}N -labeled monochloramine, Young and colleagues (1995) studied this question with natural waters and dichloroacetonitrile (DCAN) formation. They concluded that most of the nitrogen in DCAN came from the inorganic chloramines and not from naturally occurring nitrogen in the NOM.

One possible result of ammoniation reactions is the formation of carcinogenic nitrosamines from organic amines. Among this group, it is nitrosodimethylamine (NDMA) that has been observed most commonly and studied most widely. NDMA levels in finished drinking water are rarely above the low nanogram per liter level, and it is observed more often in systems using chloramines, especially those affected by wastewater. Although cationic polymers and anion exchange resins used in water treatment can harbor NDMA precursors (e.g., Najm and Trussell, 2001), it now seems clear that a significant amount of organic precursors to NDMA formation originate from municipal and domestic wastewater. Schreiber and Mitch (2006) have formulated a mechanism for NDMA formation from dimethylamine precursors (Fig. 19-6). This explains many of the observations surrounding NDMA formation in drinking water, including the elevated concentrations under conditions that favor dichloramine formation (e.g., high $\text{Cl}_2\text{:N}$ ratios). Since some NDMA formation has been observed at plants using free chlorine, there may be other important mechanisms not involving inorganic chloramines.

When used in water treatment, chloramines are formed *in situ*, that is, within the plant. This usually involves addition of ammonia after or at the location of addition of chlorine. While the reaction between chlorine and ammonia is rapid at near-neutral pH (Weil and Morris, 1949), yields of the intended product (i.e., monochloramine and dichloramine) typically are less than 100 percent, especially at high $\text{Cl}_2\text{:N}$ ratios. Nitrogen species of elevated oxidation state have long been postulated as necessary intermediates in the formation of the final breakpoint products (i.e., nitrogen gas and nitrate). These include $\text{N}(-\text{I})$ species (e.g., hydroxylamine, NH_2OH) and $\text{N}(+\text{I})$ species (e.g., nitroxyl, HNO , and hyponitrous acid, $\text{H}_2\text{N}_2\text{O}_2$) (Chapin, 1931; Wei and Morris, 1974; Saunier and Selleck, 1979). There is also strong evidence for at least one related N-Cl species (Leung and Valentine 1994a, 1994b).

FIGURE 19-6 Proposed pathway for NDMA formation during chloramination. (Source: Based on work by Schreiber and Mitch, 2006.)

Little is known about the reactivity of these compounds or their occurrence in drinking water systems.

Although dismissed by Saunier and Selleck (1979), Shank and Whittaker (1988) asserted that small amounts of the known carcinogen hydrazine ($\text{H}_2\text{N}-\text{NH}_2$) could be formed by reaction of ammonia with monochloramine when drinking waters are chloraminated. Models based on known hydrazine formation rates predict that 10 ng/L concentrations could form in chloraminated waters at pH above 9 (Najm et al., 2006). However, little data exist on actual hydrazine concentrations in drinking water distribution systems.

Chlorine Dioxide By-Products. Chlorine dioxide undergoes a wide variety of oxidation reactions with organic matter to form oxidized organics such as aldehydes, ketones, and acids, as well as inorganic chlorite, ClO_2^- (see Table 19-1 and Chap. 7). The concentration of the resulting chlorite accounts for 50 to 70 percent of the chlorine dioxide consumed (Rav Acha et al., 1984; Werdehoff and Singer, 1987). Chlorite also may be formed, along with chlorate (ClO_3^-), by the disproportionation of chlorine dioxide (see Chap. 7). All three of the oxidized chlorine species (chlorine dioxide, chlorite, and chlorate) are considered to have adverse health effects, and their presence in finished water above regulated levels is a source of concern; see Chaps. 1 and 2 for coverage of regulations and health effects.

Chlorine dioxide also can undergo a limited number of chlorine substitution reactions. For example, reaction with dimethoxyphenylethanol, a lignin model compound, produces many initial products, including a ring-chlorinated derivative (Svenson et al., 2002). Trihalomethanes, however, have not been detected as reaction products when water containing NOM is treated with chlorine dioxide. As with the other chlorine-containing oxidants, chlorine addition/substitution products are favored at low oxidant-carbon ratios, and oxidation reactions are favored at high ratios. Studies using drinking waters and NOM have shown that small amounts of TOX form on treatment with typical levels of chlorine dioxide (e.g., Hua and Reckhow, 2007). Aside from direct reactions between NOM and molecular ClO_2 , as noted earlier, this also may be due to the formation of HOCl when chlorine dioxide reacts with NOM and subsequent reaction with other NOM compounds (Werdehoff and Singer, 1987). The relatively small amount of HOCl formed in this manner probably leads to sparsely halogenated macromolecular TOX, which would account for the lack of identifiable organohalide by-products.

Ozonation By-Products. Ozonation can lead to the formation of brominated by-products when applied to waters with moderate to high bromide levels. This is a direct result of ozone's ability to oxidize bromide to hypobromous acid and related species (see Chap. 7). Some of this oxidized bromine continues to react to form bromate ion. Much of the remaining hypobromous acid reacts with NOM to form brominated organic compounds. These by-products encompass the same general classes reported for the halogenated by-products of chlorine [i.e., THMs (bromoform), HAAs (dibromoacetic acid), HANs (dibromoacetonitrile), and halonitromethanes (bromopicrin)]. It has been estimated that 7 percent of the raw water bromide becomes incorporated as TOX (or total organic bromide, TOBr) following ozonation under conditions typical of drinking water treatment (Song et al., 1997). The extent of TOBr formation from HOBr versus further oxidation of HOBr to form bromate depends markedly on pH, with elevated pH values (above 6.5–7) favoring bromate formation.

In contrast to the situation with bromide, ozonation will not lead to the formation of iodinated DBPs when water containing iodide is ozonated. This is so because ozonation rapidly oxidizes the hypoiodous acid formed to iodate (see Chap. 7).

Most ozonation by-products are not halogenated, and the majority of these are similar to the general oxidation products reported for other disinfectants. For example, field studies with ozone and chlorine dioxide showed that both produced about the same level of low-molecular weight carboxylic acids (Griffini and Iozzelli, 1996). Nevertheless, there

FIGURE 19-7 Yields of major ozonation by-products normalized per milligram of ozone applied, as reported in the literature. (Source: Reckhow, 1999, Awwa Research Foundation.)

are a number of studies that suggest ozone produces higher levels of simple aldehydes and ketoacids (or aldoacids) than the other major disinfectants. Figure 19-7 presents some dose-specific yield data for these major by-products. High levels of aldehyde and ketone by-products are characteristic of ozonation and generally are attributed to the Creigee ozonolysis mechanism (Fig. 19-8).

Other oxidation by-products attributed to ozone include hydroxyacids (e.g., pyruvic acid), aromatic acids (e.g., benzoic acid), and hydroxyaromatics (e.g., catechol) (see Table 19-1). Organic peroxides and epoxides are also expected ozonation by-products, although their detection in treated drinking waters has proved to be a challenge.

Because of the strong correlation between ozonation by-product formation and biodegradable organic matter (BOM) concentrations, attempts have been made to attribute this BOM to specific compounds. Krasner and colleagues (1996) have shown that as much as 40 percent of the assimilable organic carbon (AOC) and 20 percent of the BDOC can be assigned to known major ozonation by-products. However, these known by-products still represent less than 5 percent of the overall DOC concentration.

UV By-Products. Given the recent growth of ultraviolet (UV) disinfection technology in drinking water treatment (see Chaps. 17 and 18), questions have arisen as to how UV treatment might affect finished water DBP levels. Many also have asked whether UV irradiation produces unique DBPs. While it is widely acknowledged that THMs and HAAs do not

FIGURE 19-8 Creigee ozonolysis mechanism, which results in the formation of acids, aldehydes, and ketones. (Source: Reckhow, 1999, Awwa Research Foundation.)

form from UV irradiation, several researchers have shown that low levels of aldehydes and carboxylic acids can form from UV irradiation (Malley et al., 1995; Peldszus et al., 2000; Thomson et al., 2002; Liu et al., 2002).

Most studies also have shown that UV irradiation at doses typical of drinking water disinfection (i.e., ≤ 40 mJ/cm²) does not significantly affect THM and HAA formation from subsequent chlorination and chloramination (Malley et al., 1995; Liu et al., 2002; Reckhow et al., 2010). Nevertheless, there are indications that UV treatment can alter the structure and reactivity of NOM in measurable ways (e.g., the formation of aldehydes and acids, as mentioned previously). Others have studied the overall effect of UV irradiation on organic matter from treated surface waters using high-performance size exclusion chromatography (Frimmel, 1998; Frimmel et al., 2005) and electrospray mass spectrometry (Magnuson et al., 2002). The results suggested that the molecular size distribution of NOM shifts toward smaller molecules after UV irradiation at levels typical of drinking water disinfection. Changes in NOM size and functional group content would be expected to have an impact on its reactivity with chlorine. Most studies to date on UV/Cl₂ have focused on the two major regulated groups, the THMs and the HAAs. Far less has been done with other known DBPs. However, Reckhow and colleagues (2010) have shown recently that medium-pressure UV can cause elevated chloropicrin concentrations during subsequent chlorination. These authors have attributed this effect to formation of nitroorganic precursors by photonitration reactions.

Factors Influencing By-Product Formation

Time. Reaction time is among the most important factors determining DBP concentrations under conditions where a disinfectant residual persists. Because the major halogenated DBPs (e.g., THMs and HAAs) are chemically stable, their concentrations typically increase with reaction time for as long as a disinfectant residual exists (Fig. 19-9). However, there are cases where HAA concentrations drop to near zero after long residence times in drinking water distribution systems. This phenomenon is generally attributed to biodegradation, which does not appear to occur with the THMs (the latter appear to be biodegradable only under anoxic conditions).

Laboratory tests have shown that HAAs form somewhat more rapidly than THMs. Studies also have shown the brominated analogues to form more rapidly than the purely chlorinated compounds. This causes the HAA-THM or the THM-chloroform ratio to be high in the early stages of the reaction and drop slowly with reaction time. These observations are supported by data collected from full-scale treatment plants and distribution systems.

FIGURE 19-9 Effect of reaction time on the major chlorination by-products. (Data from Reckhow and Singer, 1984.)

In contrast to the case for chlorine, ozonation by-products form quickly and show little increase with time. This is due to the rapid dissipation of ozone residuals. Once dissolved ozone is depleted, by-product formation can continue only by means of hydrolysis reactions, which represent a relatively minor contribution to the total formation of these by-products.

In contrast to the THMs and HAAs, many other halogenated DBPs are chemically unstable and are subject to hydrolysis or further oxidation. For these compounds, the concentration reaches a maximum value, after which the concentration declines with time (see discussion on pH effects below). Some DBPs, such as dichloroacetonitrile, decompose slowly and reach a maximum concentration after reaction times on the order of days. Others (e.g., 1,1-dichloropropanone) are more reactive and decrease to undetectable levels within minutes to hours though hydrolysis or halogenation pathways.

Disinfectant Dose and Residual. Disinfectant dose has a variable impact on DBP formation. Small changes in the dose used for residual disinfection often have minor effects on DBP formation. This is so because these systems have an excess of disinfectant, and therefore, the DBP formation reaction is precursor limited.

When the disinfectant residual drops below about 0.3 mg/L, DBP formation becomes disinfectant limited. Under these circumstances, changes in disinfectant dose have a large effect. Figure 19-10 shows that when 3 and 5 mg/L of chlorine is added to Connecticut River water, THMs are produced in direct proportion to that dose. However, when an excess is added (>5 mg/L), a residual persists, and the extent of THM formation with increasing dose levels off. The other two waters in this figure show only the latter behavior because they had lower TOC values and their chlorine demand was less than the minimum dose tested (3 mg/L).

As a general rule, disinfectant dose plays a greater role in DBP formation during primary disinfection than during secondary disinfection. This is so because primary disinfectants usually are added in amounts well below the long-term demand. Therefore, the disinfectant is the limiting reactant, not the organic precursors. Figure 19-10 shows a near-linear

FIGURE 19-10 Observations on effect of disinfectant dose on DBP formation (chlorination conditions: pH 7, 20°C, 3-day reaction time). (Figures redrawn from Coombs, 1990, and Reckhow et al., 1993.)

relationship between ozone dose and glyoxalic acid formation. When the ozone is applied after coagulation and filtration (postozone in the figure), glyoxalic acid formation starts to plateau. This is a reflection of the removal of ozone-demanding organics and the approach to precursor-limiting conditions.

The relationship between disinfectant dose and DBP formation can be illustrated with a simple kinetic model. Figure 19-11 shows the results of a kinetic simulation for the simple second-order reaction (Eq. 19-1):

where A represents the NOM precursor material, B is the disinfectant, C is the particular DBP, and k is the second-order rate constant. If the initial precursor level (A_0) is held constant, and a rate constant and reaction time t is arbitrarily chosen, the extent of DBP formation can be calculated as a function of the disinfectant dose (B_0). The three curves in Fig. 19-11 are the result of this calculation for three different combinations of k and t . As

FIGURE 19-11 Theoretical second-order kinetic plot showing effect of reactant dose on product formation.

the product of k and t gets large, the DBP formation curve approaches two straight lines (one where DBP formation increases linearly with dose and one where DBP formation is independent of dose). The upward-sloping line corresponds to the disinfectant-limiting case. The horizontal line corresponds to the precursor-limiting case. This model is consistent with the experimental observations in Fig. 19-10.

When using chloramines, the chlorine-nitrogen ratio is also an important consideration. As the $Cl_2:N$ ratio increases from 2 to 5 (on a weight basis), the presence of transient free chlorine residuals increases substantially. For example, at a $Cl_2:N$ ratio of 2 mg/mg and a chlorine dose of 2 mg/L (pH 7, 10°C), the measureable free chlorine residual should

disappear (i.e., drop below 10 $\mu\text{g/L}$) at about 8 seconds after initial mixing, whereas it takes about 4 minutes at a $\text{Cl}_2\text{:N}$ ratio of 5 mg/mg (calculation based on data from Morris and Isaac, 1983). This results in a shift in the DBP character (yields and types) from that typical of pure chloramines to that of free chlorine. Model compound studies (Merlet, 1986) have shown that highly reactive precursors (e.g., resorcinol) will experience this shift at lower $\text{Cl}_2\text{:N}$ ratios than the slower-reacting compounds (e.g., acetone). It is likely that the same could be said for waters with highly reactive NOM versus less reactive waters. This observation regarding transient free chlorine residuals attests to the importance of mixing when ammonia is added to convert a free chlorine residual to a combined residual.

pH. The overall reaction between chlorine and NOM is relatively insensitive to pH over the range of typical water treatment practice. However, the formation of TOX and specific halogenated by-products is strongly influenced by pH (e.g., Fleischacker and Randtke, 1983; Reckhow and Singer, 1984). Nearly all the by-products (e.g., trihaloacetic acids, halopropanones, haloacetonitriles, etc.) decrease in concentration with increasing pH, but one important exception is the THMs. Although pH can influence chlorination reactions in many ways, it is probably base-catalyzed hydrolysis mechanisms that have the greatest overall effect. Many DBPs (e.g., 1,1,1-trichloropropanone) are decomposed by base-catalyzed hydrolysis. These compounds are less prevalent in waters with high pH, and they tend to decrease in concentration at long residence times. The THMs increase at high pH because many hydrolysis reactions actually lead to THM formation. Other by-products are themselves unaffected by base hydrolysis (e.g., the HAAs), but their formation pathways may be altered at high pH, resulting in lesser formation. It is important to note that the dihaloacetic acids have a different pH dependency than the trihaloacetic acids. Their pathway of formation is different, and dihaloacetic acid formation tends to be relatively independent of pH, whereas trihaloacetic acid formation, as indicated earlier, decreases with increasing pH.

Chloramines exhibit some unique pH behavior that ultimately affects DBP formation from these disinfectants. pH values below 7 tend to favor the formation of dichloramine over monochloramine, especially at chlorine-nitrogen values near the breakpoint (Palin, 1975). This may affect DBP formation because monochloramine and dichloramine react differently with precursor materials. For example, the NDMA formation pathway in Fig. 19-6 suggests that conversion of monochloramine to dichloramine should increase the formation of this DBP. Also, chloramine decay is acid catalyzed, so the total residual drops rapidly at pH values of 6 and below. If not compensated with higher doses, the resulting loss of residual could lead to suspension of DBP-forming reactions and growth of DBP-degrading organisms.

None of the major ozonation by-products are subject to alkaline hydrolysis. Instead, pH plays a role by altering the rate of decomposition of ozone to hydroxyl radicals (see Chap. 7). As pH increases, ozone decomposition accelerates, and this is thought to be responsible for a decrease in the classical by-products of ozonation (e.g., aldehydes) (Schechter and Singer, 1995). However, the chemistry of ozone and hydroxyl radical reactions with NOM is not well understood, and there may be cases where some carbonyl by-products increase with pH (e.g., Itoh and Matsuoka, 1996).

Bromate is formed in ozonated waters from a series of reactions between ozone and/or hydroxyl radicals and naturally occurring bromide (see Chap. 7). A key intermediate in the formation of bromate is hypobromite ion (OBr^-). At lower pH, more of the hypobromite becomes protonated, forming hypobromous acid (HOBr), which is less reactive with respect to bromate formation. This causes the overall concentration of bromate to decrease as pH is decreased. On the other hand, lower pH favors the formation of TOBr during ozonation (Song, 1997). This is probably due to suppressed decomposition of ozone, changes in the speciation of the oxidized bromine favoring HOBr , and less base-catalyzed hydrolysis of brominated by-products.

Temperature. The rate of formation of DBPs generally increases with increasing temperature. Laboratory and full-scale plant data suggest that chloroform formation is more sensitive to temperature than DCAA formation. The relationship is not as clear for TCAA formation. At high temperatures, accelerated depletion of residual chlorine slows DBP formation even though the rate constants for DBP-producing reactions might increase. This may be especially true for TCAA because its formation is more sensitive to chlorine residual than is chloroform or DCAA formation. This is another example that suggests that dihaloacetic acid chemistry is quite different from trihaloacetic acid chemistry. Nevertheless, because more chlorine typically is added to compensate for the more rapid depletion of residual chlorine at high temperatures, overall DBP formation increases with increasing temperature.

High temperatures also may accelerate DBP degradation processes. Biodegradation of HAAs (see below) would be expected to proceed more quickly at high temperature. Reactive DBPs, such as the haloacetonitriles and halopropanones, would undergo abiotic reactions with bases or active chlorine at a faster rate as temperature increases. For this reason, increases in temperature actually may cause a decrease in the concentration of certain DBPs.

Bromide and Iodide. Bromide is readily oxidized by aqueous chlorine and ozone to form hypobromous acid (see Chap. 7). The hypobromous acid reacts with NOM to form brominated DBPs. In the presence of residual free chlorine, mixed chloro-bromo DBPs are formed. As bromide levels increase, formation of the more heavily brominated DBPs increases. Figure 19-12 shows how increasing bromide concentration causes shifts in the THM speciation from chloroform to progressively more brominated members of the group.

FIGURE 19-12 The effect of bromide concentration on THM speciation. (Redrawn from Minear and Bird, 1980.)

A similar effect has been observed for the HAAs, halopicrins, halopropanones, haloacetaldehydes, and haloacetonitriles (e.g., Trehy and Bieber, 1981; Pourmoghaddas and Dressman, 1993; Xie and Reckhow, 1993; Cowman and Singer, 1996). Although Fig. 19-12 extends to high bromide levels rarely seen in practice, Fig. 19-13 presents some actual occurrence data on bromine content of THMs. Note that both indicate a bromide concentration of just over 100 $\mu\text{g/L}$ as the point where the THMs become more heavily populated with bromine atoms. Figure 19-13 also suggests that this characteristic bromide level drops

FIGURE 19-13 Dependence of bromine incorporation among trihalomethane species on bromide concentration in ICR waters. (Source: McGuire et al., 2002, Awwa Research Foundation.)

considerably as the THM level, and therefore the precursor level, drops. Most laboratory studies also have shown that the molar formation of THMs increases slightly with bromide concentration. Since the brominated forms are heavier than their chlorinated analogues, the mass-based THM level (e.g., micrograms per liter) increases even more sharply with increasing bromide level. The formation of nonhalogenated DBPs is probably insensitive to varying bromide levels. One study of ozonation by-products showed only minor effects of bromide on aldehyde concentrations (Schechter and Singer, 1995).

Bromine (and iodine) incorporation among species in different DBP classes occurs in a predictable fashion. Cowman and Singer (1996) presented a simple competitive model that results in a binomial distribution function describing the relative concentrations of the different bromine-containing species. This model has been shown to accurately reflect actual full-scale THM concentrations (Fig. 9-14). The x axis in this figure represents the mole ratio of bromine to total halogen averaged over all THM molecules in any particular sample [sometimes called the *bromine substitution factor* (BSF)]. This is related to the *bromine incorporation factor* (BIF), which is the average number of bromine atoms per molecule. Plant-scale data from the ICR database show that the extent of bromine

FIGURE 19-14 Relationship between THM species and degree of bromine incorporation. (The x axis is the molar ratio of bromine incorporated in the THM species to the total THM concentration.) (The geometric model is after Cowman and Singer, 1996.)

incorporation among the dihaloacetic and trihaloacetic acid species closely matches bromine incorporation among the THM species (Obolensky and Singer, 2005). In fact, this parallelism has allowed researchers to predict overall HAA formation (all nine bromine- and chlorine-containing HAAs) from measured values of the four THMs and the five regulated HAAs (Roberts et al., 2002).

The impact of iodide on DBP speciation is qualitatively similar to that of bromide. As inorganic iodide levels increase, the formation of iodinated DBPs is greater, as is the incorporation of iodide into the THMs. Because iodine is more volatile than chlorine or bromine, continental waters (i.e., surface waters and groundwaters that have not been affected by salt water) tend to be enriched in iodide compared with seawater. Nevertheless, iodide levels are thought to be roughly correlated with bromide levels. As a result, Weinberg and colleagues (2002) showed about 10 percent molar ratio of I:Br in THM species.

Organic Precursor Material. It is well established that halogenated DBP formation is strongly correlated with the DOC concentration of the water being chlorinated. For this reason, many calculations regarding DBP formation are based on specific yields normalized to a fixed organic carbon level (e.g., micrograms of chloroform per milligram of DOC). While the relationship between TOC or DOC and DBP formation may be quite strong for selected waters, the correlation becomes much weaker when considering waters of different character, originating from different ecoregions (i.e., geographic areas differing in hydrology, landforms, soil types, and vegetation), different climatic conditions, and different times of the year. The reasons for this can be seen in model compound studies. Common biological molecules such as carbohydrates and sugars are relatively poor DBP precursors, whereas tannins and lignins produce large amounts of measurable by-products on a per-carbon basis. Waters collected from different locations and at different times of the year will have distinctly different mixtures of these biomolecules. As a result, the specific DBP yields can vary substantially between natural waters.

Chlorination studies with NOM extracts and whole waters have suggested that the activated aromatic content of the organic material is an important determinant in its tendency to form major chlorination by-products (Reckhow et al., 1990). This probably explains why UV absorbance is such a good predictor of a water's tendency to form THMs and HAAs because UV absorbance by NOM generally is attributed to activated aromatic chromophores. Accordingly, UV absorbance is a better predictor of chlorine reactivity and halogenated DBP formation potential than overall DOC. See Chap. 3 for coverage of UV absorbance as a surrogate parameter for TOC/DOC and DBP precursors.

Lignin is a major constituent in terrestrial vascular plants. It is quite resistant to biodegradation yet reactive with oxidants owing to a high density of activated aromatic rings. This combination of high terrestrial production, persistence, and high level of reactivity makes lignin an extremely important source of aquatic NOM and DBP precursors.

Perdue and Ritchie (2004) have summarized five literature sources and found a mean of 1 percent of total DOC attributable to phenolic lignin monomers. This is probably an underestimate because direct analysis of commercially derived lignin results in low recoveries of the monomeric compounds (Kim and Reckhow, 2009). If recoveries with commercial lignin and aquatic NOM are assumed to be comparable, aquatic fulvic acid could be in the range of 15 to 50 percent lignin derived.

Terpenoids are hydrocarbons produced in large quantities by a wide range of plants, both terrestrial and aquatic. There are indications that these compounds, which exist in various linear, branched, and cyclic forms, may account for a major fraction of the NOM in fresh waters (Leenheer et al., 2003; Lam et al., 2007). In particular, they may be dominant in waters of low aromaticity. These compounds are not likely to be as reactive as the activated aromatic structures in lignin. However, they certainly will react with oxidants by virtue of their abundant olefinic bonds. Given their presumed abundance and likely reactivity, it seems that the terpenoids could play a major role in oxidant demand and by-product formation in many types of waters.

General NOM reactivity often is expressed as some measure of the tendency to form major organic by-products. For chlorination, this means formation of THMs and HAAs, among others, and it is commonly done by means of an empirical laboratory chlorination test. To assess DBP formation in a valid reproducible fashion requires the use of a standard set of chlorination conditions. Standardized conditions facilitate the comparison of data from different investigators and allow the evaluation of precursor characteristics of different types of raw water sources at different times of the year. Since the 1970s, researchers have used a wide range of chlorination protocols, some calling for fixed chlorine doses and high residuals, some using fixed chlorine dose–TOC ratios, and some aiming for fixed chlorine residuals that are more representative of real systems. The former frequently has been called a *formation potential (FP) test*, and it is intended to maintain a relatively constant $C \times T$ (concentration times time) product in the face of changing chlorine demands. While each has its own advantages, the lack of standardization has hindered direct comparisons.

In an effort to solve this problem, many researchers are now using a single low-dose precursor test protocol called the *uniform formation conditions (UFC) test*. Summers and colleagues (1996), based on a meeting with several DBP researchers, developed this test, in which a sufficient amount of chlorine is applied to the water to produce a 1 mg/L free chlorine residual after 24 hours of contact at pH 8.0 and 20°C. This protocol is especially useful for assessing the effectiveness of various types of treatments on DBP precursor removal while using conditions that are typical of many systems. Because the chlorine doses are typical of those used in practice (on the order of 1.5–2 mg Cl₂ per milligram of C) (Obolensky et al., 2007), the distribution among bromine- and chlorine-containing DBP species is not distorted by use of an excessive chlorine dose. A related protocol using a 7-day reaction time at 25°C, pH 7.0, and a target chlorine residual of 4 mg/L also has been widely endorsed (APHA et al., 2005).

The preceding tests are distinguishable from the *simulated distribution system (SDS) test*, in which treated water is held under the specific conditions (pH, temperature, and chlorine residual) of distribution (e.g., APHA et al., 2005). The SDS test is useful to predict the extent of THM and HAA formation in a given water at various distribution system water ages. Comparisons between SDS tests and actual distribution system measurements made as part of the ICR effort were found to be good (McGuire et al., 2002). Although useful for predictive purposes in a specific system, the SDS test cannot be used in a more generic sense to predict DBP formation at conditions other than those used in the actual test.

Several researchers have examined THM precursor levels across a broad geographic distribution of sites. One of the largest of these studies encompassed 133 data points from five literature sources (Chapra et al., 1997). They concluded that the THM formation potential (THMFP) of this broad spectrum of natural waters increases with TOC in a nearly linear fashion. Reckhow and colleagues (2007) have reanalyzed these data, correcting for differences in chlorination conditions, and they found almost no relationship between THMFP and TOC. Not surprisingly, laboratory tests have shown that THM formation from dilutions of a single sample of NOM is constant when expressed on a per milligram of carbon basis. This is only true when the conditions are held reasonably constant, including the profile of chlorine residual versus time. For this reason, a normalized THM yield, defined as the specific THM formation under a UFC protocol (specific THM-UFC), has been used by Reckhow and colleagues (2007) as the characteristic measure of THM yield. This value is the concentration of THMs formed from reaction under the uniform formation conditions divided by the initial TOC of the water. Analysis of the preceding data by Chapra and colleagues (1997) show a regressed value of 21.5 $\mu\text{g}/\text{mg}$ of C at 1 mg/L TOC, which increases only slightly with TOC (Eq. 19-2). The yield is expected to change for different conditions of temperature, pH, and contact time, as discussed below.

$$\text{Specific THM-UFC} \equiv \frac{\text{THM-UFC}}{\text{TOC}} = 21.5(\text{TOC})^{0.095} \quad (19-2)$$

There are many other good databases that can be incorporated into a statistical analysis of THM formation. Reckhow and colleagues (2007) have compiled 27 data sets from the open literature and critically assessed the THM formation potential under the standardized specific conditions cited earlier in connection with Eq. 19-2. Within these 27 papers and reports were hundreds of single water assessments. A visually direct way of presenting the data is through a cumulative frequency plot, as found in Fig. 19-15. This reinforces the belief that groundwaters generally have lower specific formation potentials than surface waters, albeit not that much lower. In addition, one can extract median values and population percentiles from these data. Note that the median THM yield for surface waters is about 24 $\mu\text{g}/\text{mg}$ of C under the standardized conditions.

Figure 19-15 illustrates clearly that even when normalized to the organic carbon level and subject to the same set of reaction conditions, there still remains a substantial range in THM formation from one NOM sample to the next. The same has been observed for dihaloacetic acid and trihaloacetic acid formation (Reckhow et al., 2007). Some of this variability can be captured with the specific UV absorbance, as will be shown below.

In an effort to better understand the extent of DBP formation from NOM (DOC) in different types of waters and at different times of the year, many investigators have resorted to methods of fractionating the DOC into different subgroups. The most common and one of the simplest of these fractionation methods uses a series of macroporous resins with different degrees of hydrophobicity and is based on an extraction procedure by Thurman and Malcolm (1981). Most often the organic material is fractionated into hydrophobic acids, transphilic acids, and hydrophilic constituents. Chlorination of the different fractions tends to show that, in most waters, the THM and HAA yield on a per milligram

FIGURE 19-15 Specific precursor content in North American waters. (Source: Reckhow et al., 2007, Awwa Research Foundation.)

of C basis is greatest for the hydrophobic acid fraction (e.g., Liang and Singer, 2003). More recent studies have focused on fractionating dissolved organic nitrogen (DON) and assessing the formation of nitrogenous DBPs from these fractions (Leenheer et al., 2007; Dotson et al., 2009).

Another common, simple metric for characterizing DOC in waters with respect to its DBP formation potential is UV absorbance, with units of cm^{-1} . As indicated earlier, UV absorbance measurements reflect the activated aromatic content of organic carbon, and it is these activated aromatic structures that are dominant contributors to THM and HAA formation. While UV absorbance reflects the bulk concentration of precursors in a water (Fig. 19-16), the nature and reactivity of the precursors can be assessed by normalizing the UV absorbance, dividing it by the DOC concentration, and multiplying that number by 100 cm/m . The resulting specific UV absorbance (SUVA, in units of $\text{L}/\text{mg} \cdot \text{m}$) is a good indicator of the specific DBP formation potential of a water, as shown in Fig. 19-17 for three independent data sets. See Chap. 3 for additional coverage of the use of UV absorbance as a surrogate parameter for DOC and DBP precursors and coverage of SUVA.

Seasonal Effects. DBP concentrations are strongly influenced by season. The underlying factors are temperature and seasonally induced changes in water quality (NOM concentrations and characteristics, bromide, pH). In general, DBP concentrations are highest in summer. This is at least partly attributed to high temperatures, which accelerate DBP-forming reactions. Furthermore, disinfectant demand reactions are faster, requiring higher disinfectant doses to maintain target residuals. Competing with this are the facts that chemical degradation of selected DBPs (see below) is faster at high temperatures, and biodegradation may play a larger role in warmer waters.

With some sources, water quality changes also may be important. For example, in many watersheds, heavy spring rains cause allochthonous (terrestrial-derived) NOM, which has

FIGURE 19-16 Relationship between total organic halide formation potential and UV absorbance for 27 different raw and coagulated waters from across the United States. (Source: Archer and Singer, 2006.)

FIGURE 19-17 Correlations for normalized THM formation potential versus SUVA. (Source: Croué et al., 1999.)

a high lignin content and is rich in hydrophobic organic acids, to run off into the water source. In the summer, a larger portion of the NOM is autochthonous and hydrophilic in nature, arising from algal activity. In the fall, decomposed leaf litter washes into source waters. Hence the seasonal DBP signatures resulting from the application of disinfectants are expected to be different.

Likewise, the San Francisco Bay Delta, which provides raw drinking water for a large portion of the population in central and southern California, experiences significant seasonal variations in bromide concentration. During the spring season, high freshwater flows from the Sierra Nevada Mountains keep salt water, with its concomitant high bromide content, out of the delta so that chlorinated DBPs comprise most of the DBP content of the treated drinking water. In contrast, during the summer and early fall when fresh water flows are low, more salt water intrusion into the delta occurs, and bromine-containing species are the dominant DBPs formed.

Disinfection By-Product Formation Models

Since the very earliest work on DBPs, researchers and practitioners have proposed mathematical models to describe the formation of these compounds at different contact times and as a function of treatment conditions (e.g., disinfectant dose, pH, temperature) and treated water quality (e.g., DOC, UV absorbance, bromide). Fully empirical models composed of multiplicative power terms have proven to be useful and robust tools (e.g., Amy et al., 1987). This approach has been used in formulating a more general water treatment model that has been valuable in assessing central tendencies on a regional and national basis (Harrington et al., 1992; Solarik et al., 2000; Swanson et al., 2002). Unfortunately, the complex and diverse nature of naturally occurring DBP precursors requires that these DBP models be partially recalibrated before they can be used on specific systems. Models based on simplified chemical rate laws have been proposed in an effort to improve model performance (e.g., McClellan et al., 2000). These are more computationally intensive, and their development is an ongoing area of research.

CONTROL OF OXIDATION/DISINFECTION BY-PRODUCTS

There are three general approaches to controlling DBP concentrations: (1) minimize DBP formation by reducing the concentration of organic precursor material at the point of disinfection, (2) minimize DBP formation by reducing the disinfectant dose or contact time, changing the nature of the disinfectant or optimizing the conditions of disinfection, and (3) remove DBPs after their formation. Most efforts have focused on approach 1, as represented by optimizing the coagulation process (see Chap. 8) for removal of both TOC and particles (turbidity), and approach 2, reflected by changing from free chlorine to ozone or UV for primary disinfection and from free chlorine to chloramination for secondary disinfection. The third approach (DBP removal) is most appropriate for control of biodegradable by-products, especially those produced by ozonation, and possibly for removal of highly volatile DBPs such as chloroform.

Removing Organic Precursors

The objective of this particular strategy is to minimize the amount of organic precursors at the point of disinfection. This can be done by either reducing the precursor content of the raw water, improving precursor removal through the plant, shifting the point of disinfection to a later stage of treatment after precursors have been removed, or some combination of the three. It has been suggested that watershed management practices that help to reduce primary productivity in impoundments also will result in reduced THM precursor

levels (Karimi and Singer, 1991; Chapra et al., 1997). Reductions in organic precursor and bromide levels also may be achieved through careful source water selection, blending, or storage. Once they have entered the plant, DBP precursors may be removed or rendered less active by coagulation, adsorption, anion exchange, oxidation, biodegradation, or membrane separation. Each of these is discussed in the text that follows, with special focus on DBP control. For a broader and more comprehensive discussion of each process, the reader should consult the appropriate chapters earlier in this book.

Source Control. Control of DBP precursors at the source is an option that has received some attention, but with little practical experience to date. Cooke and Carlson (1989) prepared an early summary of established methods for reservoir and watershed management, including the likely impacts on DOC levels. Their ideas were based on a general understanding of allochthonous and autochthonous sources of NOM. Techniques intended to minimize terrestrial inputs (e.g., buffer strips) would control the former, and techniques intended to reduce algal and macrophyte contributions (e.g., application of copper sulfate) would control the latter. If DOC could be reduced, so would the levels of DBP precursors.

Twenty years later, we still know very little about the long-term impacts of watershed management practices on DBP precursor levels. However, we have made progress on one of the most fundamental questions—the relative importance of terrestrial versus aquatic sources of precursors. Water quality investigations and watershed modeling studies across the United States have revealed that some supplies are dominated by terrestrial or allochthonous sources, whereas others are largely algal or autochthonous in nature (e.g., Palmstrom et al., 1988; Canale et al., 1997; Stepczuk et al., 1998; Fuji et al., 1998; Speiran, 2000; Waldron and Bent, 2001; Nguyen et al., 2002; Garvey and Tobiasson, 2003; Reckhow et al., 2007).

Aquifer storage and recovery (ASR) has been used as a method of source water control (see Chap. 15). By storing high-quality treated water in the subsurface when raw water quality is good, this stored water later can be withdrawn when the raw water quality is poor, with only a minor degree of additional treatment. Similar raw water storage concepts can be considered in cases where the raw water is affected by high bromide concentrations. Storage of raw (or treated) water during times of the year when bromide levels are low allows utilities to use the stored water when bromide levels are elevated. ASR also may result in lower DOC and reduced DBP precursor levels as a result of long storage times in contact with aquifer minerals and microorganisms.

Oxidation. Pretreatment with a nonhalogenating oxidant can result in a net destruction of precursor sites and thereby reduce the subsequent formation of chlorinated DBPs after final disinfection with chlorine or chloramines. This phenomenon has been most widely studied with ozone, although the effect also has been demonstrated with chlorine dioxide, permanganate, and several advanced oxidation processes. From model compound studies, it has been shown that preozonation most often results in intermediates with lower DBP formation potential, although the reverse does sometimes occur. Since NOM is a broad mix of molecules with different structures and reactivities, it is not surprising that most types of NOM seem to show a downward trend in DBP formation with oxidation, much like the majority of model compound studies. Because of its selectivity for olefinic bonds, molecular ozone appears to be more effective than the less selective hydroxyl radicals. Oxidative precursor destruction is minor for most waters at typical oxidant doses used in water treatment. For example, Reckhow and colleagues (1986) showed that ozone doses of 0.25 to 0.5 mg of O_3 per milligram of C can result in THM precursor destruction of about 5 to 25 percent depending on the concentration of bicarbonate. The role of bicarbonate is to suppress ozone decomposition (by serving as a hydroxyl radical scavenger), thereby

enhancing the persistence of molecular ozone and possibly encouraging the formation of bicarbonate radicals.

The tendency of ozone to destroy DBP precursors is greater for systems where chlorine is added at acidic pH. The effect of ozone may disappear entirely or even reverse for systems that chlorinate at pH above 8 (Reckhow et al., 1986). Impacts of ozonation on subsequent trihaloacetic acid formation (e.g., TCAA) generally follow its impact on THMs. In contrast, precursors of dihaloacetic acids (e.g., DCAA) are far less affected by preoxidation.

Chlorine dioxide has been shown to produce similar removals of THM precursors as ozone at the same dose levels (Fig. 19-18).

FIGURE 19-18 Comparison between ozone and chlorine dioxide in the destruction of THM precursors. (Data from Reckhow, 1984; Werdehoff and Singer, 1987.)

Permanganate also appears to be capable of oxidizing THM precursors to a limited degree, although effective removal has been observed in hard waters owing to calcium-assisted adsorption of NOM on the manganese oxides produced (Colthurst and Singer, 1982).

Ozonation also has been shown to most effectively destroy the fastest-reacting DBP precursors. This has the effect of making ozonation appear more effective in systems where the chlorine contact time is short. Figure 19-19 shows the relative destruction of TCAA precursors by ozonation when the results are evaluated at different chlorine contact times. Precursor destruction in this case is as high as 75 percent when the chlorine is allowed to react for only 30 minutes. Precursor destruction was only 35 percent when the chlorine contact time was 1 week.

Advanced oxidation processes (AOPs) may be less effective for precursor destruction than simple ozonation. Frimmel and colleagues (2000) examined the use of moderate ozone doses (~1 mg/mg C) with waters of low TOC (1.2–2.3 mg/L) and found that increasing

FIGURE 19-19 Destruction of TCAA precursor by ozone, as determined at various chlorine contact times. (Source: Data from Reckhow et al., 1993.)

levels of peroxide caused a decrease in the destruction of THM precursors (Fig. 19-20). In related work, Kleiser and Frimmel (2000) explored the impacts of peroxide and UV irradiation on Ruhr River water (2.3 mg/L DOC). They found that UV treatment caused a small increase in THM precursor content even though the UV absorbance was partly destroyed (Fig. 19-21). Parallel experiments with ozone alone showed a monotonic decrease in THM precursor with increasing ozone dose.

FIGURE 19-21 Impact of UV dose on THM precursor control from combined UV-peroxide treatment. (Source: Kleiser and Frimmel, 2000.)

Use of ozone and UV light may present some unique disadvantages, especially with respect to halonitromethane formation. The highest levels of halonitromethanes (e.g., chloropicrin) have been reported for plants with preozonation followed by chlorine/chloramines. It has been proposed that nitration reactions may be partly responsible (e.g., Choi and Richardson, 2004), although there also may be some activation of preexisting N organics. Thibaud and colleagues (1986) have shown that *m*-nitrophenol can produce halonitromethanes at 5 to 50 percent yield depending on pH. UV light from medium-pressure lamps has been shown to enhance halonitromethane formation substantially, probably due to photonitration reactions resulting in the incorporation of ambient nitrate into the NOM (Reckhow et al., 2009).

Coagulation and Clarification. The reader is also referred to Chap. 8 for additional coverage of this subject. Coagulation with alum or ferric salts generally is quite effective for removal of NOM (e.g., as measured by DOC) and its constituent DBP precursors (Kavanaugh, 1978; Young and Singer, 1979; Babcock and Singer, 1979; Edzwald et al., 1985). In fact, there is a tendency for the humic and fulvic fractions of NOM to be removed more completely during coagulation and subsequent settling or filtration than the more hydrophilic NOM (Liang and Singer, 2003; Archer and Singer, 2006). Since these humic materials bear a higher density of THM, trihaloacetic acid, and TOX precursor sites, this leads to slightly higher removals of THM, trihaloacetic acid, and TOX precursors on a percentage basis than bulk DOC (e.g., see Reckhow et al., 2005; Archer and Singer, 2006) (Fig. 19-22).

There are indications that some DBP precursors are more closely aligned with the hydrophilic fraction of organic carbon. One example is the 1,1,1-trichloropropanone precursors, which are probably associated with aliphatic ketones and related compounds. Figure 19-23 shows that these precursors are less amenable to removal by alum coagulation than the bulk organic carbon.

FIGURE 19-22 Comparison of the reduction in total organic halide formation potential and removal of TOC by coagulation for 27 raw waters across the United States. (Source: Archer and Singer, 2006.)

FIGURE 19-23 Removal of NOM and DBP precursors by alum coagulation, settling, and filtration. (Source: Reckhow and Singer, 1990.)

The effectiveness of coagulation for the removal of NOM and DBP precursors is the basis for including “enhanced” coagulation as a requirement of the Stage 1 Disinfectants/Disinfection By-Products Rule (see Chaps. 1 and 8). In addition to promulgating specific maximum contaminant levels for THMs and HAAs, the Stage 1 Rule requires a specified degree of TOC removal prior to disinfection. The objective of this requirement is to limit the formation of unidentified DBPs that may have an adverse public health effect. The TOC removals specified depend on the TOC concentration and alkalinity of the raw water (see Chap. 8). In general, raw waters with high SUVA values (and high DBP formation potentials) are more amenable to TOC removal by coagulation than waters with low SUVA values. This is in recognition of the general consensus that raw waters with higher TOC concentrations tend to contain higher concentrations of hydrophobic organic carbon that is more amenable to TOC removal by coagulation than waters with low TOC concentrations.

Ion Exchange. Because much of the NOM that harbors DBP precursor structures contains carboxylic acid functional groups and therefore is anionic in nature, anion exchange has been proposed as a promising technology for precursor control. Most recently, this interest has been directed toward the use of magnetic ion exchange resins (MIEX) of low particle size. Early batch tests suggested that MIEX could remove both hydrophilic and hydrophobic organic acids from water (Boyer and Singer, 2005) and thereby offer some advantages over coagulation, which removes primarily the hydrophobic fractions. Additional studies (Johnson and Singer, 2004; Boyer and Singer, 2006) also showed that MIEX could remove bromide in waters with low levels of competing anions (e.g., bicarbonate and sulfate). These studies also demonstrated THMFP, HAAFP, and DOC removals of 70 percent or more (Fig. 19-24). There are concerns, however, that iron and hydrophobic

FIGURE 19-24 Summary of optimal MIEX treatment from four pilot-plant studies. (Source: Singer et al. 2007.)

organic matter in some waters may foul the MIEX resin and limit its reuse (Mergen et al., 2008). Ion exchange processes are discussed more extensively in Chap. 12.

Adsorption. Use of granular activated carbon (GAC) for adsorption of NOM has been studied widely, including its impacts on the removal of constituent DBP precursors. Because biological activity occurs so readily in GAC beds, it is sometimes difficult to separate removal owing to adsorption from loss to microbial degradation. Nevertheless, fresh GAC medium is effective at removing DBP precursors through abiotic adsorption. Important variables are the empty-bed contact time, GAC surface area, pore size distribution of the GAC, and temperature. In general, THMFP breakthrough parallels DOC breakthrough. Sometimes it lags the DOC breakthrough, making DOC a good conservative surrogate (e.g., Summers et al., 1995). Nevertheless, it should be recognized that use of GAC in a strictly adsorptive mode to control DBP precursors is relatively expensive for most systems, although it has been shown that biodegradation of DBP precursors in biologically active GAC beds can remove on the order of 20 percent of these precursors.

Powdered activated carbon (PAC) also can be used for the removal of DBP precursors. However, at typical water treatment doses and contact times, a limited degree of precursor removal can be expected. Processes that increase the standing concentration of PAC in the contactor or its residence time, such as contact clarifiers containing suspended PAC, are expected to be more effective. For greater coverage of adsorption, the reader should consult Chap. 14.

Biological Filtration. Biological filtration generally refers to the use of granular media filters in a way that encourages growth of attached biomass and results in high levels of biodegradation in the filter bed. Biological filtration has been practiced for more than a century in the form of slow sand filtration. More recently, rapid media filters have been operated for biological activity, especially when following ozonation. Important parameters that affect the performance of biological filters include pretreatment, contact time in the filter bed, oxidant/disinfectant residuals, media surface properties, and temperature.

There are numerous reports in the literature documenting the effectiveness of biological filtration for removing DOC and DBP precursors (e.g., Wang et al., 1995; Urfer et al., 1997; Niquette et al., 1999). These types of studies usually are designed to isolate the impacts of biological activity, separating biological effects from physicochemical adsorption. For GAC processes, this is sometimes done by assuming that long-term (postbreakthrough) removal of DOC represents the steady state biological removal. The extent of this steady state removal will depend on the fraction of biodegradable organics in the influent water, as determined by raw water quality and impacts of upstream treatment (e.g., ozonation). As an example, Snoeyink and Knappe (1994) found that 30 percent of the THM precursors were removed on GAC columns through long-term biodegradation.

In general, removal of THM precursors by biologically active GAC parallels the removal of DOC. While studied less commonly, the removal of precursors to other DBPs appears to reflect the gross removal of DOC, with some notable differences. These are illustrated here using pilot-plant studies conducted for the Massachusetts Water Resources Authority (MWRA). The raw water is a low-DOC, low-alkalinity surface water. Three trains were examined, all including preozonation, with one going directly to filtration, one with dissolved air flotation (DAF) and granular media filtration, and one with an upflow roughing filter (contact adsorption clarifier) with GAC media. Three types of filters were studied: an anthracite single-medium filter operated intermittently and two GAC/sand filters, one operated intermittently and one operated continuously. The intention was to limit biological activity in some of the filters by “starving” them via intermittent operation. The acclimated dual-media filters resulted in substantially lower precursor levels than the nonacclimated single-medium filter in the direct filtration train. Table 19-2 shows average precursor

TABLE 19-2 Average Precursor Removal from Wachusett Pilot-Plant Studies

Treatment process or change in process	TTHM	DCAA	TCAA	Chloral hydrate
<i>Percent removal across process</i>				
DAF alone	13	27	38	20
DAF + anthracite bed filtration	37	40	65	27
Anthracite bed filtration	37	40	58	30
Acclimated anthracite bed filtration	49	54	70	67
Acclimated GAC bed filtration	62	65	76	78
<i>Additional percent removal across process</i>				
Acclimated anthracite bed filtration	12	14	9	38
Anthracite → GAC	13	9	6	11

removal at various stages of the different process trains. Removals shown are calculated as the difference between the concentration in the ozone contactor effluent and the indicated process effluent divided by the concentration in the ozone contactor effluent.

Table 19-2 shows that removals by DAF always were less than removals by treatment trains that included some form of filtration. Some of this difference was due to removal of particulate organic carbon that escaped DAF, and some was due to biodegradation in the filters. As expected, pretreatment with DAF did not ultimately result in better filtered water quality (compare “DAF + Anthracite Bed Filtration” with “Anthracite Bed Filtration”), although it certainly would reduce head-loss buildup in the filters. The acclimated anthracite filters showed better removal of all four classes of precursors than the intermittently operated (i.e., nonacclimated) filters. This difference is shown in the second to last row in Table 19-2. Note that the difference is greatest for the chloral hydrate precursors, a group that is expected to be dominated by aliphatic aldehydes, which are readily biodegradable. The acclimated GAC media seems to have supported a higher level of removal for all the precursors compared with the acclimated anthracite filters. This difference is shown in the bottom row of Table 19-2. Elevated biological activity with GAC media relative to sand or anthracite has long been noted (e.g., Wang et al., 1995) and has been attributed to differences in the pore size distribution or surface chemistry of the GAC.

While ozonation and biofiltration ultimately will result in lower overall DBP levels in the finished water, they also will result in a shift toward a higher fraction of brominated species. This is especially noticeable in waters that contain high levels of bromide because ozone will oxidize some of the bromide to hypobromous acid and bromate. The hypobromous acid will react with NOM in the water to form low levels of brominated DBPs, even before the addition of any halogen-containing disinfectants. Second, improved removal of DOC by the GAC will result in higher ratios of bromide to DOC in the finished water. This has the unintended consequence of more heavily populating precursor carbon with bromine atoms rather than chlorine atoms. The end result is a higher level of bromine incorporation (e.g., Shukairy and Summers, 1996). This same phenomenon exists for most processes that target DOC removal, for example, coagulation, GAC adsorption, anion exchange, nanofiltration (see below).

Membrane Separation. Although low-pressure membranes (microfiltration and ultrafiltration) generally are not effective at removing dissolved organic substances, high-pressure processes can be quite effective. Nanofiltration (NF) membranes typically reject 50 to 95 percent of the THM precursors depending on the molecular weight cutoff of the membrane (Chellam, 2003). Since NF is capable of removing a large fraction of the organic

DBP precursors, but not bromide, NF-treated water can be expected to have high Br:DOC ratios. This leads to higher levels of bromine incorporation during subsequent chlorination (e.g., Chellam, 2003; Ates et al., 2009), similar to that observed for biofiltration. Reverse-osmosis (RO) processes are capable of removing essentially all the THM and HAA precursors, as well as rejecting some of the bromide. The performance, design, and operational considerations for NF and RO are covered in detail in Chap. 11.

Modifying Disinfection

Various elements of the disinfection step sometimes can be changed to help control DBP formation. One obvious approach is to reduce the disinfectant dose or contact time to the extent possible within the constraints of good disinfection practice. For example, primary and secondary disinfectant doses may be reduced in some plants while relying on booster disinfection out in the distribution system to take care of areas susceptible to low residuals (see Carrico and Singer, 2009). Additionally, disinfectant addition may be delayed until after a substantial portion of the DBP precursors have been removed, for example, by coagulation, anion exchange, adsorption, or membrane filtration. pH adjustment also can be used to favorably affect DBP formation. Base addition for corrosion control might be delayed until after disinfection with chlorine to help depress formation of THMs (see earlier section on the effects of pH). A widely used approach to control the formation of currently regulated DBPs is to substitute an alternative disinfectant for chlorine. Common examples include the use of chloramines as a secondary disinfectant in place of free chlorine or the use of ozonation, UV irradiation, or chlorine dioxide as a primary disinfectant in place of chlorination. Implementation of any of these options must be done in such a manner that disinfection is not compromised.

Moving the Point of Chlorination. It is well established that halogenated DBP formation is, by a first approximation, proportional to the TOC concentration at the point of chlorination. This is why, in waters with high DBP precursor concentrations, shifting the point of chlorination from before coagulation to after clarification yields substantial reductions in DBP formation. This was first demonstrated in full scale by Young and Singer (1979). These authors monitored the Durham, N.C., water treatment plant over the time period when they switched from addition of chlorine prior to rapid mix to addition at a point between sedimentation and dual-media filtration. The drop in THMs after the switch (early January 1977) was quite clear and was based on a series of bench-scale chlorination tests using raw and coagulated water (Fig. 19-25). The Stage 1 Disinfectants/Disinfection By-Products Rule requirement that certain levels of TOC removal be achieved prior to final disinfection is based on recognition that chlorinating after effective coagulation and clarification substantially reduces the formation of THMs and HAAs and most (if not all) other halogenated DBPs.

Furthermore, a 40 percent reduction in TOC across conventional treatment often translates to a 50 percent or more reduction in some DBPs when this switch is made. This is partly attributed to preferential removal of precursor organics by coagulation and the accompanying shift in the nature of the NOM at the point of chlorination to less reactive compounds (see Fig. 19-23).

Delaying the addition of chlorine until after filtration may serve to further reduce finished-water DBP concentrations. Organic precursors deposited on filter media are subject to reaction with chlorine in the water applied to the filters. The end result is that these retained organic precursors are converted to DBPs at a high yield (Corbin et al., 2003). However, the need to control manganese by means of catalytic removal on filter media may preclude this option in some plants (see Chap. 7).

FIGURE 19-25 Impact of moving the point of chlorination from before to after coagulation and sedimentation. (Source: Young and Singer, 1979.)

Alternative Primary Disinfectants. A number of utilities have adopted the use of ozone, UV irradiation, or chlorine dioxide as alternative primary disinfectants in place of free chlorine. These agents, although more expensive, generally are better disinfectants than free chlorine (see Chap. 17). As noted earlier and in Chap. 7, however, while these alternative disinfectants do not form THMs and HAAs to any appreciable degree, ozone is associated with the formation of bromate in bromide-containing waters, and chlorine dioxide produces chlorite as a by-product. Both bromate and chlorite are public health concerns and are regulated in finished drinking water.

Alternative Secondary Disinfectants: Chloramines. Research has shown that inorganic chloramines result in little or no formation of trihalogenated species, that is, THMs and the trihaloacetic acids (Cowman and Singer, 1996, Zhang et al., 2000). In contrast, monochloramine produces dichloroacetic acid, but at much lower concentrations than free chlorine. The addition of preformed monochloramine, however, is not commonly practiced. Still, because chloramines are almost always applied after a period of free chlorine contact (or use of an alternative primary disinfectant), they have the effect of greatly reducing the formation of THMs and HAAs (e.g., Speitel, 1999). Figures 19-26 and 19-27 demonstrate the impact of ammonia addition to chlorinated finished water from three water treatment plants in North Carolina (Singer et al., 1998). Ammonia was added at a 1:4 weight ratio relative to chlorine, and waters were held at pH 8.0 and 20°C for the times indicated. As shown, little additional THM or HAA6 formation is apparent.

As a result of the Stage 2 Disinfectants/Disinfection By-Products Rule and the shift to a locational running annual average instead of the historical system-wide running annual average as a basis for regulation and the fact that chloramines essentially stop the continuing formation of THMs and HAAs, many utilities have switched or are planning to switch to the use of chloramines as a secondary disinfectant to comply with the Stage 2 Rule.

Changing the Chemistry of Disinfection. A good example of how knowledge of the chemistry of DBP formation can be used to effect DBP control is the case of bromate. This

FIGURE 19-26 Impact on THM formation from ammonia addition to chlorinated finished water from three water treatment plants in North Carolina. (Source: Singer et al., 1998.)

FIGURE 19-27 Impact on HAA formation from ammonia addition to chlorinated finished water from three water treatment plants in North Carolina. (Source: Singer *et al.*, 1998.)

inorganic DBP is produced almost exclusively from the ozonation of inorganic bromide ion. Von Gunten and Hoigne (1994) have shown that multiple pathways are important in bromate formation in drinking water, involving some combination of molecular ozone and the hydroxyl radical (see discussion in Chap. 7 and Fig. 19-28).

With this knowledge, it is easy to see that there are at least three feasible strategies for interrupting the formation of bromate: (1) prechloramination: depress bromide (Br^-) concentrations by adding chlorine to produce HOBr/OBr^- and ammonia to convert the HOBr/OBr^- formed to bromamines prior to ozonation; (2) acidification: depress hypobromite (OBr^-) concentration by lowering the pH and forming HOBr , which is less reactive than OBr^- with respect to bromate formation; and (3) preammoniation: add ammonia to convert hypobromous acid and hypobromite formed from the oxidation of bromide by ozone to bromamines. All three of these have been tested and found to be effective to varying degrees, with prechloramination attracting the most attention (e.g., Buffle *et al.*, 2004; Wert *et al.*, 2007).

Removing Disinfection By-Products after Formation

In general, DBPs are hydrophilic and have low molecular weights, characteristics that make them difficult to remove by most physicochemical processes. For example, the removal of THMs in chlorinated water requires either air stripping or granular activated carbon (GAC) adsorption with frequent regeneration. On the other hand, some DBPs are biodegradable and therefore may be removed by biologically active filtration. The most common example of this is the removal of aldehydes, acids, and ketoacids produced by ozonation. There is also evidence that HAAs produced from chlorination can be removed in this way. These postdisinfection options are discussed below.

Adsorption. Granular active carbon is the adsorbent of choice for removing trace levels of organic compounds, especially synthetic organic contaminants, from drinking water.

FIGURE 19-28 Bromate formation pathways and strategies for bromate control.

Batch isotherm tests show that the capacity and affinity of GAC for low-molecular-weight polar organic compounds is limited, rendering GAC adsorption an expensive solution for removal of many DBPs. While chloropicrin and 1,1,1-trichloropropanone are strongly adsorbed, chloroform and the other THM species are not. The HAAs are also poorly removed largely because they are almost completely ionized at pH conditions typical of drinking water treatment.

Pilot- and full-scale adsorber studies support the conclusions from bench-scale testing. Graese and colleagues (1987) showed that only 5000 to 6000 bed volumes (BV) of water could be processed before reaching 20 percent breakthrough (80 percent chloroform removal), corresponding to 50 to 100 days of service (Fig. 19-29). Throughput and bed life diminish as the empty-bed contact time (EBCT) drops below 8 to 10 minutes owing to changes in the length of the mass transfer zone. Nevertheless, Savitz and colleagues (2005) have shown that several point-of-use devices containing GAC have the ability to remove substantial amounts of THMs and HAAs for extended periods of time.

It has been suggested that bromate can be removed by GAC (Kirisits et al., 2000). Such removal probably occurs through reaction of bromate with reduced sites on the carbon, and as a result, competition exists with NOM and some inorganics for those sites. There are indications that preozonation may help to improve bromate removal via this mechanism because ozone can render NOM more hydrophilic and less readily adsorbable.

Biological Filtration. While biodegradation has been used for enhancing removal of NOM and DBP precursors in filters, it also may be used to remove preformed DBPs. The

FIGURE 19-29 Field data on chloroform removal by GAC. (Source: Adapted from Graese et al., 1987.)

most widely studied cases involve ozonation by-products such as the low-molecular-weight aldehydes and ketones. Reckhow and colleagues (1992) conducted biofiltration pilot studies in a Connecticut utility where they challenged the filters with high levels of ozonation by-products. They found that common by-products such as glyoxalic acid are removed almost completely at conventional filtration rates (Fig. 19-30). They also found that backwashing the filters with water containing a chlorine residual could be detrimental to the activity of the attached growth; thus filters 2 and 3 were less effective than filters 1 and 4. Similar findings have been reported by DiGiano and colleagues (2001) for removal of formaldehyde, glyoxal, and methyl glyoxal at EBCTs of 10 minutes.

Removal of chlorination by-products via biofiltration is practiced less commonly. Wu and Xie (2005) demonstrated that all HAAs could be removed effectively by GAC/sand filters at high temperatures. However, at lower temperatures (e.g., $<10^{\circ}\text{C}$), removal of TCAA was poor (<50 percent), except at EBCTs of 10 minutes or more. Kim and Kang (2008) confirmed that TCAA was not as well removed as DCAA by biological filtration. They also confirmed that the THMs are not degraded in biologically active filters.

Based on the limited research on HAA degradation in filters, and by analogy with the larger body of work on ozonation by-products, it seems that the following factors are likely to encourage biodegradation of a broad range of oxidation by-products: (1) absence of a disinfectant residual in the filter bed during normal operation, (2) little or no disinfectant residual in the backwash water, (3) extended EBCTs, that is, 10 minutes or more, (4) warm temperatures, (5) prior acclimation by exposure to the DBPs that are to be removed (this is often accompanied by partial exhaustion of adsorption capacity if GAC is used), and (6) media with high external surface area for good microbial attachment.

Biological filtration also may be effective for control of bromate. Pilot-plant studies have shown removals in the range of 40 to 60 percent (Kirisits and Snoeyink, 1999). Bromate seems to serve as a terminal electron acceptor, and as a result, this process may require that most of the dissolved oxygen be depleted prior to filtration. In like manner, bromate removal has been seen in anoxic groundwaters (Butler et al., 2004).

FIGURE 19-30 Impact of filtration rate and backwash on removal of glyoxalic acid by biologically active filters. (Post-O₃, RM and O₃/RM refer to raw water samples treated with ozone, alum, and combined ozone and alum, respectively.) (Source: Reckhow et al., 1992.)

Aeration. THMs are among the most volatile of the chlorination by-products. Accordingly, packed tower aeration has been studied by Umphres and colleagues (1983) for removal of THMs. As the level of bromine incorporation increases, the rate of loss by aeration decreases owing to the lower volatility of the heavier bromine-containing species (Fig. 19-31). Aeration is discussed further in Chap. 6.

FIGURE 19-31 Comparison of THM removals from pilot-plant studies on packed tower aeration. (Source: Umphres et al., 1983.)

Membrane Separation. While high-pressure membrane processes are quite effective at removing DBP precursors, preformed DBPs usually are much smaller in molecular size and therefore less well removed. Reverse osmosis (RO) has exhibited THM rejections as high as 90 percent (Reinhard et al., 1986). Membrane composition is likely to be more important than molecular weight cutoff ratings. For these small-molecular-weight compounds, rejection depends more on specific chemical properties of both the compound and the membrane and on the affinity between the solute and the membrane. In particular, charge effects may be an important characteristic in determining rejection. For example, Chalati and colleagues (2009) found that high-density negatively charged NF membranes are capable of removing 90 percent or more of the anionic HAAs. On the other hand, uncharged DBPs such as NDMA are poorly removed, even by RO (Steinle-Darling et al., 2007). Partial fouling of membranes may result in improved removal of these difficult solutes. The performance, design, and operational considerations for NF and RO are covered in detail in Chap. 11.

DISINFECTION BY-PRODUCTS IN THE DISTRIBUTION SYSTEM

Stability of Disinfection By-Products

The THMs generally are considered to be stable end products of the reaction between NOM and chlorine. Although the HAAs are also considered to be stable end products of chlorination, they are known to degrade abiotically by decarboxylation or by reductive dechlorination. The rate and extent of their degradation tend to be proportional to their bromine content (Zhang and Minear, 2002), with tribromoacetic acid being the least stable of the bromine- and chlorine-containing trihaloacetic acids. The trihaloacetic acids primarily exchange a bromine atom for a hydrogen atom, forming the corresponding dihaloacetic acids. There also may be some conversion of dibromoacetic acid to bromoacetic acid and bromochloroacetic acid to chloroacetic acid. Loss of bromine atoms is substantially faster than loss of chlorine atoms. Zero valent iron associated with pipe walls can readily dehalogenate HAAs (Hozalski et al., 2001), with chloroacetic acid being the final product of di- and trichloroacetic acid degradation. Furthermore, linear free-energy calculations by Zhang and Minear (2002) suggest that all iodinated trihaloacetic acids except dichloroiodoacetic acid are also likely to undergo decarboxylation in drinking water distribution systems.

Reports of the biological degradation of HAAs in drinking water distribution systems are well known. Starting with the work of Williams and colleagues (1994), numerous researchers have observed a decrease in HAA concentrations in regions of the distribution system that have no chlorine residual (e.g., Speight and Singer, 2005), especially when the water temperature is high. This loss is particularly noticeable for the dihaloacetic acids. Figure 19-32 illustrates, for a utility in the southeastern United States using combined chlorine as a secondary disinfectant, the loss of HAAs in the system at high residence times when the chlorine residual is depleted. The THM concentration at this same location is essentially unchanged. Nitrification also was observed at this same location, indicating the presence of ammonia-oxidizing bacteria. Figure 19-33 shows a similar situation for a utility in California using combined chlorine. Again, HAA concentrations are decreased at locations where the combined chlorine residual is low. [Note that the water ages (residence times) shown are based on hydraulic modeling, and therefore, the hierarchical order of residence times may not be accurate.] The speciation of the HAAs for this utility is shown in Figure 19-34, which illustrates that the decrease in total HAA concentration is due to loss of the dihaloacetic acid species.

FIGURE 19-32 Trihalomethane and haloacetic acid concentrations and total chlorine residual at various water ages for a utility in the southeastern United States. (Source: Baribeau et al., 2006, Awwa Research Foundation.)

The fact that HAA levels tend to decrease at high water ages in the distribution system means that unlike THM concentrations, which are highest at distribution system locations with the highest residence times, HAA concentrations often tend to peak elsewhere in the system. For many systems, different patterns are observed at different times of the year because biodegradation is limited at colder temperatures, and it is also easier to maintain chlorine residual in remote parts of the system when the temperature is colder. This

FIGURE 19-33 Haloacetic acid concentrations and total chlorine residual at various water ages for a utility in California. (Source: Baribeau et al., 2006, Awwa Research Foundation.)

FIGURE 19-34 HAA speciation at various water ages for a utility in California. (Source: Baribeau et al., 2006, Awwa Research Foundation.)

has regulatory implications with respect to choosing locations for compliance monitoring where THM and HAA concentrations are at a maximum.

Many of the other halogenated DBPs normally formed during chlorination are chemically unstable. Once in the distribution system, they will continue to react with constituents of the water or materials attached to pipe walls to form secondary by-products. Examples of reactive DBPs, as noted earlier in this chapter, include the haloacetonitriles, the halo ketones, and the cyanogen halides. It is quite likely that many other metastable compounds have eluded detection in finished drinking water because of their innate chemical instability.

Monitoring for Regulatory Compliance

Historically, DBPs have been regulated based on annual average levels in the distribution system. For larger systems, the Stage 1 Disinfectants/Disinfection By-Products Rule requires that THMs and HAAs be measured quarterly at four locations in the system for each water treatment plant and that the *system-wide* running annual average (the average of the last four quarters) be below the maximum contaminant levels of 0.08 mg/L for the THMs and below 0.06 mg/L for the HAAs that are regulated—five of the nine bromine- and chlorine-containing HAAs. The four locations were designated as three with average distribution system residence times and one remote location. For small systems, compliance is based on monitoring once a year, when the levels are expected to be highest, and at only one location, again where the levels are expected to be highest. The Stage 2 Rule keeps the same maximum contaminant levels but bases compliance on a *locational* running annual average, meaning that compliance must be achieved at all sampling locations. Moreover, the four sampling locations must be at points in the system where THM and HAA levels are expected to be highest.

As noted earlier, because of their stability, THM concentrations in chlorinated systems are expected to be highest where the contact time between free chlorine and the water is greatest, that is, at locations with the highest water age. For HAAs, this is not always the

case, particularly in warmer waters, where biodegradation occurs at high water ages. For chloraminated systems, because monochloramine does not produce THMs and produces only limited amounts of the dihaloacetic acids, THM and HAA levels are expected to be relatively uniform throughout the distribution system, except at high water ages, where biodegradation may affect HAA levels. The fact that THMs and HAAs do not increase appreciably in the system when monochloramine is the residual disinfectant is one of the reasons why many utilities have converted or are planning to convert to a combined chlorine residual for compliance with the Stage 2 Rule.

Spatial Temporal Variability of DBP Levels

Until recently, the temporal and spatial variability in DBP concentrations in distribution systems have not been fully appreciated. While it has always been understood that DBP levels change seasonally because of changes in temperature (kinetics of DBP formation) and the nature and amount of precursors in the raw water and that DBP levels change with increasing residence time in chlorinated systems, short-term (day-to-day and hour-to-hour) variations generally have not been recognized.

Singer (2001) showed that THM concentrations at various locations in chlorinated systems exhibit appreciable diurnal variations that match the diurnal variations in residual chlorine and water age. At times of the day when water demand is low and storage tanks in the system are filling, water age at sampling locations influenced by these tanks is low, and THM concentrations tend to be at a minimum. At other times of the day, when water demand is high and water levels in storage tanks are being drawn down, water age is higher, chlorine residuals are lower, and THM levels are correspondingly higher. Such diurnal variations are not seen in chloraminated systems because DBP levels do not increase appreciably with water age. Of course, as noted earlier, such variations can be seen if biodegradation of HAAs occurs with increased water age.

Short-term variations in DBP levels also have been reported at the point of entry to the distribution system, particularly for THMs (Periera et al., 2004; Obolensky et al., 2008). THM levels were observed to change by a factor of up to 2 over a relatively short period of time. These variations were unexpected and were traced to operational variations in the treatment plants associated with chlorine addition, ammonia addition, and pH adjustment. The findings suggest that water utilities should examine their operations routinely to make sure that their chemical feed systems are designed and operated appropriately.

Accordingly, in view of this short-term variability in DBP levels in the distribution system, regulators and utility personnel may wish to review the current reliance on quarterly averaging to assess DBP exposure and to determine MCL compliance.

ABBREVIATIONS

AOC	assimilable organic carbon
BCAA	bromochloroacetic acid (also BrClAA)
BCAN	bromochloroacetonitrile
BDCM	bromodichloromethane
BDOC	biodegradable dissolved organic carbon
BIF	bromine incorporation factor
BOM	biodegradable organic matter

BSF	bromine substitution factor
CH	chloral hydrate
CP	chloropicrin
DAF	dissolved air flotation
DBAA	dibromoacetic acid (also Br ₂ AA)
DBAN	dibromoacetonitrile
DBCM	dibromochloromethane
DBPs	disinfection by-products
DCAA	dichloroacetic acid (also Cl ₂ AA)
DCAN	dichloroacetonitrile
DCP	dichloropropanone
D/DBP	disinfectants/disinfection by-products
DiHAA	dihaloacetic acids (DCAA + BCAA + DBAA)
DOC	dissolved organic carbon
DON	dissolved organic nitrogen
DOX	dissolved organic halogen
EBCT	empty-bed contact time
FP	formation potential
GAC	granular activated carbon
HAAFP	haloacetic acid formation potential
HAA9	nine haloacetic acids (MCAA + MBAA + DiHAA + TriHAA)
HAAs	haloacetic acids
HAN4	four haloacetonitriles (DCAN + TCAN + BCAN + DBAN)
HANs	haloacetonitriles
HPIA	hydrophilic acids
HPOA	hydrophobic acids
ICR	Information Collection Rule
MBAA	monobromoacetic acid (also BrAA)
MCAA	monochloroacetic acid (also ClAA)
MCL	maximum contaminant level
MIEX	magnetic ion exchange resin
NDMA	nitrosodimethylamine
NF	nanofiltration
NOM	natural organic matter
MW	molecular weight
MWRA	Massachusetts Water Resources Authority
PAC	powdered activated carbon
RM	rapid mix
RO	reverse osmosis
SDS	simulated distribution system

SUVA	specific UV absorbance
TBAA	tribromoacetic acid (also Br ₃ AA)
TCAA	trichloroacetic acid (also Cl ₃ AA)
TCAN	trichloroacetonitrile
TCP	trichloropropanone
THMFP	trihalomethane formation potential
THM4	four trihalomethanes (chloroform, BDCM, DBCM, and bromoform)
THMs	trihalomethanes
TPHA	transphilic acids
TriHAA	trihaloacetic acids (TCAA + bromodichloroacetic acid + dibromochloroacetic acid + tribromoacetic acid)
TOBr	total organic bromine
TOC	total organic carbon
TOCl	total organic chlorine
TOI	total organic iodine
TOX	total organic halogen
UFC	uniform formation conditions
USEPA	U.S. Environmental Protection Agency
USGS	U.S. Geological Survey
UV	ultraviolet
UV ₂₅₄	ultraviolet absorbance at 254 nm

INTRODUCTION

Corrosion is one of the most important problems in the drinking water industry. It can affect public health, public acceptance of a water supply, and the cost of providing safe water (Edwards, 2004; WHO, 2006). Maintaining the integrity of drinking water distribution system materials and distribution system water quality are important objectives of drinking water suppliers. Corrosion, microbiological regrowth, disinfectant demand, water flow restrictions due to excessive pipe scale buildup, discolored or turbid water resulting from metal release from pipe materials or scale, and metallic tasting water are examples of specific distribution system issues.

Deterioration of materials resulting from corrosion can necessitate huge yearly expenditures of resources for repairs, replacement, and system maintenance. A recent assessment by the U.S. Environmental Protection Agency (USEPA) of drinking water infrastructure needs in the United States estimated that a 20-year capital investment of \$335 billion will be needed for costs for repairs and replacement of transmission lines and storage, treatment equipment, and other health-related projects for the 70,000 community and not-for-profit, non-community water systems (USEPA, 2009a). Many times the problem is not given the attention it needs until expensive changes or repairs are required. Often overlooked, plumbers and plumbing code development and enforcement play vital roles in risk identification and management in drinking water (WHO, 2006).

Corrosion tends to increase the concentrations of many metals in tap water, although in the United States only two of them (lead and copper) are regulated as corrosion by-products at the consumers' taps. The occurrence of the toxic metals lead and cadmium is attributable almost entirely to leaching caused by corrosion of plumbing materials. Three metals—copper, iron, and zinc—cause staining of fixtures, or metallic taste, or both. Low levels of tin and antimony can be caused by the corrosion of lead-free solders (Herrera et al., 1982; Subramanian et al., 1991; Subramanian et al., 1994). Nickel has sometimes been mentioned as a potential contaminant from the plating of decorative plumbing fixtures (Kimbrough, 2009). The promulgation of the Lead and Copper Rule by USEPA (1991), which has undergone several revisions, has created an awareness and emphasis on corrosion control in distribution systems, as well as domestic, public, and institutional plumbing systems (USEPA, 2009b).

Corrosion products attached to pipe surfaces or accumulated as sediments in the distribution system can shield microorganisms from disinfectants (see Chap. 21). These organisms

can reproduce and cause problems such as bad tastes, odors, slimes, and additional corrosion. Corrosion control within the distribution system, therefore, is an important factor in secondary disinfection and maintenance of high water quality (Camper, 1996; Ki  n   et al., 1996; Olson, 1996; Rompr   et al., 1996; Schreppel et al., 1997). Corrosion deposits on pipes also provide a major reservoir for a broad variety of elements, some of which could have considerable health consequences if ingested (Reiber and Dostal, 2000; Schock, 2005; Schock et al., 2008a).

The term *corrosion* is also commonly applied to the dissolution and carbonation reactions of cement-based materials. An increase in pH often occurs as a result of this reaction, which can be detrimental to disinfection and the aesthetic quality of the water, as well as reducing the effectiveness of phosphate corrosion inhibitor chemicals intended to control the corrosion of metals. The release of asbestos fibers is of regulatory concern, and in extreme cases, the chemical attack on the pipe by the water may cause a reduction of structural integrity and, ultimately, failure.

Even when a water system passes all regulatory requirements, the release of corrosion by-products by miles of distribution system and domestic piping and the application of corrosion inhibitor chemicals containing metals such as zinc can be significant sources of metal loading of wastewater treatment plants. This contamination source can affect compliance with discharge or sludge disposal limits. Phosphate-based corrosion inhibitors can increase nutrient loading to wastewater plants and can cause violations of wastewater or other discharge regulations or contribute to water quality problems in ecosystems receiving the water.

Long-term corrosion-related failure of piping can cause many indirect health consequences, ranging from subtle effects such as intrusion from pressure transients to catastrophic failures and massive potential contamination. Edwards (2004) describes in detail many of these potential impacts.

Each material that can corrode has a body of literature devoted to it. Detail on the form of corrosion for each metal or piping material, possible secondary trace contaminants that can be released into the water, and specific corrosion inhibition practices that might be effective, can be found in a comprehensive text (AwwaRF-TZW, 1996) and numerous specific water treatment journal articles. In general, plastic plumbing materials are more corrosion resistant, but they have their own degradation mechanisms and other potential problems, such as brittleness, taste, odor, biofilms support, and both organic and inorganic leachates.

The purpose of this chapter is threefold: (1) to provide an introduction and overview of the chemistry and treatment concepts involved in corrosion and deposition phenomena in drinking waters, (2) to provide a guide to more specialized literature that describes the intricacies of material corrosion in more depth, and (3) to provide general guidance on preventing, diagnosing, and mitigating corrosion and deposition effects in drinking water distribution, storage, and premise plumbing systems.

CORROSION, PASSIVATION, AND IMMUNITY

Electrochemical Reactions

Metal species can be released into water either from the simple dissolution of, or desorption or scouring from, existing scale materials. For corrosion of any metal to occur, all of the components of an electrochemical cell must be present (AwwaRF-TZW, 1996; MWH, 2005). These include an *anode*, a *cathode*, a *connection* between the anode and cathode for electron transport, and an *electrolyte solution* that conducts ions between the anode and cathode. The anode and cathode are sites on the metal that have different electrical potential. If any one of these components is absent, a corrosion cell does not exist and corrosion does not occur.

Oxidation and dissolution of the metal take place at the anode. The electrons generated by the anodic reaction migrate to the cathode, where they are discharged to a suitable electron acceptor, such as oxygen. The positive ions generated at the anode tend to migrate to the cathode, and the negative ions generated at the cathode tend to migrate to the anode. Migration occurs to maintain electroneutrality.

At the phase boundary of a metal in an electrolyte solution an electrical potential difference exists between the solution and the metal surface. This potential is the result of the tendency of the metal to reach chemical equilibrium with the electrolyte solution. This oxidation reaction, representing a loss of electrons by the metal, can be written as

Equation 20-1 indicates that the metal corrodes, or dissolves, as the reaction goes to the right. This reaction will proceed until the metal is in equilibrium with the electrolyte containing ions of this metal.

Corrosion results from the flow of electric current between electrodes (anodic and cathodic areas) on the metal surface. These areas may be microscopic and in very close proximity in the case of uniform corrosion. Alternatively, they may be large and somewhat remote from one another, causing non-uniform corrosion or pitting, with or without *tuberculation*. Two examples of this situation are tuberculation of iron and galvanized steel piping, and *pinhole leak* formation in copper pipes. The former can greatly impede water flow, whereas the latter causes leakage and loss of integrity of premise plumbing or service lines. The type of corrosion can be controlled by various factors that include but are not limited to the type of metal, characteristics of the water, flow patterns, impurities in or on the metal surface, sediment accumulations and bacterial slimes.

The current that results from the oxidation of the metal is called the *anodic current*. In the companion reaction the electrons are removed by reaction with oxidants via the *cathodic current* (the reaction, Eq. 20-1, going to the left). In drinking water, the cathodic reaction is with a combination of oxygen, disinfectant (usually, but not always, free chlorine or monochloramine), or occasionally some other strong oxidizing agent. The situation of true equilibrium is only rarely the case. In almost all forms of pipe corrosion, the metal goes into solution at the anodic areas. As the metal dissolves, a movement of electrons occurs and the metal develops an electric potential.

The Nernst Equation

The Nernst equation is a relationship that allows the driving force of the reaction to be computed from the difference in free-energy levels of corrosion cell components (Pankow, 1991; Stumm and Morgan, 1996; Langmuir, 1997; Butler and Cogley, 1998). The free-energy difference under such conditions depends on the electrochemical potential, which, in turn, is a function of the type of metal and the solid- and aqueous-phase reaction products. Electrons (electricity) will then flow from certain areas of a metal surface to other areas through the metal. A metal may go into solution as an ion, or may react in water with another element or molecule to form a soluble aqueous complex, ion pair, or insoluble compound. The equilibrium potential of a single electrode can be calculated by using the Nernst equation, which is described in Chap. 3. In drinking water systems, the oxidation half-cell reaction of a metal, such as iron, zinc, copper, or lead, is coupled with the reduction of some oxidizing agent, such as dissolved oxygen or chlorine species. Example half-cell reactions are the following:

Equations 20-3 and 20-4 can be combined to yield the net reaction.

which represents a significant oxidizing half-cell reaction for metals in drinking water.

If Eq. 20-2 is written in the Nernst form (Eq. 20-6) and the ionic strength of the water is low enough that it can be assumed to have unit activity ($\{\text{H}_2\text{O}\} = 1$), then

$$E_{\text{O}_2/\text{OH}^-} = E_{\text{O}_2/\text{OH}^-}^\circ - \frac{0.0591}{4} \log \frac{\{\text{OH}^-\}^4}{\{\text{O}_2\}} \quad (20-6)$$

The oxidation potential for this reaction clearly depends on pH, because the $\{\text{OH}^-\}$ is raised to the fourth power in the numerator. Similarly, the oxidation potential of the hypochlorous acid reaction is directly related to pH.

$$E_{\text{HOCl}/\text{Cl}^-} = E_{\text{HOCl}/\text{Cl}^-}^\circ - \frac{0.0591}{2} \log \frac{\{\text{Cl}^-\}}{\{\text{HOCl}\} \{\text{H}^+\}} \quad (20-7)$$

because of the $\{\text{H}^+\}$ term in the denominator.

Reactions such as Eqs. 20-2 and 20-5 can be combined with metal oxidation half-cells (Eq. 20-1) to show overall corrosion reactions likely to occur in drinking water. Examples are

As an example, the overall Nernst expression for Eq. 20-11, at 25°C, is

$$E_{\text{Cu}^{2+}/\text{OCl}^-} = E_{\text{Cu}^{2+}/\text{OCl}^-}^\circ - \frac{0.0591}{2} \log \frac{\{\text{Cu}^{2+}\} \{\text{Cl}^-\}}{\{\text{OCl}^-\} \{\text{H}^+\}^2} \quad (20-12)$$

Note that in Eq. 20-12, the activities are for the free aqueous species, not the total concentrations. The overall potential of the reaction will depend on several factors: the ionic strength, the temperature, the degree of hydroxide complexation of the metal, the presence of complexing agents for the metal, side reactions of any ligands with other species, and the limits on the free metal ion caused by solubility, such as the formation of corrosion product solids. The amount of the driving force and the rate of the corrosion reactions can also be impacted by barriers that slow or limit the diffusion of oxidants to the surfaces of the materials, where “fresh” metal is available to oxidize.

Although metal levels and oxidant depletion in drinking water may ultimately be controlled by near-equilibrium solubility mechanisms, particularly with prolonged stagnation and low flow situations, corrosion cell activity is rarely entirely stopped. Thus, the control of the electrochemical cell reaction rate is usually the most critical factor in corrosion control.

Types of Corrosion

Many different types of corrosion exist (Pourbaix, 1973; Snoeyink and Wagner, 1996; MWH, 2005), and only some of the most significant to the corrosion of drinking water systems are covered here.

The kind of attack depends on the material, the construction of the system, the scale and oxide film formation, and the hydraulic conditions. Corrosion forms range from uniform to intense localized attack. Specialized corrosion texts should be consulted for more comprehensive discussions.

Uniform Corrosion. Uniform corrosion of a metal surface can proceed via sites that are anodic one instant and cathodic the next. When these sites are microscopic, close to one another, and the potential differences between the sites are small, uniform corrosion is favored (Snoeyink and Wagner, 1996). Reduction of oxygen occurs at the film surface, and transport of ions to and away from the oxide film takes place. The overall rate of corrosion is controlled by the presence and properties of the film or by transport of reaction products, especially hydroxide ion, away from the film-solution interface. This duplex film model was originally described by other researchers, notably by Ives and Rawson (1962a) for copper.

Plumbosolvency and *cuprosolvency* are terms that should specifically apply to the release of soluble lead and copper, respectively, resulting from uniform corrosion of piping, although in common use the terms sometimes generate confusion by being incorrectly applied to total metal release.

Galvanic Corrosion. Galvanic corrosion occurs when two different types of metals or alloys physically contact each other. One of the metals serves as the *anode*, with its corrosion rate accelerated, while the other serves as the *cathode*, with its corrosion rate reduced (AwwaRF-TZW, 1996; MWH, 2005). Available metals and alloys can be arranged in order of their tendency to be anodic, called the *galvanic series*. This order, in a potable water environment, depends on the temperature and solution chemistry (particularly the anionic components), as well as the simple relative ordering of the standard electrode potentials of the oxidation or reduction half-cells or simple metal-ion redox reaction couplings. Hence, tables developed for seawater would not always be the same as those for demineralized water or for any given finished drinking water. Therefore, any such published galvanic series should only be used as approximate guidance. Depending on generalizations about the range of chemical characteristics expected for the water in contact with the metals, different galvanic series can be measured or computed. For example, Larson (1975) described an empirical series (without giving solution composition specifics) as the following, going from the *anodic* end (corroded) to the *cathodic* end (noble): zinc, aluminum 2S, cadmium, aluminum 17ST, steel or iron, cast iron, lead-tin solders, lead, brasses, copper, bronzes, monel, silver solder, and silver.

The rate of galvanic corrosion is increased by greater differences in potential between the two metals. When cathodically controlled, the rate is increased by large areas of cathode relative to the area of the anode, and it is generally increased by closeness of the two metals and by increased mineralization or conductivity of the water. The relative size of the cathode relative to the anode may be of particular concern in the corrosion of lead-tin soldered joints in copper pipe, or when piping of two different types are interconnected, such as replacement of lengths of lead pipe with copper pipe (Britton and Richards, 1981; Gregory, 1990; Reiber, 1991; Singley, 1994).

Research has also suggested that the galvanic corrosion of copper alloys, lead, and leaded solder, when coupled with copper, creates local areas of low pH, increasing the solubility and rate of release of the metal or metals that are at the anodic sites (Dudi and Edwards, 2005; Edwards and Triantafyllidou, 2007; Nguyen et al., 2008, 2009). Further research is needed to refine the mechanisms, particularly with respect to possible different roles of free chlorine versus monochloramine in driving the reactions, buffering systems controlling pH changes, and the role of specific solids and complexes in accelerating or mitigating the effect.

Galvanic corrosion is often a great source of difficulty where brass, bronze, or copper is in direct contact with aluminum, galvanized iron, or iron. An example of a combination of deposition corrosion and galvanic corrosion occurs when copper can attack spots on galvanized pipe, thereby causing copper-zinc galvanic cells (Kenworthy, 1943; Fox et al., 1986). In waters of low conductivity, the influence of the galvanic cell is intense, but only in the immediate vicinity of the contact between the metals (MWH, 2005). In waters of high conductivity, however, the effect of the galvanic cell is spread widely across the surface of the less-noble (anodic) metal.

Pitting Corrosion

Pitting is a type of non-uniform corrosion that forms pits or holes in the pipe surface (Fig. 20-1). It takes relatively little metal loss or overall corrosion to cause a pinhole in a pipe wall, and failure can occur in as little as a few weeks. Pitting failures have little or no correlation to high copper release. Pitting can begin or concentrate at a point of surface imperfections, scratches, or surface deposits.

FIGURE 20-1 Pit formed in copper pipe, showing build-up of cupric hydroxycarbonate, hydroxysulfate and hydroxychloride solids in cap, and filling of cuprous oxide and cuprous chloride crystals inside the pit. (USEPA Photo.)

Dealloying or Selective Leaching. Dealloying, or selective leaching, is the preferential removal of one or more metals from an alloy in a corrosive medium, such as the removal of zinc from brass (dezincification), or the removal of pockets of lead from brass (Schock and Neff, 1988; Lytle and Schock, 1996; Oliphant and Schock, 1996; Schock et al., 1996). This type of corrosion weakens the metals and can lead to pipe failure in severe cases. The stability of brasses and bronzes in natural waters depends in a complex manner on the water chemistry and the formation of protective films. Dezincification is common in brasses containing 20 percent or more zinc and is rare in brasses containing less than 15 percent zinc (Oliphant and Schock, 1996). The occurrence of plug-type dezincification and dezincification at threaded joints suggests that debris and crevices may initiate oxygen concentration cells and result in dezincification.

Lead occurs in lead-tin solder as a disseminated phase, acting principally as a diluent for the tin that actually does the binding with the copper (Parent et al., 1988). Factors governing the removal of lead from the soldered joint are presumably similar to those affecting the leaching of lead from brass. Soldered joints in service for a long time frequently show a depletion of lead from the exposed solder.

Selective leaching also applies to the dissolution of asbestos-cement (A-C) pipe, or the deterioration of cement mortar linings of iron water mains (see the section Corrosion of Specific Materials).

Tuberculation. Tuberculation occurs when pitting corrosion products build up at the anode next to the pit (Smith and McEnaney, 1979; Snoeyink and Wagner, 1996; Sarin et al., 2001; Sarin et al., 2004a; 2004b). Tuberculation can occur in many types of metallic pipes. In iron or steel pipes, the tubercles are made up of various iron oxides and oxyhydroxides. These tubercles are usually rust colored and soft on the outside and are both harder and darker toward the inside. Sometimes they are considerably layered with iron minerals indicative of anoxic environments, such as sulfide minerals (Singley et al., 1985; Benjamin et al., 1996).

Tuberculation of iron has often been attributed to poorly buffered waters, where pH can get extremely high under localized surface conditions. Hence, many consultants and researchers have recommended a balance of minimum hardness and alkalinity to provide a water that is resistant to iron corrosion and tuberculation (Stumm, 1956, 1960; Larson and Skold, 1957, 1960; Weber and Stumm, 1963; Merrill et al., 1978; Smith and McEnaney, 1979).

Microbiologically Influenced Corrosion. Microbiologically influenced corrosion (MIC) pertains to the general class of corrosion resulting from a reaction between the pipe material and organisms such as bacteria, their metabolic by-products, or both (Little and Wagner, 1997). Algae and fungi may also influence corrosion by producing changes in the pH, dissolved oxygen level, or other chemistry changes to the microenvironment at the metal surface or under corrosion deposits in treatment plant or water storage scenarios. MIC may be an important factor in the taste and odor problems that develop in a water system, as well as in the degradation of the piping materials. Microbial activity and its impacts potentially extend from the finished water entry point, all the way through distribution system and storage, and on into the premise plumbing, finally reaching all of the way to consumers' taps. Thus, residential impacts have been poorly studied, yet they can be very significant in some circumstances.

Biofilms in pipes are often characterized by stratification, with different families of organisms with different functions existing in the different zones and conditions (Little and Wagner, 1997). Controlling such growths is complicated because they can take refuge in many protected areas, such as mechanical crevices or accumulations of corrosion products. Bacteria can exist within porous scale layers or under tubercles, where neither chlorine nor oxygen can destroy them. Mechanical cleaning may be necessary in some systems before control can be accomplished by residual disinfectants. Preventative methods include good corrosion control to avoid tuberculation and accumulating corrosion by-products, avoiding dead ends, and preventing stagnant water in the system by flushing or bleeding.

Microbial activity can strongly influence the mineralogy of iron corrosion deposits (Allen et al., 1980; Lazaroff et al., 1982; LeChevallier et al., 1993; Camper, 1996; Postma and Jakobsen, 1996; Brown et al., 1997; Lewandowski et al., 1997; Appenzeller et al., 2002; Mikutta et al., 2008; von Blanckenburg et al., 2008). Some researchers have linked reduced microbial activity in distribution mains with the application of effective corrosion control treatment in distribution system mains, as well as controlling limiting nutrients. One proposed mechanism for the effectiveness of corrosion control toward bacterial regrowth and biofilms by corrosion inhibitors is the prevention or saturation of sorption sites at the pipe surfaces, allowing less *natural organic matter* (NOM) sorption and attachment (LeChevallier

et al., 1993; Camper, 1996). Thus, there would be a decreased attached nutrient base for the colonizing organisms if potential organic material attachment sites were already occupied by phosphate or other corrosion inhibitor material. Because microbial activity can affect pH, metal solubility, and the oxidation-reduction potential of the surrounding microenvironment, microbial activity in pipe or storage tank scales and deposits could also impact the stability of manganese or other redox sensitive metals in deposits and the mobility of trace metals associated with the formation or decomposition of those coatings.

The ways in which bacteria can increase corrosion rates are numerous. One pathway is the formation of oxygen concentration cells that produce lowered pH and localized corrosion and pitting. Lee et al. (1980), for example, showed increased localized corrosion when cast iron was exposed to a water with extensive biological activity, compared with the same water under sterile conditions. Associations have been found between nitrification activity and copper corrosion problems (Marani, 1992; Murphy et al., 1997a–c). Cantor has reported several cases of particularly copper pitting corrosion in which microbes are believed to play a pivotal role (Cantor et al., 2006; Cantor, 2009).

Nitrification, depending on the extent of completion of the reaction, can produce 2 moles of hydrogen ion, for every mole of ammonia consumed (Metcalf and Eddy Inc., 2003; Schock, 2005). Accordance with the sequential microbially-mediated reactions is shown in Eqs. 20-13 and 20-14.

Recently, a comprehensive review of nitrification and drinking water corrosion has been published (Zhang et al., 2009a). Additional recent research has provided direct evidence for long-suspected increases in lead and copper release caused by lower pH conditions resulting from nitrification (Zhang et al., 2008a and b, 2009b). Microbes may also enhance corrosion or solubility because extracellular material and metabolites of microorganisms may include polymers that are good complexing agents (Garrels and Christ, 1965; Geesey et al., 1986, 1988; Geesey and Bremer, 1991), or they may influence the redox chemistry of the scales at the surface (Allen et al., 1980; Lee et al., 1980; LeChevallier et al., 1993; Lewandowski et al., 1997). Conversely, microbes can also dramatically reduce corrosion and leaching of metals such as galvanized iron, if they remove agents that would reduce dissolved oxygen (Zhang et al., 2008a and b, 2009b).

Iron bacteria derive energy from oxidation of ferrous iron to ferric iron. Nuisance conditions often result because the ferric iron precipitates in the gelatinous sheaths of the microbial deposits, and these can be sloughed off and be the cause of red-water complaints. Sontheimer et al. (1981) noted that they can also interfere with the development of passivating scales and, thus, that the rate of corrosion is higher in their presence than in their absence.

The sulfate-reducing bacteria may be one of the most important organisms causing MIC in many water systems (Sontheimer et al., 1981). Sulfate can act as a reducing agent at low redox potentials.

and the sulfate-reducing organisms facilitate this reaction. Sulfate reducers have been found in the interior of tubercles, and thus may be responsible for maintaining corrosion at these locations (Ainsworth, 1980). Sulfate reducers are often present regardless of whether the supply is aerated (Little and Wagner, 1997). Some observations that higher levels of sulfate cause more corrosion (Larson, 1975) may possibly be related to microbial activity (Snoeyink and Wagner, 1996; Lytle et al., 2005a). Recent research has found sulfide to be a contributor to

copper pitting that is particularly destructive and difficult to control (Jacobs et al., 1998), and once started, the microbial mediation may be very difficult or impossible to stop. The high-chloride, low-pH environments of pits can lead to continued propagation within pits, even if the microbes are killed by biocides (Little and Wagner, 1997).

Erosion Corrosion. Erosion corrosion involves multiple mechanisms of attack, which can include cavitation and concentration cells formed by differential velocity. High velocities disrupt the formation of protective films, such as metal oxides, hydroxycarbonates, and carbonates, that serve as protective barriers against corrosive attack. When cavitation occurs, it can also remove the metal of the pipe itself. Erosion corrosion can be identified by grooves, waves, rounded holes, and valleys it causes on the pipe walls.

Crevice Corrosion. Crevice corrosion is a subset of concentration cell corrosion, in which changes in acidity, oxygen depletion, and dissolved ions and the absence of an inhibitor cause irregular localized corrosion. As the name implies, this corrosion occurs in crevices at gaskets, lap joints, rivets, and surface deposits.

Concentration Cell Corrosion. Concentration cell corrosion is usually deduced by inference. It occurs when differences in the total or the type of mineralization of the environment exist. Corrosion potential is a function of the concentration of aqueous solution species that are involved in the reaction, as well as of the characteristics of the metal. Differences in acidity (pH), metal ion concentration, anion concentration, or dissolved oxygen cause differences in the solution potential of the same metal. Differences in temperature can also induce differences in the solution potential of the same metal.

When concentration cell corrosion is caused by dissolved oxygen, it is often referred to as *differential oxygenation corrosion* as discussed by Snoeyink and Wagner (1996). Common areas for differential oxygenation corrosion are between two metal surfaces, for example, under rivets, under washers, under debris, or in crevices.

Oxygen concentration cells develop at metal-water interfaces exposed to air, such as in a full water tower, accelerating corrosion a short distance below the surface. The dissolved oxygen (DO) concentration is replaced by diffusion from air and remains high at and near the surface, but does not replenish as rapidly at lower depths because of the distance. Therefore, the corrosion takes place at a level slightly below the water contact surface.

Graphitization. Graphitization is a form of corrosion of cast iron in highly mineralized water or waters with a low pH that results in the removal of the iron-silicon metal alloy making up one of the phases of the cast-iron microstructure. A black, spongy-appearing, but hard mass of graphite remains.

Stray Current Corrosion. Stray current corrosion is a type of localized corrosion usually caused by the grounding of home appliances or electrical circuits to the water pipes. It is well accepted that stray currents can cause failures on the outside of pipes, but the actual contribution of stray current to internal corrosion remains controversial. There has been some evidence presented by a number of researchers that both ac and dc current can affect corrosion rates and metal levels in the water (Williams, 1986; Horton and Behnke, 1989; Horton, 1991; Bell et al., 1995a and b; Goidanich et al., 2010). However, in some studies there was a concurrent substantial water temperature increase as a result of the amount of current passed, and in other studies electrochemical models did not seem to fit the observed polarization measurement data, leaving interpretation of mechanisms still inadequate. In municipal distribution systems, increased corrosion of steel-reinforced concrete pressure pipe has occasionally been noted and has been believed to be related to stray currents.

Corrosion Products on Pipe Surfaces

Metal surfaces may be protected by their being either immune or by rendering them passive. If a metal is protected by *immunity*, the metal is thermodynamically stable, and is therefore incorrodible (Pourbaix, 1973). In practice this occurs for plumbing materials used for water supplies only for copper in deaerated water without sulfides. *Passivation* occurs when the metal is not stable, but becomes protected by a stable film. The protection from a film can vary from nearly perfect to highly imperfect, depending on the extent to which the film effectively shields the metal from contact with the solution (Pourbaix, 1973). In pure water, the reaction product would consist of a metal oxide or hydroxide. However, in drinking waters, anions and other cations are present that can precipitate under these local surface chemistry conditions and contribute to passivation.

Several studies have shown that the pH at the surface of pipe can be significantly different from that in the bulk solution (Snoeyink and Wagner, 1996), although many studies reporting extremely high pH at the surface have neglected to adequately include consideration of buffering by the carbonate system in the water and the possible role of solids such as $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$ (Watkins and Davies, 1987; Dexter and Lin, 1992; Lewandowski et al., 1997). The deposits that form on pipe surfaces may be: (1) a mixture of corrosion products that depend both on the type of metal that is corroding and the composition of the water solution [e.g., $\text{FeCO}_3(\text{s})$, $\text{Fe}_3\text{O}_4(\text{s})$, $\text{FeOOH}(\text{s})$, $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2(\text{s})$, $\text{Zn}_3(\text{CO}_3)_2(\text{OH})_6(\text{s})$], (2) precipitates that form because of pH changes that accompany corrosion [e.g., $\text{CaCO}_3(\text{s})$], (3) precipitates that form because the water entering the system is supersaturated (e.g., $\text{CaCO}_3(\text{s})$, $\text{SiO}_2(\text{s})$, $\text{Al}(\text{OH})_3(\text{s})$, $\text{FeOOH}(\text{s})$, $\text{Fe}(\text{OH})_3(\text{s})$, $\text{MnO}_2(\text{s})$, etc.), and (4) precipitates or coatings that form by reaction of components of inhibitors, such as silicates or phosphates with the pipe materials (e.g., lead or iron).

The nature of the scales or deposits that form on metals is important because of the effect that these scales have on the corrosion rate, through a combination of physical and chemical factors such as (but not only): chemical composition and crystal structure; porosity to water, oxidants, complexing ligands, and corrosion product ions; semiconductor properties; solubility; magnetic properties; particle size; and surface area.

A long time, from many months to years, may be required for the corrosion rate of iron, steel, and copper to stabilize because of the complex nature of the scales. If a scale considerably reduces the rate of corrosion, it is said to be a relatively *protective* scale; if it only reduces the rate of corrosion slightly, it is termed *non-protective*.

Changes in water treatment or source water chemistry over time can produce successive layers of new solid phases, remove or change the nature of previously existing deposits, or both. Scales of similar chemical composition can have a significantly different impact on corrosion and metal protection because properties such as uniformity, adherability, and permeability to oxidants can vary depending on such factors as trace impurities, presence of certain organics, temperature of deposition, length of time of formation, and so forth.

Scales that form on pipes may have deleterious effects in addition to the beneficial effect of protecting the metal from rapid corrosion or limiting the levels of toxic metals (such as lead) in solution. Aluminum scales have had well-documented hydraulically detrimental impacts (Snoeyink et al., 2003), as have many unwanted secondary deposits formed by corrosion control approaches for lead and copper (Grigg, 2010). In theory, water quality should be controlled so that the scale is protective but as thin as possible, because as the bulk of scale increases, the capacity of the main to carry water is reduced. In practice, it is difficult to maintain uniform chemistry conditions throughout a distribution system to achieve the ideal pipe surface coating. The formation of uneven deposits such as tubercles increases the roughness of the pipe surface, reducing the ability of the mains to carry water, and may provide shelters for the growth of microorganisms.

Understanding that there may be significantly different reactions occurring between the water constituents and the surfaces of new pipes compared with old pipes is important to the interpretation of field and laboratory data from corrosion control studies. Conceptually, this is illustrated in Fig. 20-2 for lead pipe. On the new surface Fig. 20-2a, the full suite of anodic and cathodic reactions can occur, with oxidation of lead followed by the beginning of the development of a passivating film. Once the film is sufficiently developed (Fig. 20-2b), in this case after many decades, the oxidants in the water no longer can directly contact the metal of the pipe material itself. Therefore, the oxidation step will not occur, and metal release will become a strong function of the physical adherence or the solubility of the surface deposit. Thus, corrosion inhibitor chemicals that stifle reactions occurring at cathodic surface sites may appear much better in tests using new metal surfaces than they may operate when applied to distribution system pipes covered by thick scales or corrosion deposits. With well-developed surface deposits present, the solubility and surface chemistry of the existing scales is much more important in developing water treatment targets than predictions based on the pure corrosion chemistry of the metal.

FIGURE 20-2 Different reactions dominate the corrosion and metal release of lead pipe, depending on the surface condition. (a) Fresh lead surface, where a full suite of anodic and cathodic reactions take place. (b) Exhumed 90-year-old lead service line coated with a thick mixture of PbCO_3 and $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$, where the surface reaction is dominated by simple $\text{Pb}(\text{II})$ solubility chemistry and ion diffusion. Corrosion Kinetics

In addition to the understanding of the overall *thermodynamic* driving forces for corrosion and corrosion control approaches, an examination of important dynamic electrochemical reactions taking place is also important to understand many drinking water corrosion-related phenomena. A three-step process is involved in governing the rate of corrosion of pipe: (1) transport of dissolved reactants to the metal surface, (2) electron transfer at the surface,

and (3) transport of dissolved products from the reaction site (James M. Montgomery Consulting Engineers, 1985). When either or both of the transport steps are the slowest, *rate-limiting step*, the corrosion reaction is said to be under *transport control*. When the transfer of electrons at the metal surface is rate limiting, the reaction is said to be under *activation control*. The formation of solid natural protective scales that inhibit transport are often an important factor in transport control.

Corrosion has often been described in terms of numerous tiny galvanic cells on the surface of the corroding metal. Such localized anodes and cathodes as those described are not fixed on the surface, but are statistically distributed on the exposed metal over space and time. The electrochemical potential of the surface is determined by the mixed contributions to potential of both the cathodic and anodic reactions, averaged over time and over the surface area. When the electrode is at its equilibrium, the rates of reaction in both the cathodic and anodic half-cells are equal. A sophisticated treatment of the electrokinetics of corrosion reactions based on *mixed-potential theory* is given by MWH (2005). Mixed-potential theory is the most powerful conceptual tool now available for understanding the short-term dynamics of the corrosion process.

Given the thermodynamic basis for corrosion described above, and the body of knowledge about kinetic factors that affect the rate of corrosion of metals, several properties of the water passing through a pipe or device that influence the rate of corrosion can be identified. Some of the water-related properties are (1) concentration of dissolved oxygen, (2) pH, (3) temperature, (4) water velocity, (5) concentration and type of disinfectant residual, (6) chloride and sulfate ion concentrations, (7) concentration of dissolved inorganic carbon (DIC) and calcium, and (8) the concentration and type of remaining NOM.

These properties interrelate, and their effect depends on the plumbing material as well as the overall water quality. References specific to the type of plumbing situation (pipe, soldered joint, galvanic connection, faucet, or flow-control device) and the material of interest should be consulted for the most appropriate information on corrosion rate control.

Solubility Diagrams

The solubility of passivating films on the pipe surface is the most important factor in determining whether a given water quality can meet many drinking water regulations that are based on health effects of ingested metals. In the case of distribution mains, where solubility equilibrium is rarely attained, asbestos fibers are frequently physically released into the water because of the dissolution of the cement matrix originally holding them. Reducing the solubility of that cement matrix, or depositing an insoluble coating over the fibers, would be two pathways to mitigate the problem. Solubility is also a governing factor in the deposition of often unwanted interior coatings of iron, manganese, and aluminum present in the water entering the distribution system.

Focusing more on premise plumbing where cyclical stagnation periods are the norm, solubility is a major factor in lowering maximum soluble metals levels that can be controlled by modifying water chemistry at the treatment plant. Solubility reflects an ideal equilibrium condition, and should not necessarily be expected to correspond to tap water levels (Britton and Richards, 1981; Schock, 1990). Other factors are important, such as the physical location of the plumbing materials relative to the sample collected, the release of particulates from the deposits on the pipes, the rate of the chemical reactions that affect the mobilization of the metals relative to the standing time of the water before collection, and many other variables. However, trends in the response of tap water copper levels to changes in key water chemistry variables followed the predictions of solubility models in principle, in a survey of over 2500 U.S. utilities of all sizes (Edwards et al., 1999). More recent studies on lead pipes that revealed the extensive presence of PbO_2 deposits in waters of low pH

and frequently high alkalinity (Schock et al., 2001, 2005a) have now explained several of the apparent discrepancies in lead release trends noted in the earlier Edwards et al. (1999) work, which was limited to consideration of Pb(II) equilibria.

To display solubility relationships in a relatively simple two-dimensional manner, the total solubility of a constituent is plotted as a function of a master variable (Stumm and Morgan, 1996; Butler and Cogley, 1998). Other solution parameters can affect solubility such as the ionic strength, or the concentration of dissolved species (ligands) that can form coordination compounds or complexes with the metal. The solubility diagram does not necessarily give the information needed to minimize the rate of corrosion because rate is affected by kinetic parameters that depend on the relative rates of the oxidation, dissolution, diffusion, and precipitation reactions. It also cannot predict the ability of a pipe coating to adhere to the pipe surface, or the permeability of a coating to oxidants from the water solution or pitting agents. It does, however, give important information for estimating trends in water quality impacts on compliance with maximum contaminant levels (MCLs) or action levels (ALs) for drinking water, the potential for precipitating passivation films on pipe surfaces. Solubility diagrams are also useful for predicting the onset of scaling phenomena that can constrain effective corrosion control treatment, such as precipitation of calcium carbonate, octacalcium phosphate, and aluminum or ferric hydroxide.

To construct this type of diagram, an aqueous mass balance equation must be written for the metal (or other constituent of interest), with the total solubility (S_T) as the unknown. The mass balance expression should include the concentration of the uncomplexed species (free metal ion), along with all complexes to be included in the model. For Pb(II), the simple relationship for the free ion, plus only the hydroxide and carbonate complexes (the simplest system for potable waters), is

$$\begin{aligned} S_{T,\text{Pb(II),CO}_3} = & [\text{Pb}^{2+}] + [\text{Pb}(\text{OH})_2^\circ] + [\text{Pb}(\text{OH})_3^-] + [\text{Pb}(\text{OH})_4^{2-}] \\ & + 2[\text{Pb}_2(\text{OH})^{3+}] + 3[\text{Pb}_3(\text{OH})_4^{2+}] + 4[\text{Pb}_4(\text{OH})_4^{4+}] + 6[\text{Pb}_6(\text{OH})_8^{4+}] \\ & + [\text{PbHCO}_3^+] + [\text{PbCO}_3^\circ] + [\text{Pb}(\text{CO}_3)_2^{2-}] \end{aligned} \quad (20-16)$$

If the concentration of a complex is going to be relatively negligible compared with the total solubility across the pH range of interest, it can be excluded from the model for simplicity. Frequently, only four or five species are significant in a system. Substituting in the aqueous species and conditional formation constants, the full expression for computation becomes (Schock, 1980, 1981)

$$\begin{aligned} S_{T,\text{Pb(II),CO}_3} = & [\text{Pb}^{2+}] + \frac{\beta'_{1,1}[\text{Pb}^{2+}]}{[\text{H}^+]} + \frac{\beta'_{1,2}[\text{Pb}^{2+}]}{[\text{H}^+]^2} + \frac{\beta'_{1,3}[\text{Pb}^{2+}]}{[\text{H}^+]^3} + \frac{\beta'_{1,4}[\text{Pb}^{2+}]}{[\text{H}^+]^4} \\ & + 2\frac{\beta'_{2,1}[\text{Pb}^{2+}]^2}{[\text{H}^+]} + 3\frac{\beta'_{3,4}[\text{Pb}^{2+}]^3}{[\text{H}^+]^4} + 4\frac{\beta'_{4,4}[\text{Pb}^{2+}]^4}{[\text{H}^+]^4} + 6\frac{\beta'_{6,8}[\text{Pb}^{2+}]^6}{[\text{H}^+]^8} \\ & + \beta'_{1,1,1}[\text{Pb}^{2+}][\text{H}^+][\text{CO}_3^{2-}] + \beta'_{1,0,1}[\text{Pb}^{2+}][\text{CO}_3^{2-}] \\ & + \beta'_{1,0,2}[\text{Pb}^{2+}][\text{CO}_3^{2-}]^2 \end{aligned} \quad (20-17)$$

In these equations, $\beta'_{m,h,c}$ represents the formation constant for the complex having a stoichiometry of m metal ions, h hydrogen ions, and c carbonate ions, corrected for ionic strength and temperature (Stumm and Morgan, 1996). To obtain the predicted solubility, the solubility constant expression for each solid of interest is rearranged and solved to isolate the free metal species concentration, here $[\text{Pb}^{2+}]$, and is substituted into each term of the mass balance equation (e.g., Eq. 20-16). Sometimes, an iterative technique is used to simultaneously solve several related mass balances, depending on exactly the type of diagrams

desired and assumptions about the availability of components involved in the precipitation and dissolution reactions in the system.

A diagram is then constructed for each solid, and the curves are superimposed. The points of minimum solubility are then connected, giving the final diagram. This procedure is discussed in more detail by Schock (1980, 1981) for Pb(II), Schock et al. (1995) for copper, and Snoeyink and Jenkins (1980) for Fe(II).

Additional equivalent terms for sulfate, chloride, orthophosphate, and any other relevant complexes should be appended to this expression when the concentrations of the given Pb(II) species would be significant with respect to $S_{T,Pb(II),CO_3}$. As an example, the contribution to Pb(II) solubility from aqueous orthophosphate species is represented by

$$S_{T,Pb(II),PO_4} = [PbHPO_4^-] + [PbH_2PO_4^+] \quad (20-18)$$

So, the total lead(II) solubility becomes $S_{T,Pb(II)} = S_{T,Pb(II),CO_3} + S_{T,Pb(II),PO_4}$, or

$$\begin{aligned} S_{T,Pb(II)} = & [Pb^{2+}] + [Pb(OH)_2^0] + [Pb(OH)_3^-] + [Pb(OH)_4^{2-}] + 2[Pb_2(OH)^{3+}] \\ & + 3[Pb_3(OH)_4^{2+}] + 4[Pb_4(OH)_4^{4+}] + 6[Pb_6(OH)_8^{4+}] + [PbHCO_3^+] \\ & + [PbCO_3^0] + [Pb(CO_3)_2^{2-}] + [PbH_2PO_4^+] + [PbHPO_4^-] \end{aligned} \quad (20-19)$$

Because these diagrams are two-dimensional (solubility on the y-axis, pH on the x-axis), there are often additional variables that have an important impact on solubility (such as temperature, ionic strength, carbonate concentration or alkalinity, and orthophosphate concentration), these diagrams must display solubility and species concentration lines for fixed concentrations or values of the other variables. For instance, Fig. 20-3 displays a solubility diagram for lead in the system containing only carbonate species and water, showing the important aqueous species and the stability domains of two lead solids. In this figure, the DIC concentration was fixed at 2.5×10^{-4} mol/L (3 mg C/L), with a temperature of 25°C and an assumed ionic strength of 0.005 M. Figure 20-4 shows the same basic system, but with a total DIC concentration of 2.5×10^{-3} mol/L (30 mg C/L). In both diagrams, the implicit assumption was also made that the solution redox potential was not high enough to cause the formation of Pb(IV) aqueous or solid species. Additionally, when metal solubility becomes high, care must be taken to ensure that computational constraints on the system, such as the fixed ionic strength and the total ligand concentration (mass balance), are not violated by the presence of high concentrations of dissolved metal species.

Note that if the same complex formation constants were used, but a less soluble constant were used for $PbCO_3(s)$ (cerussite) solubility, the simple carbonate solid would be predicted to be stable over a wider pH range. Likewise, a less soluble constant for $Pb_3(CO_3)_2(OH)_2$ (hydrocerussite) would expand its stability field relative to that of cerussite. Analogous information can be obtained through the careful construction and study of solubility diagrams for other metals, such as copper and zinc. Similarly, different assumptions about the formation constants for the Pb(II) complexes or the inclusion of mixed Pb(II) hydroxide carbonate complexes would alter the shapes of the diagrams, and therefore the predicted lead concentrations at different pH values.

When constructing solubility diagrams for any metal, the selection of solid and aqueous species must truly represent the system to be modeled, or very erroneous conclusions can result. For example, the aragonite form of calcium carbonate, rather than the calcite form, is frequently found in deposits formed in systems having galvanized pipe. In addition, the ferric iron deposits formed in mains are frequently a relatively soluble hydroxide or oxyhydroxide form $[Fe(OH)_3]$ or $[FeOOH]$, rather than an ordered form such as hematite (Fe_2O_3). Manganese also tends to form a variety of solid phases with varying degrees of valence state

FIGURE 20-3 Solubility diagram showing dissolved lead (II) species in equilibrium with lead (II) solids in a pure system containing 3 mg C/L DIC (2.5×10^{-4} mol/L) at 25° and $I = 0.005$ mol/L. (Source: Data from Schock et al., 1996.)

mixing, crystal disorder, degrees of hydration, and so on. To go along with this concept, the equilibrium constants selected must be appropriate to the nature of the solid phases of interest and accurate to give realistic concentration estimates. Knowledge of changes in the equilibrium constants with temperature is essential, especially when projections of depositional tendency have to be made into hot or very cold water piping systems. Critical evaluation of data appearing in handbooks and published papers is necessary to avoid using incorrect values, and occasionally review articles or major works by rigorous researchers can be consulted for reliable values.

Sometimes improvements can be made in predictions by using metastable species in the calculations, although it is not thermodynamically rigorous to do so. Metastable solids have been found to govern copper levels in drinking water via what has been

FIGURE 20-4 A solubility diagram showing dissolved lead (II) species in equilibrium with lead (II) solids in a pure system containing 30 mg C/L DIC (2.5×10^{-3} mol/L) at 25° and $I = 0.005$ mol/L. (Source: Data from Schock et al., 1996.)

termed the *aging process* (Schock and Lytle, 1994; Schock et al., 1995, 2000; Edwards et al., 1996, 2000).

Stumm and Morgan have discussed the formation of precipitates and how this is related in a conceptual way to solubility diagrams, as illustrated by Fig. 20-5 (Stumm and Morgan, 1996). They define an *active* form of a compound as one that is a very fine crystalline precipitate with a disordered lattice. It is generally the type of precipitate formed incipiently from strongly oversaturated solutions. Such an active precipitate may persist in metastable

FIGURE 20-5 Solubility and saturation. A schematic solubility diagram showing concentration ranges versus pH for supersaturated, metastable, saturated, and undersaturated solutions. (Source: *Aquatic Chemistry*, W. Stumm and J.J. Morgan. Copyright © 1980, John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

equilibrium with the solution and may convert (age) slowly into a more stable *inactive* form. Measurements of the solubility of active forms of solids give solubility products that are higher than those of the inactive forms. Laitinen and Harris (1975) cite a definition of aging that includes all irreversible structural changes that occur in a precipitate after it has formed, such as recrystallization of primary particles; cementing of primary particles by recrystallization in an agglomerated state; thermal aging, transformation of a metastable modification into a more stable form; and processes involving changes in composition. Langmuir has described a similar natural analogous process for particle size effects on iron mineral transformation (Langmuir, 1971). Examples of changing solubility related to various physical properties abound in the literature. Noteworthy for copper have been both controlled bench solubility experiments (Scaife, 1957; Schindler, 1967; Patterson et al., 1991; Marani et al., 1995) and practical observations in water treatment or natural systems (Ma et al., 2006). For lead, the transformation in a phosphate-treated system from $\text{Pb}_3(\text{PO}_4)_3\text{OH}$ (hydroxypyromorphite) to $\text{Pb}_3(\text{PO}_4)_3\text{Cl}$ (chloropyromorphite) may also be an aging phenomenon (Harmon, 1999).

Hydroxides and sulfides often occur in amorphous and several crystalline modifications. Initially formed amorphous precipitates or active forms of unstable crystalline modifications tend to evolve toward forming a more stable modification, though it may be a nonhomogeneous solid. Similar phenomena can occur with basic carbonates, such as a transition from one form to another with changes in pH or DIC over time, or the alteration of existing solid phases by prolonged interaction with sorbed silicates species (Leggett, 1978).

Pourbaix or Potential-pH Diagrams

Potential-pH diagrams, which are also called E_h -pH or *Pourbaix diagrams*, are designed to predict what aqueous species or corrosion by-product solid phases are thermodynamically stable under different conditions of electrochemical potential and pH. Potential-pH diagrams have been popularized by Pourbaix and his coworkers in the corrosion field to

define areas of passivation, immunity, and active corrosion (Pourbaix, 1966, 1973; Obrecht and Pourbaix, 1967), and by numerous authors in natural water and geochemistry (Garrels and Christ, 1965; Stumm and Morgan, 1996; Langmuir, 1997) for mineral stability predictions. An equivalent version of the diagram uses the concept of electron activity, pE , which is analogous to the concept of pH (Snoeyink and Jenkins, 1980; Stumm and Morgan, 1996). Most aquatic chemistry textbooks give detailed instructions on the computation of potential-pH diagrams, and many computer software packages include them as options.

A potential-pH diagram is related to the solubility versus pH plots discussed earlier. This relationship is shown schematically in Fig. 20-6. If a conventional two-dimensional solubility diagram is considered as a vertical plane, a potential-pH diagram may be thought of as a slice that is perpendicular to the solubility plane, which cuts through that plane at a single level concentration of the metal. In actuality, potential-pH diagrams are usually computed in terms of thermodynamic activities rather than concentrations, but the difference is usually not important for practical purposes. The activities of all aqueous and solid species must be fixed, while the electrical potential of the solution and the pH become the master variables.

Potential-pH diagrams are particularly useful to study speciation in systems that could contain species of several possible valence states within the range of redox potential normally encompassed by drinking water, such as manganese, iron, arsenic, lead, and copper. Obtaining an accurate estimate of the redox potential of the drinking water is usually an important limitation in using potential-pH diagrams, and the actual corrosion potential at the surface of the pipe is important. The latter differs from the bulk-solution redox potential (MWH, 2005).

Figure 20-7 is a potential-pH diagram for lead in water, illustrating the simultaneous incorporation of two weak polyprotic acids: carbonic and phosphoric. The aqueous species in the diagram are heavily influenced by the carbonate concentration in the water, but the orthophosphate phases are less soluble than the lead(II) carbonates, so they are predicted to provide the actual passivation and plumbosolvency control.

Many references can be consulted for details of potential-pH diagrams for other metals of interest, bearing in mind that the metal concentration, and concentrations of the background constituents in the water, the forms of solid and aqueous species considered in the diagrams, and the stability (or metastability) of the solids must all be relevant for the system under consideration. Because of the metastability and aging issues noted previously, environmental time frames are often different from time frames implicit in potential-pH diagrams for geological systems, so diagrams are not automatically applicable. Equilibrium constants and other key thermodynamic data are not even available for some of the important aqueous and solid species involved in potable water system corrosion. Note that because the total activity is fixed across the entire pH range, the phase relationships predicted by the potential-pH diagram may deviate somewhat from those predicted in the previously described solubility diagrams.

FIGURE 20-6 Schematic relationship between potential pH and conventional solubility versus pH diagrams.

Very few statements regarding corrosion resistance can be made that do not have noteworthy exceptions (NACE, 1984). The corrosion of metals and alloys in potable water systems depends on both the environmental factors (solution composition and flow) and the composition of the plumbing or fitting material. Concern about the consequences of corrosion varies with the material. Sometimes, it is toxicity from trace metal dissolution and contamination of the drinking water, but for materials such as iron, steel, and mortar linings, the concern is more one of aesthetic and material degradation or, ultimately, pipe failure.

Physical Characteristics

Flow velocity and temperature are the two main physical characteristics of water that affect corrosion.

Velocity. High flow velocities can sometimes aid in the formation of protective coatings by transporting the protective material to the surfaces at a higher rate. High flow velocities, however, are sometimes associated with erosion corrosion or impingement attack in copper pipes, in which the protective wall coating or the pipe material itself is mechanically removed. High-velocity waters combined with other corrosion-causing water constituents can rapidly deteriorate pipe materials with minimal metal release to the water because of dilution. For example, the combination of high velocity with low-pH and high-DIC concentration is extremely aggressive toward copper. High flow velocity can also increase the rate at which oxidant species come in contact with pipe surfaces, increasing corrosion. It is hard to quantify *high*, but a common guideline for 1.3 cm ID (1/2 in) copper is about 1.2 m/s (4 ft/s) (AwwaRF, 1990), and plumbing handbooks should be consulted for the materials of interest for initial guidelines.

A water that behaves satisfactorily at medium to high velocities may still cause incipient or slow corrosion with serious red water problems at low velocities, because the slow water movement allows for the development of reducing conditions that facilitates rapid dissolution of iron from the metal surface.

High water velocity can also mobilize loosely adherent scale material and cause elevated metal release levels and erratic exposure to consumers. Britton and Richards (1981) pointed out that there are several reasons why the pickup of lead into the water is not a simple function of sampling flow rate. Differences in flow rates and velocity at the pipe-water interface can severely complicate assessments of metal exposures and comparisons to regulatory standards.

Temperature. The influence of temperature is also often misunderstood. Confusion can often be avoided by considering basic equilibrium in water chemistry and by remembering that temperature effects are complex and depend on both the water chemistry and the type of plumbing material present in the system. Multiple phenomena often operate simultaneously, such as changes in solubility of solids; changes in the formation of complex ions; changes in diffusion rates of dissolved gases and solution species; changes in composition or physical properties of the metals, alloys, or solids; and changes in water properties. Thus, generalizations are often stated that are overly simplistic and often misapplied.

The electrode potential (the driving force for any corrosion cell) is proportional to the absolute temperature, and therefore, theory predicts that the thermodynamic driving force for corrosion rate will increase with temperature. This relationship is observed in some controlled laboratory experiments over short time periods, but in practice is less obvious unless wide differences occur (i.e., hot versus cold water systems). In distribution system transmission and service lines, temperature fluctuations are somewhat limited over short time frames, so whatever effect they have is obscured by other factors. Seasonal changes in temperature are often accompanied by significant changes in one or more major chemistry parameters.

Household and building plumbing systems present some additional complications. The relatively high thermal conductivity of the metallic piping materials normally used causes the water standing inside pipes or passing through long stretches of pipe to rapidly equilibrate to the temperature of the air surrounding the pipe. Water temperature is governed by many site-specific construction characteristics, such as (but not constrained to) the locations of the pipes being sampled relative to heating or air-conditioning ductwork, plumbing routed through slab flooring, existence of crawl spaces, presence or absence of pipe or floor/wall insulation, or spaces above ceilings or below floors. Thus, interpreting the metal release and corrosion mechanisms is difficult. For example, cold water pipes running next to a heating duct could actually produce the counterintuitive situation of higher water temperature in the winter in those homes. Fluctuations in temperature from many causes also makes it difficult to define a single temperature as “representative” of sampling or normal usage conditions. Attempts to apply simple correlations with water temperature leaving the treatment plant are tempting, but could be very misleading.

Hot water is often observed to be more corrosive than cold water (AWWA, 1971). Water showing few corrosive characteristics in the distribution system can cause severe damage to copper or galvanized iron hot-water heaters at elevated temperatures. In some hot water systems, however, the opposite is true, as is shown by the example in Fig. 20-8, where the net effect is the facilitation of a better passivating duplex scale of Cu_2O and CuO on the copper tube. Lead monitoring data also have shown in some cases that lead orthophosphates sometimes form more quickly in waters with higher temperatures and, therefore, the highest tap lead levels occur in the winter in some water systems. Water systems should collect appropriate water samples for corrosion and metal release throughout the year and

FIGURE 20-8 Temperature induced change in mineralogy of copper pipe scale between hot and cold water having free chlorine, high pH and low alkalinity. The net result was better passivation and lower metal release at elevated temperature, where CuO formation was accelerated. (*D. Lytle, USEPA.*)

determine their own trends. Water chemistry characteristics play a critical role, and blind generalizations on temperature effects should not be made.

Larson has pointed out that the effect of temperature on pH is seldom recognized (AWWA, 1971). For pure water, as temperature increases the water dissociates more (the pK_w goes down), causing increases in both the H^+ concentration and the OH^- concentration. Drinking waters all contain carbonate species at some concentration, so the degree of influence of temperature on pH is also a function of the alkalinity and DIC of the water, as a result of changes in the dissociation constants for carbonic acid with temperature. Increasing concentrations of bicarbonate increasingly buffer or reduce this effect of temperature on pH. The net pH decrease from heating tends to be less than the net decrease in overall $CaCO_3$ solubility, causing increased scaling tendency at higher temperatures for waters with higher alkalinities. For waters of low alkalinity (less than approximately 50 mg $CaCO_3/L$), the higher temperatures decrease the pH at a faster rate than the rate of decrease in solubility of $CaCO_3$. Consider a water at 15°C having the following characteristics: pH = 8.71; Ca = 17.3 mg/L; Na = 17 mg/L; Cl = 35 mg/L; and total alkalinity = 30.6 mg $CaCO_3/L$. The water is at saturation equilibrium with calcite. Therefore, it has a *saturation index* (or *Langelier Saturation Index* (LSI)) of 0.0. At this temperature, the solubility constant for the simple dissolution of calcite

is equal to $10^{-8.43}$. If that water is warmed to 55°C, the saturation index drops to -0.02, even though the solubility constant decreases to $10^{-8.71}$. This phenomenon occurs because the pH also decreases, to 8.16.

Figure 20-9 gives an estimation of how the pH of waters of different alkalinities changes when warmed to a temperature of 55°C from 15°C. This figure is based on calculations

FIGURE 20-9 Change in pH for waters of different alkalinities caused by warming a water originally at 15°C to 55°C under closed-system conditions, assuming ionic strength of 0.001. The pH predicted for 55°C is obtained by adding the pH correction to the original (observed) pH at 15°C (e.g., $pH_{55} = pH_{15} + pH_{corr}$).

that assume the following: (1) an ionic strength of 0.001 M, (2) non-carbonate species contributing to alkalinity are negligible, (3) no change in inorganic carbon content during the temperature change, (4) carbonate and bicarbonate complexation are negligible, and (5) no other redox or hydrolysis reactions that significantly affect the proton balance of the system. More details on a general computational approach and some additional figures for computing the pH change resulting from intrinsic changes to water and carbonic acid dissociation have been published (AwwaRF, 1990).

An additional effect of temperature is that an increase can change the entire nature of the corrosion. For example, a water that exhibits pitting at cold temperatures may cause uniform corrosion when hot (Singley et al., 1984; AWWA, 1986). Another example in which the nature of the corrosion is changed as a result of changes in temperature involves the zinc-iron couple (Trussell and Wagner, 1996). Normally, the anodic zinc is sacrificed, or corroded, to prevent iron corrosion. In some waters, the normal potential of the zinc-iron couple may be reversed at temperatures above 46°C. The zinc becomes cathodic to the iron, and the corrosion rate of galvanized iron is much higher than would normally be anticipated, a factor that causes problems in many hot-water heaters or piping systems.

By changing solubility (as well as pH), temperature changes can influence the precipitation of different solid phases or transform the identities of corrosion products. These changes may result in either more or less protection for the pipe surface, depending on the materials and water qualities involved. When attempting to do solubility or other chemical speciation calculations in drinking waters, the effects of temperature on both the solubility constants for the potential passivating solids and the effects on the formation constants of the aqueous complexes of the metals of interest must be considered. Adjusting solubility constants but not complex formation constants, or only adjusting constants for some of the important water or solid species, are frequent errors observed in many published papers and reports. Unfortunately, analytical polynomial functions for changes in equilibrium constants with temperature, or various thermodynamic constants to enable other methods of approximations of adjustments to the equilibrium constants for temperature, are often not available for the aqueous species, solid phases, or both, in important corrosion and metal release situations for drinking water.

Manufacturing-Induced Characteristics

For several types of common plumbing materials, the manufacturing processes used may play an important role in determining the types of corrosion that will occur, and the durability of the pipe or fixtures. Pitting of galvanized pipe has been associated with several characteristics of its manufacture, such as thin, improper, or uneven galvanizing coating, poor seam welds, and rough interior finish (Fox et al., 1983; Trussell and Wagner, 1996; MWH, 2005). Impurities in the galvanizing dip solution, such as lead and cadmium, could cause concern because of their potential for leaching into the water.

In England, rapid pitting failures of copper pipe were found to be associated with a residual carbon film on their interior surfaces (Cruse and Pomeroy, 1974; Ferguson et al., 1996; MWH, 2005). Many copper corrosion researchers believe that the early history of the pipe and initial installation in residential and building plumbing has a profound impact on its susceptibility to localized corrosion later (Lane, 1993). Debris from manufacturing, transport and storage, and patchy or incomplete oxidation coatings from air and moisture exposure may set-up conditions favorable to differential oxygenation corrosion, depending on the initial exposure of the installed piping. If plumbing is not flushed thoroughly and housing is not occupied soon after construction, anoxic conditions favorable to microbiological growth and, later, to differential oxygenation corrosion, will likely result, and the corrosion cells may be hard to stifle once normal water usage is started.

CHEMICAL FACTORS AFFECTING CORROSION

Dissolved substances in water have an important effect on both corrosion and corrosion control. Many water chemistry factors may affect the rate of corrosion, metal release or dissolution, but not the equilibrium concentration. Therefore, in addition to understanding the way the chemistry factors act and interrelate, it is also important to understand the relationship between metal release and stagnation time in a water in a given situation, in order to interpret water sampling data, or to estimate impacts of various chemical parameters. This section provides a brief overview to point out some of the most important chemical factors affecting corrosion.

Alkalinity/Dissolved Inorganic Carbon (DIC)

Alkalinity is a measure of the ability of a water to neutralize acids and bases (Weber and Stumm, 1963; Loewenthal and Marais, 1976; Snoeyink and Jenkins, 1980; Butler, 1982; Pankow, 1991; Morel and Hering, 1993; Stumm and Morgan, 1996; Butler and Cogley, 1998). In most potable waters, total alkalinity is described by the relationship:

$$\text{TALK} = 2[\text{CO}_3^{2-}] + [\text{HCO}_3^-] + [\text{OH}^-] - [\text{H}^+] \quad (20-21)$$

where [] indicates concentration in mol/L and total alkalinity is in equivalents/L (eq/L). Alkalinity and DIC are discussed in detail in Chap. 3. In some waters, where the total inorganic carbon content is low (such as below approximately, 5 mg/L), other weak acids and bases such as phosphoric acid or dissociated sodium or calcium hypochlorite can contribute to alkalinity if present in high concentration, and complicate the computation of DIC from pH and alkalinity results. Because the pH of the equivalence point for the alkalinity titration changes with DIC concentration, traditional analytical methods to fixed pH endpoints (such as pH 4.5) are inherently inaccurate, except for waters with the coincidentally correct DIC (Schock and George, 1991). For waters with low DIC, this can cause appreciable errors in estimating metal solubility and even chemical dosages for optimal corrosion control.

The bicarbonate and carbonate species affect many important reactions in corrosion chemistry, including the ability of a water to form a protective metallic carbonate-based scale or passivating film, such as CaCO_3 , FeCO_3 , $\text{Cu}_2\text{CO}_3(\text{OH})_2$, $\text{Zn}_5(\text{CO}_3)_2(\text{OH})_6$, or $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$. They also affect the concentration of calcium ions that can be present, which, in turn, affects the dissolution of calcium from cement-lined or from asbestos-cement (A-C) pipe. The formation of strong soluble complexes with metals such as lead, copper, and zinc (Schock, 1980, 1981; Schock and Buelow, 1981; Schock and Gardels, 1983; Schock et al., 1995, 1996; Edwards et al., 1996; Ferguson et al., 1996; Trussell and Wagner, 1996) can accelerate corrosion or cause high levels of metal pickup given the right pH/alkalinity or pH-DIC conditions.

Ammonia

Ammonia forms strong soluble complexes with many metals, particularly copper and probably lead. Thus, ammonia may interfere with the formation of passivating films or increase the corrosion rate. Source water ammonia reacts with chlorine applied for disinfection and, therefore, results in inadvertent chloramination (see Chap. 17). Water systems that have substantial ammonia in their source waters and do not remove it need to take into account optimizing a chloramine residual and conducting oversight to guard against nitrite and nitrate production resulting from nitrifying biofilms and to monitor for possible increases in corrosivity (Lytle et al., 2008).

Buffer Intensity (β), Buffer Capacity, Buffer Index

The ability of a water to provide buffering against a pH increase or decrease caused by a corrosion process or water treatment chemical addition is closely related to the alkalinity, DIC concentration, and pH of the water (Weber and Stumm, 1963; Loewenthal and Marais, 1976; Butler, 1982; Stumm and Morgan, 1996; Butler and Cogley, 1998; Urbansky and Schock, 2000c). The *buffer intensity* of a water is defined as $\beta = (dTALK/dpH)_{DIC}$, which is essentially the inverse of the slope of the alkalinity titration curve. The basic equation for buffer intensity, β_{tot} , in terms of *total alkalinity* (TALK) is the following, for a system containing only the carbonic weak acid system in addition to water.

$$\beta_{tot,Alk} = 2.303 \left[\left(\frac{[H^+]TALK}{[H^+] + K'_2} \right) \times \left(\frac{[H^+]}{[H^+] + K'_1} + \frac{K'_2}{[H^+] + K'_2} \right) + [H^+] - \frac{K'_w}{[H^+]} \right] \quad (20-22)$$

TALK is expressed in eq/L units, $[H^+]$ is the hydrogen ion concentration in mol/L, K'_w is the dissociation constant for water, and K'_1 and K'_2 are the first and second dissociation constants for carbonic acid, respectively, all corrected for temperature and ionic strength. Similarly, buffer intensity can be written in terms of DIC (moles/L) rather than alkalinity. The resulting equation is

$$\beta_{tot,DIC} = 2.303 \times DIC \times K'_1 [H^+] \left[\frac{K'_1 K'_2 + [H^+]^2}{(K'_1 K'_2 + K'_1 [H^+] + [H^+]^2)^2} \right] + 2.303 \times \left[\frac{K'_w}{[H^+]} + [H^+] \right] \quad (20-23)$$

The units of β are normally mol/L per pH unit. If other weak acids or bases such as orthophosphate or silicate are present or if the ammonia concentration is high, additional terms must be added to Eqs. 20-22 and 20-23. These equations relate to what is often termed a *homogeneous buffer system*, in which all buffering components are aqueous species.

Figure 20-10 shows the buffer intensity for several different concentrations of DIC. Note the minimum point near pH 8, which corresponds to the point where pH is equal to $\frac{1}{2}(-\log K'_1 + -\log K'_2)$ for carbonic acid. The buffering at the pH extremes is from either hydrogen ion (low pH) or hydroxide ion (high pH). Figure 20-11 shows the effect on buffer intensity of the presence of 20 mg SiO₂/L silicate, and 5 mg PO₄/L orthophosphate, in a water having a DIC concentration of only 4.8 mg C/L. Clearly, the carbonate system provides almost all of the buffering, except when the pH is over about 9 and the silicate anion (present at a high total SiO₂ concentration) contributes sufficiently. This demonstrates that corrosion inhibitor chemicals of all types at normal drinking water dosages are a negligible component of pH buffering, except for waters of extremely low DIC (<2 mg/L). When a water body is open to the atmosphere, the exchange of carbon dioxide gas will affect the DIC concentration, and consequently, both the buffer intensity and capacity.

The difference between alkalinity and buffering intensity is often misunderstood. For example, consider four waters all with an identical total alkalinity of 20 mg/L as CaCO₃, at pH 6.0, 7.0, 8.0, and 9.0. The DIC concentrations would be 15, 5.8, 4.9, and 4.4 mg C/L, respectively, and the corresponding values for buffer intensity (β) would be 6.3, 0.2, 0.3, and 0.7 (mmol/L)/pH. The buffer intensity and DIC are considerably different for each water corresponding to the trend in Figs. 20-10 and 20-11. Thus, finished waters in the pH 8 to 8.5 range will have much poorer pH stability than if the water with the same DIC concentration was distributed at pH 7 or 9. Prevention of localized sites of high pH (such as at cathodic corrosion cell sites) by better buffering will improve the evenness of formation of corrosion-reducing scales and localized pitting, especially for ferrous materials (Lewandowski et al., 1997). Clement et al. (1998) have confirmed the practical application of these buffer relationships in the Concord, New Hampshire, distribution system, dramatically

FIGURE 20-10 Effect of DIC on buffer intensity, for 25°C, $I = 0$.

FIGURE 20-11 Combined components of buffer intensity, for DIC, silicate, and orthophosphate at high dosages and low DIC. Computed for 25°C, $I = 0.005$.

improving corrosion control and distribution system pH stability by elevating the pH above the problematic 8 to 8.5 range to 9. Additionally, it improved the overall lead and copper control characteristics of the water (see Fig. 20-12).

FIGURE 20-12 Improvement in distribution system pH stability in Concord, New Hampshire, treatment study. (Source: Clement and Schock, 1998, Clement et al., 1998.)

Buffering can also be provided by solid materials that can consume $[H^+]$ or $[OH^-]$ directly or indirectly. This defines a *heterogeneous buffer system*. Common minerals that provide buffering in natural water systems or scales at the water-pipe interface include aluminosilicates like kaolinite (a clay mineral), magnesium hydroxide, and calcium carbonate (Watkins and Davies, 1987; Dexter and Lin, 1992; Stumm and Morgan, 1996; Lewandowski et al., 1997). Although the aluminosilicates provide relatively strong resistance to pH change, the reaction rates are quite slow in comparison to those of carbonates, oxides, and hydroxides, so they may not be as significant in short time frames of water passage through pipes. In the restricted surface environments of pipe scales, essentially any of the metallic carbonate and hydroxycarbonate minerals could serve as buffers to some extent. Even oxides and oxyhydroxides can play a role in buffering, and the buffering of these scale solids is an important part of the lag time to completely achieve the new target equilibrium after treatment changes involving pH and alkalinity adjustment.

An expression for the buffer intensity at constant DIC for a solution in equilibrium with calcium carbonate (Butler, 1982; Butler and Cogley, 1998) is

$$\beta_{CaCO_3}^{DIC} = \beta_{tot,DIC} + 4.61[Ca^{2+}] \left(\frac{[HCO_3^-] + 2[CO_2]}{DIC} \right) \quad (20-24)$$

The derivation of this expression assumed that ion pairing is negligible. To use this equation, the calcium concentration is input presuming all calcium is present as free Ca^{2+} ion. Analyzed concentrations of $[\text{HCO}_3^-]$ and $[\text{CO}_2]$ must also be input, or computed values derived from a combination of pH and total alkalinity or DIC for the proper temperature and ionic strength. In principle, similar or analogous expressions can be derived for other oxide, carbonate, or hydroxide solids of relevance to corrosion and passivating scales on drinking water pipes.

Chloride and Sulfate

Chloride (Cl^-) and sulfate (SO_4^{2-}) may cause increased corrosion of metallic pipe by reacting with the metals in solution and causing them to stay soluble or interfering with the formation of normal oxide, hydroxide, or hydroxycarbonate film. They also contribute to increased conductivity of the water. Chloride is about 3 times as active as sulfate in this effect for iron materials, but recent research into copper corrosion has shown the action of chloride to be complicated and not always detrimental for copper (Edwards et al., 1994a; Meyer, 1994; Rehling, 1994; Duthil et al., 1996). Pitting of copper tubing is often strongly related to the concentrations of Cl^- and SO_4^{2-} relative to HCO_3^- , where the high salt contributions can contribute to the acidification in pits and enhanced conductivity of the water (Cruse and Pomeroy, 1974; Ferguson et al., 1996). Recently, it has been shown that sulfate is not necessary to form pits in copper tubing at high pH and low alkalinity (Lytle and Schock, 2008).

With lead-containing materials, increases in chloride and sulfate have been implicated in several cases of increased lead contamination, relating to changes in coagulant from alum to ferric chloride (Edwards and Triantafyllidou, 2007; Triantafyllidou et al., 2007; Stone et al., 2008).

Based on iron corrosion rate measurements in a large number of midwestern waters, Larson and Skold (1957, 1975) suggested that the ratio, sometimes called the *Larson ratio* (LR),

$$\text{LR} = \frac{[\text{Cl}^-] + 2[\text{SO}_4^{2-}]}{[\text{HCO}_3^-]} \quad (20-25)$$

should ideally be less than approximately 0.2 to 0.3 when expressed using concentrations as mol/L. Originally, the ratio was simply chloride over bicarbonate, but the originators felt that sulfate ion would be similarly aggressive. Other researchers suggest a higher target for the ratio, with values up to 1 as the maximum recommended value (van den Hoven and van Eekern, 1988). Some engineers and researchers express the ratio as the inverse, bicarbonate to chloride plus sulfate. In that case, the ratio should be larger than 3 to 5. Larson's ratio is also logical considering the results of other research in which the chloride ion was noted for its role in breaking down passivating films on many ferrous metals and alloys and is one of the main causes of pitting of stainless steels (Singley et al., 1985). Research in France, principally by LeRoy (1996), reported that some fundamental chemistry mechanisms support the concept of Larson's ratio.

There were limitations to Larson's original research, which did not allow the determination to be made if there were individual trends amongst the examined waters that might be directly caused by differences in pH, hardness, or alkalinity. By doing controlled laboratory investigations, LeRoy (1996) has shown that at constant pH and bicarbonate concentration, necessary because ferrous iron forms ion pairs with bicarbonate ion, the oxidation of ferrous iron is enhanced in the order $\text{Cl}^- > \text{SO}_4^{2-} > \text{NO}_3^-$. This order parallels the strength of the different aqueous complexes with free ferrous ion. The mechanism was proposed that

bicarbonate plays a role in mitigating the corrosion reaction, because calcium bicarbonate ion pairs (CaHCO_3^+) fix free oxygen radicals formed during the iron oxidation reaction. Calcium carbonate may then deposit at the high-pH cathodic sites, whereas various ferrous or ferric iron solids may form at anodic sites. This model is consistent with the frequently reported anecdotal observations that the corrosion of iron is less significant in harder and relatively well-buffered waters.

Copper

The presence of dissolved copper can cause rapid corrosion of galvanized steel and iron pipe. Free copper may occur in recirculating water systems, such as the hot-water systems commonly found in industry facilities, hotels, and apartments that have consecutive sections of copper and galvanized steel pipes in the loops. This free copper adsorbs or reacts with the galvanized steel piping, setting up small galvanic cells, which produce rapid pitting failure of the galvanized steel piping. Similar corrosion has occurred in unprotected galvanized steel pipes in consumers' homes as a result of the addition of even trace amounts of copper, either from copper sulfate as an algacide in distribution reservoirs, from flexible copper tubing connectors to hot-water heaters, or from mixed copper and galvanized plumbing in the same water line (Fox et al., 1986; Trussell and Wagner, 1996; MWH, 2005).

Disinfectant Residual

Secondary disinfectants can affect corrosivity, metal release, or both, either by their impact on the *oxidation-reduction potential* (ORP) of the bulk water, corrosion potential of the surface of the metal, or direct reaction mechanisms. The latter has been infrequently studied. The choice and amount of secondary disinfectant can play the dominant role in bulk water ORP and must be considered when determining metal release potential and treatment change impacts. For example, James et al. (2004) compared five common chemical oxidants at pH 7 and DIC of 10 mg/L and noted considerably different impacts on ORP (Fig. 20-13). Chlorine dioxide caused the greatest increase in ORP at low doses, followed by free chlorine. All oxidants tend to have diminishing effects as concentrations rise above several mg/L, presumably due in great part to the intrinsic redox buffering ability of water.

Knowing how system ORP has been impacted historically by oxidative treatments provides one of the most critical keys to determining if there are any likely adverse impacts and metal release episodes that would result from disinfection-related or other treatment changes. ORP also dramatically affects manganese speciation and solubility (Garrels and Christ, 1965; Stumm and Morgan, 1996; Langmuir, 1997), which can govern the formation and persistence of surface coatings on pipes that promote particulate release and can reduce the effectiveness of corrosion inhibitors (Fig. 20-14). In this example, three common manganese oxides were considered, along with manganese(II) carbonate (rhodochrosite). Assumptions for the calculations are given in the caption. A reference box is shown for the approximate ORP and pH ranges commonly found in drinking waters.

Gaseous chlorine can lower the pH of the water by reacting with the water to form hypochlorous acid, hydrogen ion, and chloride ion (particularly as the aqueous chlorine species decomposes). In poorly buffered waters, chlorine can increase corrosivity through a reduction in pH and, in general, by increasing corrosion rates and ORP, though there are notable exceptions to the latter. Conversely, the addition of chlorine as sodium hypochlorite, a base, raises the pH. In waters with low alkalinity or carbonate content, the tendency of chlorine addition to affect pH is greater because such waters have limited buffering at typical finished water pH values. Chlorine residual interactions with iron, copper, and lead are complex and are described in the section, Corrosion of Specific Materials.

FIGURE 20-13 Effect on ORP of different dosages of strong oxidants into a water at 5 mg C/L DIC, 23°C, pH 8. MCA = monochloramine. (Source: James et al., 2004.)

FIGURE 20-14 Potential-pH relationships for several manganese minerals at 25°C, $I = 0$, DIC = 18 mg C/L, and Mn species activities = 0.1 mg/L, Pyrolusite = $Mn^{IV}O_2(s)$; Manganite = $Mn^{III}O(OH)(s)$; Hausmannite = $Mn^{2+}Mn_2^{3+}O_4(s)$; and Rhodochrosite = $MnCO_3(s)$. Box shows approximate typical ORP-pH range for municipal drinking waters in the United States.

Whether chloramines and accompanying residual free ammonia mechanistically increase or modify corrosivity of most metals, has not been frequently studied in the detail that it deserves. Several investigations have shown differences in corrosion or metal release behavior by some metals, particularly lead and copper, when chloramine is the secondary disinfectant (James M. Montgomery Consulting Engineers, 1982, 1983; Edwards and Dudi, 2004; Eisnor and Gagnon, 2004; Edwards and Triantafyllidou, 2007). The effect could be direct or indirect, and mechanisms need considerable further study.

Dissolved Oxygen

Oxygen is often the agent that accepts the electrons given up by the corroding metal, allowing corrosion reactions to continue. For example, oxygen reacts with any ferrous iron ions and converts them to ferric iron. Ferrous iron ions, Fe^{2+} , are much more soluble in water than ferric iron, which readily forms a gelatinous orange ferric hydroxide floc when dissolved ferrous iron encounters oxygen or chlorine. Ferric iron accumulates at the point of corrosion, forming a tubercle, or settles out at some point in the pipe and interferes with flow. Similarly, oxygen reacts with metallic copper to form cuprous ions (Cu^+) or cupric ions (Cu^{2+}), depending on the amount of oxygen present (Pourbaix, 1966; Werner et al., 1994; Schock et al., 1995; Ferguson et al., 1996). Cuprous hydroxide and oxide solids are much less soluble than cupric forms over nearly all of the pH range covered by drinking waters.

When oxygen is present in water, red water may occur if soluble ferrous iron is exposed to a sudden high oxygen concentration either in the distribution system or at the tap (AwwaRF, 2002). However, it must be borne in mind that municipal drinking water systems in the United States typically maintain (or attempt to) a secondary disinfectant residual. Hence, dissolved oxygen is usually a minor factor in corrosion, metal speciation, and metal release. Reiber (1989), for example, showed the relative importance of chlorine relative to oxygen in the case of copper corrosion.

High dissolved oxygen levels may actually provide corrosion benefits in some circumstances, by facilitating the production of different and more protective mineral oxide and hydroxide solid corrosion products than in environments with limited oxygen availability. The many subtleties of the interactions of oxygen with pipe surfaces, and the effects on the physical properties and mineralogy of scales, still needs substantial research. On the basis of current knowledge, dissolved oxygen from advanced oxidation processes would not be expected to cause corrosion problems in distribution systems that have historically practiced chemical disinfection.

Hardness and Calcium Carbonate Scaling

Hardness can play many different roles that can sometimes reduce corrosivity toward many plumbing materials but, conversely, can create secondary constraints on optimizing treatment by forming unwanted calcium carbonate scales in various parts of the water transmission system (e.g., pipes, valves, meters) and in consumer or industrial facilities and processes (e.g., boilers, heat exchangers, hot water tanks, etc.). Cloudy and turbid water can also result from detrimental interactions with other treatment process residuals, causing sediment buildup in the distribution system.

Hardness is caused predominantly by the presence of calcium and magnesium ions, and is most frequently expressed as the equivalent quantity of CaCO_3 . Hard waters are generally less corrosive than soft waters toward unlined iron pipe if sufficient calcium ions and alkalinity are present at the given pH to participate in the development of calcareous scales, such as a mixed iron-calcium carbonate deposits (Stumm, 1956; Sontheimer et al., 1981; Singley et al., 1985;

Trussell, 1985). High levels of calcium also help stabilize calcium silicate phases in cement-mortar linings and A-C pipes and promote the formation of calcium carbonate to block the release of free lime (calcium hydroxide) (LeRoy, 1996). In spite of common beliefs, significant calcium carbonate films only rarely form on lead, galvanized, or copper cold-water pipes, so they are not primarily the causes of corrosion inhibition in these cases. Exceptions are sometimes found in systems that practice lime or lime-soda softening and put supersaturated (with CaCO_3) water into the distribution system, and an indirect beneficial mechanism to reduce copper corrosion has also been proposed (Elfström Broo et al., 1997).

Early research by Stumm (1956, 1960), as well as Larson (1957, 1971, 1975) and many others, showed good associations of deposition of calcium-containing carbonate scales with smooth inner pipe walls, and freedom from tuberculation in unlined iron pipe. Calcium may also assist in the heterogeneous corrosion buffering reactions at the pipe surface (Watkins and Davies, 1987; Dexter and Lin, 1992; MWH, 2005), and by coordinating with polyphosphate functional groups, it may somewhat mitigate otherwise aggressive properties toward lead, copper, and cement materials.

The prediction of the threshold for calcium carbonate formation is important for several reasons. First, it can create a constraint on the ability to adjust pH, by forming a detrimental deposit. Second, for some materials such as cement linings, it is a consideration for adjusting water chemistry to arrest deterioration. Third, it can be used to monitor the consistency of treatment processes such as lime softening or neutralization with limestone or dolomitic materials.

The Langelier saturation index (Langelier, 1936) is the most widely used and misused index in the water treatment and distribution field. The index is based on the effect of pH on the equilibrium solubility of CaCO_3 . The pH at which a water is saturated with CaCO_3 is known as the pH of saturation, or pH_s . At pH_s , a CaCO_3 scale should be neither deposited nor dissolved. The LSI is defined by the following equation:

$$\text{LSI} = \text{pH} - \text{pH}_s \quad (20-26)$$

The results of the equation are interpreted as follows:

LSI > 0. Water is supersaturated and tends to precipitate a scale layer of CaCO_3 .

LSI = 0. Water is saturated (in equilibrium) with CaCO_3 ; a scale layer of CaCO_3 is neither precipitated nor dissolved.

LSI < 0. Water is undersaturated, tends to dissolve solid CaCO_3 .

In 1994, recognition that the LSI was being frequently misused as a corrosion index and that inappropriate treatment approaches were being adopted and used in different parts of the United States, the USEPA repealed the section of the 1980 amendment to the National Interim Primary Drinking Water Regulation that required all community water supply systems to determine either the LSI or an even more approximate version, the aggressiveness index (AI), and report these values to the state regulatory agencies (USEPA, 1980, 1994). Although the LSI tends to predict if $\text{CaCO}_3(\text{s})$ will precipitate or dissolve, it does not predict how much $\text{CaCO}_3(\text{s})$ will precipitate or whether its structure will provide resistance to corrosion (Larson, 1975).

Even when a calcium carbonate saturation or precipitation index is of value for the prediction of scaling phenomena, many computational issues have been noted, depending on how the particular index is derived and needs to be solved (Rossum and Merrill, 1983; Schock, 1999a). Additionally, there are critical chemistry issues with the computations and attempts to interpret and apply the resulting index value to precipitation and scaling (Schock, 1984; Snoeyink and Kuch, 1985; Snoeyink and Wagner, 1996).

1. Corrections in the computations are often not made for complexation and ion pairing of Ca^{2+} and HCO_3^- , although this is possible if needed analytical data are available and

if the algorithms are set up in the computation scheme. This problem is most severe in hard waters and ones containing high sulfate or DIC concentrations (or both).

2. In the presence of polyphosphates, the essential equations defining pH_s are invalid. The LSI (and related) equations will *always overestimate* calcium carbonate saturation unless correction factors are added to account for complexation and poisoning of crystal growth. Little information exists that is useful to quantify such effects for different water chemistries.
3. Crystal growth poisoning and increases in the solubility of calcium carbonate polymorphs and solid solutions (such as high magnesian calcites) are commonly caused by high concentrations of sulfate, orthophosphate, magnesium, NOM, and some trace metals (zinc has been widely associated with this phenomenon). This phenomenon *essentially invalidates* the numbers obtained for LSI and related indexes.
4. In the past, the crystalline form of $\text{CaCO}_3(\text{s})$ has usually been assumed to be calcite. The presence of a more soluble form of $\text{CaCO}_3(\text{s})$, aragonite, has also been observed in drinking water plumbing deposits.
5. CaCO_3 can also be deposited from water with a negative LSI if there is localized high pH, generated by cathodic reactions at the pipe wall. This is most commonly observed in poorly buffered, low-DIC waters. Inconsistent deposition can lead to spotty surface coverage and can aggravate localized corrosion attack.
6. Maintaining a positive LSI has occasionally led to excessive deposition of $\text{CaCO}_3(\text{s})$, near the point of chemical adjustment, in valves and meters and other locations prone to pressure drops or other physical clogging conditions, and to significant decreases in the capacity of distribution systems to carry water.

Although the LSI is thermodynamically related to the driving force for the amount and rate of deposition (Trussell et al., 1977), sometimes evaluating the theoretical approximate mass of calcium carbonate that could precipitate on a pipe surface is more useful. This quantity is called the *calcium carbonate precipitation potential* (CCPP). Procedures have been given in several sources for these calculations (Loewenthal and Marais, 1976; Merrill et al., 1978; Rossum and Merrill, 1983; MWH, 2005), and it is most conveniently calculated by a variety of computer programs or spreadsheet-based applications (APHA, AWWA, and WEF, 1995; Schott, 1998; RTW, 2008). Geochemical-modeling computer codes capable of mass-transfer and reaction path modeling are also excellent tools for this kind of computation (Parkhurst et al., 1980; Schecher and McAvoy, 1998; Appelo and Postma, 1999; Bethke and Yeakel, 2007).

The relative state of saturation with respect to calcium carbonate has also been determined empirically by physical means for many years, through the use of what is commonly called the *marble test*. Though often considered crude and obsolete, this physical testing approach is often advantageous. When there are complex forming ligands in the water, such as polyphosphates, or there are other water constituents (such as phosphates, sulfate, magnesium, NOM, and certain trace metals) that tend to alter or inhibit the nucleation, crystal growth, rate of precipitation, solubility, or crystal structure of calcium carbonate that could form, the numerical methods are largely inapplicable. Thus, the empirical test is the only accurate indicator of scaling potential. Several papers have described various methodologies for this marble test (Hoover, 1938; Dye, 1964; Balzer, 1980; Notheis et al., 1995). This test simply looks at the change in pH, alkalinity, or both, when a test water is equilibrated with some calcium carbonate powder for a number of hours. A water that does not change is apparently at equilibrium with calcium carbonate, and is considered to be *stable*. Notheis (1995) has described a recent case in which the marble test enabled diagnosis and solution of a corrosion problem that was not apparent from the numerical indices. This kind of test

is particularly useful for water systems applying small amounts of polyphosphate to inhibit postprecipitation of calcium carbonate, to ensure the lowest dosage necessary to solve the problem and not aggravate lead or copper release.

A more elaborate electrochemical approach to determine the calcium carbonate saturation state has been used by chemical limnologists and oceanographers for many years. This device is called a *carbonate saturometer*, and it operates on a similar principle to the marble test (Weyl, 1961; Ben-Yaakov and Kaplan, 1971; Ingle et al., 1973; Plath et al., 1980; Köningsberger and Gamsjäger, 1990). The instrument is a modification of a pH meter, with a glass cell reaction system setup so that the pH change when calcium carbonate is introduced generates a potential difference from a reference cell at equilibrium with the water. This potential difference can then be mathematically related directly to the amount of over or undersaturation of the water. The satometry approach could have considerable merits if applied to drinking water treatment in several areas. Conceivably, the satometer could be designed with minerals other than calcium carbonate, and the status of a water relative to the formation of passivating films on metallic pipe could be directly estimated.

Hydrogen Sulfide (H₂S)

Hydrogen sulfide accelerates corrosion by reacting with metal ions to form nonprotective insoluble sulfides (Singley et al., 1985; AWWA, 1986). It attacks iron, steel, copper, and galvanized piping to form *black water*, even when oxygen is absent. Attack by H₂S is often complex, and the results may be evident immediately or they may not become apparent for months and then suddenly become severe. Hydrogen sulfide has been found to promote a particularly devastating kind of pitting in copper piping (Jacobs and Edwards, 1997). Hydrogen sulfide also has been implicated in the attack on A-C pipe in some waters, possibly through microbial reactions (LeRoy et al., 1996).

Magnesium

Magnesium, and possibly some other trace metals (such as zinc), are known to inhibit the formation of the calcite form of CaCO₃. Instead of calcite, the aragonite form or some magnesium calcites may be deposited, which are more soluble. With these conditions, most calcium carbonate precipitation or saturation indices will give erroneous predictions. Whether these CaCO₃ forms make any difference in protection against corrosion is not known.

Metallic Precipitates

Soluble iron, zinc, and to some extent, manganese can play a role in reducing the corrosion rates of A-C pipe (LeRoy et al., 1996). Through a reaction that is not yet fully understood, these metallic compounds may combine with the pipe's cement matrix to form a protective coating on the surface of the pipe. Waters that contain natural amounts of iron have been shown to reduce the rate of A-C pipe corrosion and bind asbestos fibers to the surface. When zinc is added to water in the form of zinc chloride or zinc phosphate, protection from corrosion has been demonstrated by the formation of a hard surface coating of basic zinc carbonate or a zinc silicate.

Aluminum may be widespread as a component of films on distribution system piping that can act as diffusion barriers to reduce corrosion or metal release. Many U.S. water systems have aluminum residuals leaving the treatment plants at over 0.05 mg/L. Because soluble aluminum can take a long time in distribution systems to reach equilibrium with a

precipitated Al solid and is highly dependent on the total Al concentration, pH, competing ligands, such as NOM and phosphates, and water temperature, it is likely that many U.S. drinking waters treated with alum are supersaturated with aluminum (MWH, 2005).

Even though it has not been systematically studied, several investigations have found aluminum films to significantly reduce lead leaching (Lauer and Lohman, 1994; AwwaRF, 1998; Atassi et al., 2004; Tesfai et al., 2006) and to adversely affect the hydraulic efficiency of distribution mains through depositions of solids (Kriewall et al., 1996; Snoeyink et al., 2003; Schock et al., 2008a). Aluminum was found on copper pipes even at low influent concentrations (Schock et al., 1995), suggesting also that it can be widespread. Aluminum residual and pipe coatings can consume inhibitor chemical and exacerbate the release of particulate-bound Pb from the scales (Kvech, 2001; Cantor, 2006, 2009; Cantor et al., 2006). In natural aquatic systems and groundwater, aluminum readily combines to form aluminosilicate minerals of low solubility, also suggesting that they may be common in distribution systems. Destabilization of aluminum films has been found to aggravate lead levels in the water in one system in Wales (Fuge and Perkins, 1991; Fuge et al., 1992).

Two examples of these foreign deposits on lead service lines are shown in Figs. 20-15 and 20-16, though similar deposits have been observed to form on iron, asbestos-cement,

FIGURE 20-15 Lead service line specimen coated with complex material mainly consisting of aluminum, iron, and manganese mixed with phosphate, causing problems with erratic lead release and ineffectiveness of orthophosphate treatment. (USEPA photo.)

and various types of plastic pipes. Manganese and iron coatings occur often on lead and other types of pipes and can be responsible for greatly prolonging the time it takes to build passivating films on the pipes with corrosion inhibitors, and they tend to also increase the risk of sporadic spikes of lead from particulate release. Manganese buildups throughout water distribution mains and storage are likely far more common than have been reported. Legacy deposits from decades of suboptimal manganese removal, amounting to literally tons of material in a typical distribution system, can cause discoloration from physical dislodgement (roadwork, main repairs, and flow changes) or changes in water chemistry (Fig. 20-17). Even with treatment to meet a 0.1- or 0.05-mg/L target, manganese solids can still accumulate in all types of piping, including PVC (Cerrato et al., 2006).

FIGURE 20-16 Lead service line with mainly manganese oxyhydroxide coating on top of normal lead carbonate, resulting in erratic lead release and prolonging the time necessary for passivation and conversion to hydrocerussite in the lead scale. (USEPA Photo.)

FIGURE 20-17 Effluent from a pigging operation showing slurry of accumulated manganese deposits causing hydraulic impairment and black water episodes.

Beyond just the presence of hydraulically or physically detrimental aspects of the surficial coatings, it has now been demonstrated by many researchers (and references cited by them) that radionuclides, trace elements, and rare earth elements can all accumulate within or on top of the corrosion and scale deposits (Valentine and Stearns, 1994; Reiber and Dostal, 2000; Lytle et al., 2004a; Schock, 2005; Copeland et al., 2007; Morris and Lytle,

2007; Schock et al., 2008a; Friedman et al., 2009). Therefore, water discoloration episodes are likely to be accompanied by the release of some quantity of these accumulated contaminants and should not be considered a purely *aesthetic* annoyance. Even of more concern, such contaminants could be released invisibly into clear, drinkable water, depending on the particular chemistry changes.

Natural Color and Organic Matter

The presence of natural organic matter (NOM), manifested sometimes as color, may affect corrosion in several ways (see Chap. 3 for coverage of the chemistry of NOM). Some natural organics may react with the metal surface and provide a protective film and reduce corrosion, especially over a long period of time (Campbell, 1971). Others have been shown to react with the corrosion products to increase corrosion, such as with lead (Korshin et al., 1996, 1999, 2000, 2005). NOM is regarded as one of the major challenges to plumbosolvency control using orthophosphate in the United Kingdom (Colling et al., 1987; Hayes et al., 2008). Organics may complex calcium ions and keep them from forming a protective CaCO_3 coating. In some cases, the organics may become food for organisms growing in the distribution system or at pipe surfaces. This can increase the corrosion rate in instances when those organisms attack the surface, as discussed in the section on biological characteristics. Which of these instances will occur for any specific water has been impossible to determine, so using natural color and organic matter as corrosion-control methods are not recommended (Singley et al., 1984; AWWA, 1986).

Orthophosphate

Orthophosphate usually forms insoluble passivating films on the pipe, reacting with the metal of the pipe itself (particularly with lead, iron, and galvanized steel) in restricted pH and dosage ranges. Orthophosphate formulations that contain zinc can decrease the rate of dezincification of brass (Oliphant and Schock, 1996), and can deposit a protective zinc coating (probably basic zinc carbonate or zinc silicate) on the surface of cement or A-C pipe, given the proper chemical conditions (Schock and Buelow, 1981; LeRoy et al., 1996). Available reports have not led to a consensus, but the zinc formation may be advantageous by providing cathodic inhibition in some situations with iron, galvanized, or steel pipe, particularly if a fresh surface is exposed to the water. Research has generally shown that zinc is unnecessary in the formulation for the control of lead from pipes (Schock and Buelow, 1981; LeRoy et al., 1996; Lytle and Schock, 1996; Lytle et al., 1996). Detailed well-controlled experiments have not been published so far that are definitive with respect to the desirability of zinc to mitigate lead release from leaded brasses or soldered joints. Specific effects of orthophosphate on the control of lead, copper, and iron corrosion are covered in the section Corrosion of Specific Materials. Orthophosphate dosing using blended phosphates raises the complication of the specific chemical form and complexation or sequestration ability of the polyphosphate component. Therefore, although most studies show some benefit to higher ratios of orthophosphate to polyphosphate, it is not always a benefit if the polyphosphate component is a strong complexing agent and stable against reversion. The background water chemistry, particularly iron, calcium, and magnesium concentrations, also plays a major role in blended phosphate effectiveness.

pH

pH is a measure of the activity of hydrogen ions, H^+ , present in water. In most potable waters, the activity of the hydrogen ion is nearly equal to its molar concentration. Because H^+ is one of the major substances that accept the electrons given up by a metal when it

corrodes, pH is an important factor to measure. The pH also affects greatly the formation or solubility of protective films for both metallic and cementitious materials. The effects of pH on different pipe materials are covered in the section *Corrosion of Specific Materials*.

Polyphosphates

Polyphosphates have been frequently used to successfully control tuberculation and restore hydraulic efficiency to transmission mains. Polyphosphates can sometimes cause the type of corrosion to change from pitting or concentration cell corrosion to a more uniform type, which causes fewer leaks and aesthetic complaints. Pipe walls are usually thick enough that some increase in dissolution rate is not of practical significance. A major role for polyphosphates is the sequestration and mitigation of discolored water from source water manganese and iron, as well as reducing some scaling from hard or lime-softened water. The impacts of polyphosphates on different pipe materials are covered in the section *Corrosion of Specific Materials*.

Silicate

Silicates can form protective films that reduce or inhibit corrosion by providing a barrier between the water and the pipe wall. Research has not clearly established the equivalence of natural silicate species to manufactured ones for the express purpose of corrosion control and metal release mitigation, because there are possibly polymeric forms of silicate that exist in commercial products that impart a greater reactivity toward surface deposits, facilitating passivation. Some applications of silicate used in combination with chlorination to sequester iron in groundwater while providing corrosion control have been reviewed (Schock et al., 2005b). Silicates often do not perform well in pilot-testing or coupon-testing situations for one or both of two reasons: one, because such tests are often performed with fresh metallic surfaces and fail to properly simulate the environments on an existing corroded distribution system, building and residential piping systems; and two, because the passivating film forming reactions tend to be slow relative to carbonates, phosphates, and oxides. Some insight into this issue can be gleaned from research on the observed interference of naturally occurring silica on arsenic removal using ferric-iron-based media. Logically, silicate dosages for corrosion control must exceed natural background levels to be effective.

Total Dissolved Solids (TDS)

A high *total dissolved solids* (TDS) concentration is usually associated with high concentrations of ions that increase the conductivity of the water. This increased conductivity in turn increases the water's ability to complete the electrochemical circuit and conduct a corrosive current. The dissolved solids may also affect the formation of protective films, depending on their particular nature. If sulfate and chloride are major anionic contributors to high TDS, it is likely to show increased corrosivity toward iron-based materials. If the high TDS is mainly composed of bicarbonate and hardness ions, the water may tend to be non-corrosive toward iron and cementitious materials, but highly corrosive toward copper.

CORROSION OF SPECIFIC MATERIALS

Cast and Ductile Iron (unlined)

Iron-based metals, including cast iron, steel, ductile iron, and galvanized and cement-lined iron, are common pipe materials used to distribute drinking water from the water treatment plant to the consumer's tap. Corrosion of iron materials in drinking water distribution systems can negatively impact water quality and hydrodynamics and jeopardize structural pipe integrity. The majority of distribution piping installed in the United States from the late 1800s through the late 1960s, was one form of cast and then ductile iron, and they are still the predominant materials (MWH, 2005). Iron corrosion is generally non-uniform in nature, and is characterized by localized pitting corrosion and thick tuberculated growth of corrosion deposits and scale, which can grow to 50 mm (2 in.) or more in thickness. Severe pitting and tuberculation can lead to significant energy loss through water-flow restrictions, intrusion from breaches in the pipe wall, and eventual pipe failure. Iron corrosion by-products are often layered in structure and consist of reduced, oxidized, and a mixture of these iron phases. The reduced forms can exert a significant oxidant demand, and all forms have a strong affinity to adsorb organic matter, trace metals, arsenic, radionuclides, and a variety of ions. The nature of the deposits makes them a suitable living environment for microorganisms, and they support biofilms by shielding the microorganisms from disinfectants, such as free chlorine, and providing a carbon nutrient source through sorbed organic carbon or mineral carbonate.

Iron release from distribution system sources can lead to red water as a result of two mechanisms: physical action and dissolution of iron scales. Physical action refers to the dislodgement of material from the pipe wall or scale by shearing action, and it is typically associated with hydraulic changes (e.g., changes in flow rate or direction). Dissolution of iron scales can result from chemical processes such as reduction, complexation, and protonation. Certain bacteria having the capability to reduce ferric iron can also induce dissolution. *Iron release* is a term often used to describe the transport of iron, either soluble or particulate, from a corroded iron drinking water pipe wall or scale to the bulk water. Iron corrosion differs from iron release in that corrosion refers to the specific process where electrons are transferred from the iron metal to an electron acceptor such as oxygen.

Iron Corrosion. Innumerable books and papers have described details of reactions and pathways of the oxidation, corrosion, and release of iron drinking water distribution system materials. Although strong oxidants such as free chlorine are present in drinking water at significant concentrations, they are generally not considered as the primary cathodic reactant in iron corrosion cells. Because strong oxidants react rapidly with the thick iron deposits that contain oxidizable materials (e.g., microorganisms and organic matter) and reduced iron phases, they probably do not penetrate the scale too far beyond the scale-water interface. Oxygen is less reactive and has a greater oxidation capacity; therefore, it is able to penetrate farther into the scale.

Oxygenation kinetics are affected by many factors including (1) anions in water that can complex ferric (Weiss, 1935) or ferrous iron (Schenk and Weber, 1968; Tamura et al., 1976a; Sung and Morgan, 1980; Millero, 1985, 1989, 1990a, 1990b; Millero et al., 1987a and b; King, 1998), (2) temperature (Faust and Aly, 1983), (3) ionic strength (Faust and Aly, 1983), and (4) the presence of a variety of Fe(III) [hydr]oxides acting as catalysts (Tamura et al., 1976a and b; 1980; Tamura, 2008). Tests have shown that the corrosion rate of steel is increased by free chlorine concentrations greater than 0.4 mg/L (SINGLEY et al., 1984; AWWA, 1986). Lytle et al. (2004b) has demonstrated the improvement in iron particle behavior and scale solid characteristics when substantial dissolved oxygen is present.

The *siderite model* has been widely cited as a model for the corrosion and release of iron in drinking water systems, which has often been at least qualitatively successful (Sontheimer et al., 1981; Benjamin et al., 1996). The model is based on the premise that protective scales of ferrous solids such as FeCO_3 or *green rust* (intermediate corrosion deposits between ferrous and ferric hydroxides, typically containing anions such as sulfate and chloride) are critical in protecting iron pipe surfaces from corrosion attack and iron release. The model presumes that the primary mode of iron corrosion is by the cathodic reduction of oxygen, which is controlled by diffusion and reactions between the diffusing scales. The rate of iron corrosion appeared to be dependent on the buffer capacity, as highly buffered waters tended to form more protective scales that contained a relatively large fraction of ferrous iron (presumed to be siderite) relative to scales formed in poorly buffered waters. The dependence is described by two factors: (1) the reduction of oxygen at the cathode produces OH^- , increasing pH at the pipe wall and (2) the rate of oxidation of Fe(II) to Fe(III) increasing dramatically with increasing pH. Therefore, when the buffer intensity is high, hydroxide ions formed at the cathode can be neutralized by HCO_3^- , the pH at the wall does not change much, and the rate of oxidation of Fe(II) is slowed. This allows the formation of siderite or green rust and, consequently a more protective scale. The model also postulated that any material that interferes with the oxidation of Fe(II), such as certain organic materials, can enhance the formation of protective scales.

Kuch (1983) observed that under non-flowing conditions, oxygen was lost and high concentrations of ferrous iron emerged in the overlying water. He hypothesized that the alternative oxidant was the ferric outer layer (FeOOH , for example) of corrosion scales, and this produced the conditions wherein both the anodic and cathodic reactions produced Fe^{2+} . Depending on pH, either the released ferrous iron would precipitate as one of several potential ferrous minerals or the dissolved form would diffuse, out into the water. The resumption of water flow would bring fresh oxidant into contact with the dissolved ferrous iron, forming relatively insoluble ferric iron.

Some revisions of the *siderite model* have been proposed, to better explain the variables behind iron release into the water (Beckett et al., 1998; Sarin et al., 1999, 2000, 2001, 2004a-c).

Discolored Water and Turbidity. Discolored drinking water often results from the presence of colloidal iron (generally defined as having a diameter $< 1 \mu\text{m}$), and particulate ($> 1 \mu\text{m}$) iron is commonly referred to as *yellow* or *red water*, although the color has been reported to range from light yellow to dark red, brown, or black, depending on the water chemistry. Suspended iron in the drinking water distribution system can originate from distribution system materials as well as the source water. Relatively soluble Fe(II) is the dominant oxidation state of iron in reducing environments (e.g., many groundwaters, anaerobic reservoirs, dead ends in distribution networks, and regions within pipe scale). On exposure to oxygen and/or disinfectant during water treatment and distribution, Fe(II) is oxidized to the relatively insoluble Fe(III) oxidation state, which is responsible for discolored water. Iron released from distribution system pipe corrosion scale, accumulated deposits, or sediments, is generated through some combination of physical, chemical, and microbiological pathways.

Given that iron corrosion provides sources of ferrous iron in the scales and distribution system sediments, several investigations have systematically isolated the various influences of water chemistry variables on the chemical and physical properties, aggregation, and transport of the resulting iron particles. Critical factors include the type and amount of oxidant (Eisnor and Gagnon, 2004; Lytle et al., 2004b), background pH, alkalinity, and major ions (Lytle and Snoeyink, 2003a and b; Lytle et al., 2003), and presence of different phosphates (Lytle and Snoeyink, 2002; Lytle et al., 2003). Silicates are also known to affect the formation and chemical properties of iron particulates in natural systems.

Several Awwa Research Foundation (now Water Research Foundation) projects have looked at various aspects of control of water quality from iron pipes (Singley et al., 1985; Benjamin et al., 1996; Snoeyink and Wagner, 1996; Kirmeyer et al., 1999; Clement et al., 2002). Source water iron can be removed by cation exchange, oxidation using air/oxygen, chlorine, or potassium permanganate followed by sedimentation and filtration. Combinations of oxidation and filtration are incorporated into many available packaged removal systems.

Prevention of conditions that favor the formation of discolored water is the best solution, and this may involve both chemical water treatment and a vigorous flushing program to remove sediments and loose materials. The flushing program should be in place before any significant water treatment change to minimize adverse impacts. Aesthetic impacts of discoloration can often be mitigated by sequestration.

Iron Release Models

Some of the best descriptions of the process of iron corrosion and release in water come from work conducted in the early to mid-twentieth century (Shingley et al., 1925; Baylis, 1926a and b, 1953; Smith and McEnaney, 1979; Tuovinen et al., 1980). It was recognized then, as it is today, that corrosion of iron is typically non-uniform and is characterized as pitting and tuberculation (see section Physical Factors Affecting Corrosion and Metals Release).

Recently, the structure and chemical nature of iron corrosion scales has been studied extensively using a variety of surface and solids analysis techniques (Sarin et al., 1999, 2001, 2004a). The results have shown that iron corrosion scales are complex and typically consist of layers of ferrous, ferric, and mixed (ferrous and ferric) oxides and oxy-hydroxides. An inner layer (closest to the pipe wall) consists of relatively porous ferric oxy-hydroxide (goethite). Ferrous corrosion scales such as $\text{Fe}(\text{OH})_2$ and FeCO_3 are also thought to be present; however, they are difficult to identify since they are sensitive to oxygen introduced during handling and analysis. The inner layer serves as a large source of soluble Fe^{2+} . The porous layer is covered by a dense *shell-like* layer consisting of relatively insoluble ferric phases such as $\alpha\text{-FeOOH}$ and $\beta\text{-FeOOH}$, and mixed oxides such as Fe_3O_4 . Inside the tubercles, iron sulfide minerals, sulfur, microbe-rich layers, calcium carbonate, and other unique minerals, all of which could play some role in iron release, have been reported to be present in various microenvironments (Tuovinen et al., 1980; Singley et al., 1985; Benjamin et al., 1996; Lytle et al., 2005a). Some research investigations have uncovered an unusual morphology to the formation of ferrotubes or chimneys resulting from a complex suite of inorganic and conceivably microbial reactions with iron that would be plausible in a distribution system piping environment (Smith and McEnaney, 1979; Stone and Goldstein, 2004). Some extracted unlined iron pipes display features similar to those described, as noted in Fig. 20-18, though the specific relationships among water chemistry parameters and tuberculation morphology are not understood.

Iron Corrosion Control Strategies

Carbonate, pH, and Buffering. Unlike the cases with lead and copper, calcium hardness appears to play an important role in reducing iron corrosion. The role of calcium as a corrosion inhibitor has been investigated by a number of researchers. The importance of CaCO_3 in undersaturated oxygenated waters for the formation of dense protective iron scales has been studied internationally for a long time (Tillmans et al., 1927, 1929; Stumm, 1956; Larson and Skold, 1957; Shams El Din, 1986; Sander et al., 1996). More resistant passive CaCO_3 layers were easier to form in alkaline conditions.

FIGURE 20-18 Close up of tubercles on an unlined cast iron pipe from a northeastern U.S. water system, showing actual chimney structures as described by Smith and McEnaney (1979) and Stone and Goldstein (2004). (Photo by M. DeSantis, Pegasus Technical Services.)

Pisigan and Singley (1987) examined the influence of buffer capacity, chlorine residual, and flow rate on the corrosion rate and pitting index of mild steel at water utilities in the state of Florida. In addition, total dissolved solids, Ca^{2+} , Mg^{2+} , Na^+ , Cl^- , SO_4^{2-} , alkalinity, and pH were monitored. They found that an increase in buffer capacity at a constant alkalinity of 100 mg/L as CaCO_3 over a pH range of 6.0 to 9.0 decreased the corrosion rate of mild steel. However, when the pH was increased by increasing the alkalinity, the corrosion rate was not lowered. This effect was attributed to the increased ionic strength and conductivity contributed by the additional alkalinity. If a water contains an appreciable amount of calcium, it may also act in conjunction with the pH and bicarbonate concentration to buffer the pH rise from corrosion reactions by the instantaneous formation of calcium carbonate solid, forming a heterogeneous buffer. Benjamin et al. (1996) also summarized additional research on buffering impacts.

Orthophosphate Inhibitors. Relatively little information has been reported on the use of orthophosphate for iron corrosion control and red water reduction in drinking water distribution systems. Orthophosphate has been suggested to reduce the corrosion rate of steel and iron release rate (AwwaRF-TZW, 1996). One report found that the corrosion rate of mild steel and scale accumulation was reduced by 2/3 following the addition of 5 mg/L orthophosphate whereas 1 mg/L had no effect (AwwaRF, 1990). The formation and precipitation of sparingly-soluble metal phosphate salts such as calcium phosphate phases may form protective diffusion barriers (Nancollas, 1983). Various experimental approaches have shown that the main component of films formed on iron and steel in phosphate solutions was vivianite, $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$ (Melendres et al., 1989; Smart et al., 1990). The pitting of carbon steel by chloride was reported to be reduced by phosphate addition (Ergun and Turan, 1991).

Polyphosphates. Polyphosphates consist of linear chains of PO_4^{3-} held together by a $-\text{P}-\text{O}-\text{P}-$ linkage (Van Wazer and Callis, 1958; Boffardi, 1993). Chained polyphosphate compounds can be described by the general formula $\text{M}_{n+2}\text{P}_n\text{O}_{3n+1}$, where M is a metal such as Na and the average chain length is defined by the $\text{Na}_2\text{O}:\text{P}_2\text{O}_5$ ratio.

The effectiveness of polyphosphates for corrosion control of iron and steel, as well as other metals including lead and zinc, has been reported to be dependent on the presence of divalent cations, such as calcium and zinc (Hatch and Rice, 1940, 1945a; Boffardi and Sherbondy, 1991; Rangel et al., 1992; Kowata and Takahashi, 1996), DO concentration (Uhlig et al., 1955), and flow or turbulence (Hatch and Rice, 1945a; Boffardi, 1993). Several interpretations of mechanisms have been developed to describe the inhibitory action of polyphosphates. In most cases, the theories were based on relatively extreme experimental conditions (e.g., high polyphosphate concentrations and temperature) applicable to industrial applications rather than drinking water conditions. Further, differentiation is not always made between the control of corrosion symptoms (e.g., red water or reduction in tuberculation) versus actual decreases in the speed and amount of iron corrosion and pipe degradation.

A sufficient amount of calcium has been suggested for good iron corrosion control, even with polyphosphate applications (Hatch, 1952). The ratio of calcium to polyphosphate is the most critical factor, with a weight ratio of 1:5 calcium:sodium polyphosphate ($\text{Na}_2\text{O}:\text{P}_2\text{O}_5 = 1.1:1$) recommended. Adequate water flow is necessary to transport the colloidal material to the metal surface. In the case of old deposits, polyphosphates may adsorb to metal salts or oxides. If applied too rapidly, they can destabilize loose deposits of iron oxide or calcium carbonate, resulting in red water complaints, while tightly held tubercles and corrosion products are not likely affected. Polyphosphates are most protective over a pH range of 5 to 7 (Hatch and Rice, 1945a and b; Lamb and Eliassen, 1954).

Koudelka (1982) employed X-ray photoelectron spectroscopy (XPS) analysis of scale on iron surfaces along with anodic polarization analysis to conclude that an iron oxyhydroxide and iron orthophosphate (ferric or ferrous), rather than an iron polyphosphate compound, provides corrosion inhibition. Under aggressive conditions, polyphosphate was believed to inhibit film growth, but may provide some protection when soluble ferrous or ferric polyphosphate complex ions near the anode revert and lead to the precipitation of iron orthophosphate. Calcium orthophosphate was thought to enhance the reversion of polyphosphate to orthophosphate. Positively-charged colloidal calcium-polyphosphate particles are attracted to the cathode where reversion and subsequent precipitation of calcium orthophosphate takes place.

Blended Phosphates. Blended phosphates are mixtures of orthophosphate and polyphosphates. The polyphosphate to orthophosphate ratio is likely to be important since sequestration and passivation needs must be met. It has also been reported that ortho- and polyphosphate blends containing small amounts of orthophosphate actually increase corrosion rates (Benjamin et al., 1996). Currently there is no simple guidance or formula for the selection of a product for a given case, as product and dosage choices still are largely based on experience, as well as trial and error.

Silicates. Water-soluble sodium silicates are defined by the ratio of SiO_2 to Na_2O . Viscosity and molecular weight increase with increasing ratio (Iler, 1979). N-type sodium silicate refers to a 3.22 $\text{SiO}_2:\text{Na}_2\text{O}$, contains 28.7 percent SiO_2 . This is the form most commonly applied for lead and copper corrosion control and has been effective at controlling red water problems. The role of silicate for iron, lead, and copper corrosion control is uncertain, although some have suggested that a thin silicate coating is formed that acts as a protective diffusion barrier (Stericker, 1945); there is not a strong body of scientific evidence to support this claim. Since sodium silicates are basic, they do increase the pH, which is generally beneficial with regard to reducing iron release and lead and copper solubility. Regardless of the exact mechanism of corrosion inhibition provided by silicates, several studies had documented improvements in lead, copper, and iron release (LaRosa-Thompson et al., 1997). Silicate species are known to sorb readily onto ferric oxides, and therefore, there will likely be long-term transformations of weak and soluble ferric oxyhydroxides in

the scales into stronger and more adherent iron silicates. Unfortunately, while the anecdotal evidence from most utilities using high dosages of sodium silicate is that there is a consistent improvement in color and turbidity of the water, studies have not been done to examine the mineralogy of the transformation over time and attempt to evaluate quantitatively benefits of silicate dosing for iron corrosion and water quality.

Anion Effects. Both corrosion rates and iron uptake (into the water from the pipe) have been determined to be increased sharply as the concentration of chloride or sulfate is increased in solution (Larson and Skold, 1957; Larson, 1975; Singley et al., 1985; Benjamin et al., 1996; Lytle et al., 2003, 2005b). Research concerning the Larson ratio suggests that the molar ratio of chloride plus sulfate to bicarbonate should be below approximately 0.2 to 0.3 to prevent enhanced corrosion of unlined iron.

Iron Sequestration

A symptom-based alternative to source water iron removal and actual iron corrosion control involves the addition of a sequestering chemical such as sodium silicate or polyphosphate chemicals, which prevent the visible precipitation of iron. The term *sequester* (or *chelate*) technically refers to chemical complexation, although it is most often used in the water supply industry to describe any mechanism that prevents visible precipitation.

Polyphosphate chemicals have been suggested to sequester iron through complexation of Fe(II) and Fe(III), inhibition of Fe(III) oxidation rate, and dispersion of iron oxyhydroxides. Polyphosphates complex many metals and, therefore, are used as sequestering agents to prevent iron and manganese precipitation in the distribution system and calcium deposition in filters. The strength of the complex is dependent on the water chemistry and the polyphosphate compound. Polyphosphates are also strong colloidal dispersants, which makes them effective for reducing metal precipitation and floc growth.

The use of polyphosphates for sequestration of source water iron has been practiced with success. Polyphosphates should be added prior to chlorination (Henry, 1950; Illig, 1960, 1987; Klueh and Robinson, 1988). The results of Klueh and Robinson (1988) suggested that nearly all of the sequestered iron was in the colloidal or polymeric form. They found that calcium inhibited treatment effectiveness. Without calcium, polyphosphate at a dose of 1 mg PO₄/L was able to sequester 2 mg Fe/L. When 100 mg Ca²⁺ as CaCO₃/L was present, a 2.5 to 5 mg PO₄/L was necessary. Harwood (1989) reported that the Fe(III) capacity of four polyphosphates was 2.66 ± 0.41 mg Fe/mg P, while orthophosphate had a capacity of 0.2 mg Fe/mg P. The capacity of orthophosphate to sequester Fe(II) was only 0.31 ± 0.04 mg Fe/mg P. As a negative secondary effect, polyphosphates have been shown to directly increase the solubility of metals such as lead, which raises concerns about their use (Holm and Smothers, 1990; Holm and Schock, 1991a and b; Cantor et al., 2000).

Silicates have also been used to successfully sequester iron for decades (Dart and Foley, 1970, 1972; Griffith, 1972; Robinson et al., 1987; Armstrong and Zhou, 1988; Schock et al., 2005b). The work of several researchers supports the conclusion that silicates control red water by a colloidal dispersion mechanism rather than a silica-iron complexation mechanism (Hazel, 1945; Henry, 1950; Robinson et al., 1981, 1987). In practice, sodium silicate is added at the same time or shortly after the point of oxidant (typically chlorine) addition when used to control iron precipitation from groundwater to avoid significant precipitation or increase in turbidity. After iron oxidation, silica adsorbs to and disperses the colloids. Robinson et al. (1987) found that 2 mg Fe/L was stabilized by a silicate dosage of 12 mg SiO₂/L for 10 days. Calcium, however, was reported to negatively impact the ability of silicate to disperse iron colloids. They found that 10 mg/L of calcium caused iron precipitation to occur in only 3 days, and iron precipitated after less than 1 day when 100 mg/L of

calcium was present. Although sequestration can be effective at reducing the water color associated with suspended iron particles, removal of iron from the source water is the only way to truly eliminate the particles.

Copper

Uniform Corrosion. The performance of copper in potable water systems depends on whether relatively thin and adherent films of corrosion products, cuprous oxide (cuprite, Cu_2O), cupric oxide (tenorite, CuO), or basic copper carbonate (malachite, $\text{Cu}_2(\text{OH})_2\text{CO}_3$), can be formed. Copper tends to be less prone to the effects of concentration cell or differential aeration corrosion than galvanized steel, steel, and iron pipes. The influence of copper ion concentration on the potential of copper in solution is marked. When solution velocities vary over a copper surface, the parts washed by the solution with the higher rate of movement become anodes and not cathodes, as would be the case with iron (Butler and Ison, 1966). Impingement attack of copper by high water velocities is one of the most common problems of copper pipe. High DIC concentration aggravates impingement attack, and it may manifest itself at velocities and turbulent flow areas that otherwise would not seem to be prone to damage under conventional design specifications for building and household plumbing systems.

In the most ideal case, uniform corrosion of copper is believed to be inhibited by the formation of a *duplex film*, characterized by a thin compact adherent Cu_2O (cuprite) semiconductor layer attached to the copper metal (MWH, 2005). On top of that layer is a more porous, usually CuO (tenorite) or $\text{Cu}_2\text{CO}_3(\text{OH})_2$ (malachite), depending on water chemistry conditions. When the cuprite underlayer is not able to form uniformly, both non-uniform corrosion and high copper release episodes can result.

Normally, the rate of uniform corrosion of copper in potable water systems is not rapid enough to cause failure of the tubing. However, consumer complaints of *blue water*, *green water*, and staining can result. When such copper dissolution is sufficient to cause complaints, frequently a fine dispersion of copper corrosion products discolors the water. When inspected, the inside surface of the copper tube under such circumstances is characterized by a loosely adhering powdery scale and beneath it, or in areas where no scale is present, by general dissolution of corrosion of the copper (Ferguson et al., 1996; Reiber et al., 1997). Related to green/blue water is green/blue staining, as even a few parts per million of copper in water can react with soap scum and cause green staining of plumbing fixtures. Several cases of blue water have resulted from what is apparently a dislodging of a slime created by microorganisms (Reiber et al., 1997).

The most important chemical variables in general uniform copper corrosion and copper release are pH, DIC, redox potential (ORP), and plumbing age. The ORP is important mostly in defining the conditions in which the oxidizing potential (pE , E_h) is high enough to form cupric ions. At lower redox potentials, either copper is immune to corrosion or highly insoluble cuprous oxide or hydroxide solids form that produce extremely low copper levels in the water (Schock et al., 1995; Ferguson et al., 1996). Many untreated groundwaters of neutral pH and high DIC fall into this category.

The corrosion rate and release rate of copper into the water are sensitive to the level of oxidizing agents in the system, especially free chlorine (Atlas and Zajicek, 1982; Pisigan and Singley, 1987; Schock et al., 1994, 1995; Werner et al., 1994; Ferguson et al., 1996; Lytle and Schock, 2000). Even low levels (such as 0.2 mg/L) affect the oxidation and corrosion rate. Reiber (1989) has shown that the chlorine effect is much more important than dissolved oxygen in normal drinking water situations. Several studies have been made of the influence of oxygen on the oxidation rate of Cu^+ to Cu^{2+} in natural and seawater, which is of some applicability to drinking water situations (Millero et al., 1987a; Millero, 1989, 1990a and b; Eary and Schramke, 1990). In the presence of oxidants, copper levels in

standing water in plumbing systems can increase for as many as 48 to 72 hours, so overnight standing samples do not necessarily represent building systems or nearly worst-case scenarios (Schock et al., 1995). Conversely, when oxidants are depleted, copper levels may decrease (Werner et al., 1994; Schock et al., 1995; Ferguson et al., 1996). When oxidative processes are introduced, such as for iron or manganese removal, or disinfection is initiated after low-ORP conditions, high corrosion of copper can result.

Recent research has shown that copper levels in disinfected or oxic drinking water are controlled for many years by the formation of metastable solids, apparently cupric hydroxide or cupric oxide of high surface area and solubility, which ages to either the basic cupric carbonate mineral $\text{Cu}_2(\text{OH})_2\text{CO}_3$ (malachite) or a more ordered CuO (tenorite), depending on pH (Schock et al., 1994, 1995, 2000; Hidmi and Edwards, 1999; Edwards et al., 2000; Lagos et al., 2001; Turek et al., 2006; Schock and Sandvig, 2009). The formation rate of malachite, which would lead to low copper levels in many waters of moderate DIC, appears to be slow, and in high DIC waters, rapid carbonate complexation disrupts the uniform formation of the desired uniform cuprous oxide protective underlayer. Thus, dissolved copper release for most of the sites targeted for regulatory monitoring and for newer sites is best described by looking at control by cupric hydroxide or cupric oxide solids of high surface area and small particle size. High concentrations of bicarbonate and carbonate ions at neutral to alkaline pH values enhance significantly the release of copper through aqueous complexation (e.g., CuHCO_3^+ , CuCO_3^0 , $\text{Cu}(\text{CO}_3)_2^{2-}$) (Schock et al., 1994, 1995; Ferguson et al., 1996; Edwards et al., 2000; Schock and Sandvig, 2009). Electrochemical analyses and copper release experiments of Edwards et al. (1994) also indicate bicarbonate is highly aggressive toward copper, especially below pH 8.5 (Edwards et al., 1994a).

Figure 20-19a shows the strong effect of both carbonate complexation and pH on copper solubility for relatively new plumbing systems. Thus, hard, high alkalinity (DIC) groundwaters that are protective of iron and cement-based piping are particularly aggressive toward copper materials. This is a fact that is often not appreciated, and treating these kinds of water chemistries to reduce copper release is often difficult. Conventional pH adjustment is generally impractical or inadequate, as buffering is extreme and hardness places strong limits on the pH achievable without precipitating calcium carbonate. The neutral pH conditions of these waters generally make direct aeration impractical as a mechanism for reducing DIC (Lytle et al., 1998a). Thus, conventional lime or lime-soda softening and dosing of approximately 3 mg/L or more orthophosphate are the most feasible treatment solutions for high copper release from new plumbing. A combination of hardness and DIC

FIGURE 20-19 Solubility diagrams for Cu(II), assuming conditions for new pipe (a) with cupric hydroxide scale, or (b) assuming a malachite scale.

reduction (to approximately 25 mg C/L) using membranes or ion exchange, followed by pH adjustment, should also be effective.

Figure 20-19b shows the solubility of copper(II) after the development of an aged malachite or tenorite surface scale, such as may happen after 10 to 20 years of use. This aging phenomenon, described in detail by many studies (Schock et al., 1994, 1995, 2000; Edwards et al., 2000; Lagos et al., 2001; Schock and Sandvig, 2006, 2009; Turek et al., 2006) makes field data interpretation complicated. It further illustrates the contradictory nature of treatments needed to reduce acute copper exposure to consumers or high copper contamination into wastewater, as opposed to long-term copper passivation (Schock and Sandvig, 2009).

Soft waters, particularly those with an acidic pH and typified by low alkalinities, dissolve high levels of copper rapidly. These systems can usually be treated in a straightforward manner by any of several relatively simple approaches, such as pH adjustment or pH/DIC adjustment (if added buffering for pH stability is needed). For smaller water systems, it is extremely advantageous to use mechanically simple systems, such as aeration (Whipple, 1913; Spencer, 1996; Lytle et al., 1998a–c; Schock et al., 2002) and limestone contactors (Letterman et al., 1987, 1991; Letterman and Kathari, 1996; Spencer, 1996; Jalil et al., 2002).

Generally, cations (calcium, magnesium, sodium, and potassium) exert little or no effect on the rate of corrosion or copper release, though some researchers have suggested calcium can play a beneficial role at levels and conditions substantially below calcium carbonate saturation (Ives and Rawson, 1962b; Elfström Broo et al., 1997). Anions (chloride, sulfate, bicarbonate, orthophosphate), however, do exert considerable influence on the rate of corrosion, the levels of dissolved copper in the water, and on the nature and stability of corrosion product solids on the pipe surfaces (Reiber et al., 1988; Meyer, 1994; Rehring, 1994; Schock et al., 1995; Ferguson et al., 1996). Traditionally, chloride has been considered to be a very aggressive ion toward copper. Some research suggests that chloride modifies the nature of the surface film formation (Adeloju and Hughes, 1986) and that it may not be as aggressive in the context of uniform corrosion as previously believed (Edwards et al., 1994a; Meyer, 1994; Rehring, 1994). At $\text{pH} \geq 7$, studies by Edwards et al. (1994) indicate that chloride has beneficial long-term effects toward copper corrosion and release (Edwards et al., 1994a).

Sulfate plays a complex role in copper corrosion, sometimes producing lower copper levels at slightly alkaline to somewhat acidic pH conditions, where any of several basic cupric sulfate solids may form a passivating film. Several studies, including electrochemical analyses of different types, have produced data indicating sulfate is very aggressive toward copper, particularly for aged surfaces above pH 7 (Edwards et al., 1994a; Meyer, 1994; Rehring, 1994). At higher pH, some research has suggested that these metastable cupric sulfate solids inhibit the beneficial precipitation of cupric hydroxide and subsequent transformation to tenorite (Schock et al., 1995). Marani (1992) has summarized considerable research that has investigated the conditions favorable to the formation of basic cupric sulfate solids under water chemistry conditions appropriate for drinking waters.

The role of orthophosphate in the corrosion inhibition of copper has been a source of confusion, largely because the roles of carbonate complexation and scale aging have usually been ignored. Additionally, the role of aging of the cupric (hydr)oxide and malachite scales must be considered, when evaluating whether orthophosphate would be beneficial or detrimental (Schock and Sandvig, 2006, 2009). Under some conditions, orthophosphate has appeared to promote higher copper levels (Werner et al., 1994). Electrochemical studies by Reiber (1989) suggested that orthophosphate might provide some corrosion reduction by changing the fundamental form of the anodic reaction. Extensive laboratory and field research by the USEPA and others has led to a practical understanding of the efficacy of orthophosphate treatment for cuprosolvency control, even if some mechanistic details remain to be determined (Schock et al., 1995; Lytle and Schock, 1996, 2006; Schock and Clement, 1998; Edwards et al., 2001; Edwards and McNeill, 2002; Qiu and Dvorak, 2004; Schock and Sandvig, 2006, 2009). Although the exact stoichiometry of the solid may differ, orthophosphate effects on new plumbing can be closely modeled up to a pH of approximately 8 to 8.5 by presuming

the formation of a passivating film composed of the solid $\text{Cu}_3(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. In hard waters, formation of a calcium orthophosphate deposit on the pipes is also possible, although not clearly proven. With fresh plumbing surfaces, a thin phosphate film is formed on the surface of copper pipe, inhibiting oxidation by chlorine and oxygen and subsequent growth of normal hydroxide, oxide, or hydroxycarbonate passivating solids. These results were generally supportive of the observations of Reiber (1989) about possible interference and altering of normal anodic site reactions and the solubility models predicting lower solubility of the phosphate solids at these pH conditions. At higher pH of 8 to 9, higher copper levels were observed in the presence of the orthophosphate, consistent with the inhibition of growth of the less soluble and protective cupric oxide. These observations help explain contradictory conclusions about the effectiveness of orthophosphate in full-scale applications with different water qualities. The experimental evidence also suggests that the orthophosphate may be less effective in inhibiting copper corrosion if an oxidized carbonate, hydroxycarbonate, or oxide scale already exists on the pipe surface under many water chemistry conditions. Figure 20-20 shows trends of copper solubility with different dosages of orthophosphate at different pH values and DIC concentrations. In practice, the amount of cuprosolvency

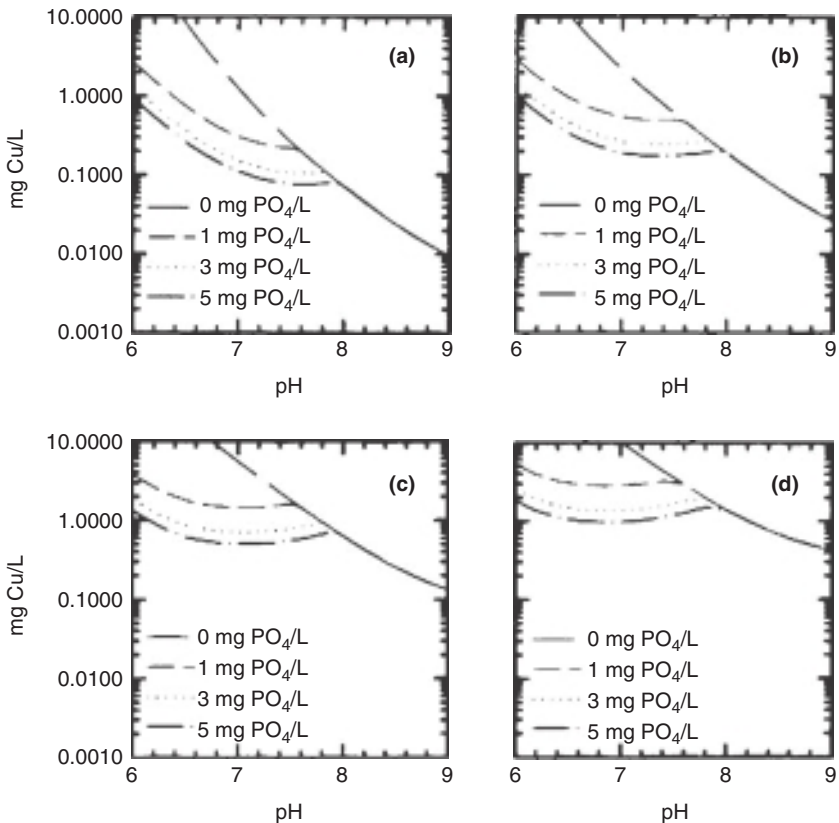

FIGURE 20-20 Effect of orthophosphate on solubility of new copper assuming equilibrium with either $\text{Cu}(\text{OH})_2$ or $\text{Cu}_3(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ at different DIC and orthophosphate concentrations. Computed for 25°C: (a) DIC = 4.8 mg C/L, $I = 0.005$; (b) DIC = 14.4 mg C/L, $I = 0.01$; (c) DIC = 48 mg C/L, $I = 0.01$; (d) DIC = 96 mg C/L, $I = 0.02$. (Source: Schock, Lytle, and Clement, U.S. EPA, EPA 600/R-95/085, Cincinnati, Ohio, 1995b.)

reduction in new plumbing is slightly less than predicted by the current solubility model, so dosages should be increased slightly over the predictions. Long- versus short-term impacts have been recently discussed (Schock and Sandvig, 2009).

For water systems with high DIC and new copper plumbing, determining the correct orthophosphate dosage to ensure compliance with the Lead and Copper Rule requirements were shown to be possible using a straightforward jar test approach (Lytle and Schock, 2006). For these waters, a generalization that has proven successful for DIC levels of 60 to 75 mg C/L is a residual of about 3 to 4 mg PO_4 /L orthophosphate. Despite the recommendation by many distributors, blended phosphates have often been unsuccessful at sufficiently reducing copper release from new plumbing to a 1.3 mg/L level for overnight standing samples in high-alkalinity groundwaters.

In the presence of oxidants, such as chlorine or dissolved oxygen, complexing ligands such as ammonia accelerate the corrosion and dissolution of copper. Excess ammonia in the presence of chloramines was found to be associated with increased copper levels in one study (AwwaRF, 1990), but the results were not conclusive and more research needs to be done. Natural organic matter has also been found to increase copper corrosion and copper release under many circumstances (Kristiansen, 1982; Rehring, 1994; Rehring and Edwards, 1994, 1995).

Dissolved silica and silicate anion have not been studied in great detail with respect to corrosion effects on copper. Several studies have shown that high dosages of silicate at pH near 8 are effective in reducing copper release, though a mechanism has not been clearly defined (Lytle et al., 1996; LaRosa-Thompson et al., 1997). In one study, malachite was replaced by an amorphous cupric silicate of low solubility (Schock et al., 2005b, 2006).

The presence of dissolved sulfide, or sulfide produced by sulfate reducing bacteria, is especially troublesome to copper (Jacobs and Edwards, 1997). Copper sulfide scales have been shown experimentally to increase copper corrosion rates by 1 to 2 orders of magnitude at pH 6.5 and 9.2 and copper release by 500 to 5000 percent, respectively. Subsequent removal of sulfide from the water by deaeration, chlorination, and superchlorination all failed to restore normal corrosion rates to the pipe containing sulfide scales. Experiments suggested that more than a year might be needed for the corrosion rate to reach levels below those observed in the presence of sulfide.

Pitting Corrosion. Pitting corrosion of copper in water has been studied by many researchers (Lucey, 1967; Kasul and Heldt, 1993; Edwards et al., 1994a and b; Duthil et al., 1996; Marshall and Edwards, 2005), which has led to a number of theories to describe copper pit initiation and growth in drinking water systems through chemical reactions. Pit initiation has also been associated in various studies with microbial activity, material imperfections, carbonaceous manufacturing residues on the pipe surface, stray currents, soldering flux, and others. Despite past research efforts and given its complexity, pitting corrosion of copper in water remains poorly understood and difficult to predict and control. Most likely, pitting has multiple causes and no single all-encompassing theory will be applicable.

Pitting attack is most common in new installations, with 80 to 90 percent of the reported failures occurring within the first 2 to 3 years (Trussell, 1985). In extreme cases, pits can break through within only a few months. Pitting occurs in all types of copper pipe and tubing. If unfavorable water quality conditions occur before the protective coat has formed, then serious pitting attack may occur. These conditions often result from leaving water stand in unoccupied housing for months, after pressure and leak-testing the plumbing systems. Incomplete flushing of flux residue and particulate debris set up conditions favorable to differential oxygenation corrosion. Disinfectant residuals are usually lost within a day or two at most, and microbial growth may occur over long periods of water stagnation. Microbes residing in sheltered areas can promote and accelerate reactions within incipient pits, and they become very hard to disinfect. Once started, pits of this type cannot usually be stopped without strong physical cleaning processes.

Localized copper corrosion in water has been categorized into at least three types of water based on chemistry and physical features: cold water (type I) (Campbell, 1950; Cruse and Pomeroy, 1974; Kasul and Heldt, 1993), hot water (type II) (Mattsson and Fredriksson, 1968), and soft water (type III) (Page et al., 1974). Soft water copper pits are described as being relatively wide and shallow and consist of an exterior layer of brochantite and/or malachite over a layer of crystalline red-brown cuprite layer and the corroding copper surface. The voluminous corrosion deposits of the exterior layer are released to the water and can potentially even cause water blockage. Waters having low conductivity, low alkalinity, and relatively high pH are typically associated with soft water pitting.

Lucey (1967) is generally credited with developing the modern framework for the structure and propagation of copper corrosion pits and proposed the *membrane cell theory* of copper pitting corrosion that identified the chemical reactions involved in this type of corrosion. The work was based on field observations, bench-scale studies, and electrochemical approaches. Lucey stated that a porous membrane of cuprous oxide (cuprite) is an essential feature of a copper corrosion pit and concluded that pitting arises as a result of a deposited cuprous chloride layer between the corroding copper and the membrane. In the model, the anodic reaction occurs between the cuprite membrane and pipe wall where copper metal is oxidized into cuprous ions. Some of cuprous ions react with oxygen to form cuprite, which precipitates between the membrane and the pipe wall. The remaining ions pass through the membrane and are further oxidized into cupric ions. Some of these cupric ions precipitate as insoluble copper salts (i.e., malachite or brochantite), and the remaining ions are cathodically reduced to the cuprous state. This cathodic reaction differs from conventional pitting theory in that the cathode's external cathodic surface is not necessary and no large-scale flow of electrons through the metal occurs. In the past decade, many researchers have continued to investigate and expand on the work of Lucey. Some have suggested modifications to his theory, and others have proposed alternative pitting theories. For example, Sosa et al. (1999) revisited the work of Lucey on cold water pitting by repeating experimental conditions using an electrochemical approach. They showed that currents carried through the bulk metal accounted for more than 80 percent of the weight loss in the pit. This observation contradicts the membrane cell theory that places the cathode above the anode in location.

Water chemistry is clearly important with respect to pitting. In addition to relatively high pH, high free chlorine, and low alkalinity (i.e., having low dissolved inorganic carbon or bicarbonate concentrations) specific to soft water attack, sulfate, and chloride are typically associated in one way or another to all forms of pitting. The relative importance of chloride versus sulfate in copper pitting corrosion is debatable. A number of studies have been conducted to evaluate the role of chloride in copper pitting corrosion (Akkaya and Ambrose, 1985; Drogowska et al., 1987; Nishikata et al., 1990). Historically chloride has been thought to be the species responsible for pitting in most theories (Lucey, 1967; Cornwell et al., 1973; Shalaby et al., 1989). Edwards et al. (1994b) concluded that sulfate and nitrate play important roles in pit initiation and development, and they believed these ions may be more critical to copper pitting than chloride. They found that chloride increased copper corrosion rates short term; however, with time, chloride actually produced protective surfaces at pH 7.6. Sulfate initially was not aggressive, but corrosion rates increased above those of chloride over time as scale formed. They noted that brochantite, $\text{Cu}_4(\text{OH})_6(\text{SO}_4)$, was always present over soft water pits and hypothesized that its formation may be the key to hot water pitting. Thermodynamic calculations showed that brochantite formation was favored over malachite and atacamite in waters having high sulfate to chloride or sulfate to bicarbonate ratios. Research by Duthil et al. (1996) also reported on the role of chloride and sulfate on the pitting of copper, based on pit germination rates using an electrochemical approach. They showed both chloride and sulfate can be responsible for copper pitting when present alone in water. When both anions are present, chloride can

have either an accelerating or inhibiting effect depending on the relative concentrations of both sulfate and chloride.

Schmitt et al. (2001) used an electrochemical noise technique to investigate the effect of chlorides, sulfates, and bicarbonate anions on copper pitting corrosion. They concluded that sulfate typically has an activating effect, chloride has a passivating effect, and bicarbonate acts as buffering agent. However, the combination of all three anions in a narrow range of concentrations leads to pitting corrosion.

Although there are a few differences in the details, many of these observations and interpretations are corroborated by Taxèn (1996), who especially observed differences in pitting when Cu(I) was involved more than Cu(II). He also found sulfate and carbonate were most aggressive toward copper, especially in the bulk solution. In contrast, Lytle and Schock (2008) presented experimental data from sulfate-free systems, showing that a combination of free chlorine, low DIC (5 mg/L), and high pH (9.0) alone were sufficient to cause pitting corrosion within several months. Modest amounts of carbonate appeared to reduce the initiation of pits, presumably through buffering against localized acidic conditions believed to be present in soft water pitting. High redox potential could be a factor in pit propagation.

A number of other works have proposed theories on how levels of chloride, sulfate, and/or alkalinity in water impact the nature of copper minerals that are often associated with localized copper corrosion and affect the protective nature of the cuprous oxide layer (Feng et al., 1996a and b; Mankowski et al., 1997). Proper identification of these solids is particularly useful in understanding pitting mechanisms and the conditions within the pit. Unfortunately, many past studies did not apply appropriate analysis approaches, and their descriptions of the nature of these solids have largely been speculative. Secondly, appropriate thermodynamic analyses and evaluations of redox sensitive relationships were rarely computed or performed, even semiquantitatively, to validate the interpretations proposed.

Marshall and Edwards (2005) investigated the role of aluminum on copper pitting corrosion in drinking water. They demonstrated that water containing aluminum, high chlorine residual, and relatively high pH caused pinhole leaks in a laboratory setting. Specifically, a chlorine residual goal of 1.5 mg/L at pH 9.2 and 2 mg/L of aluminum hydroxide solids produced conditions that caused pinhole leaks. Also the water had a low alkalinity and significant levels of chloride and sulfate, putting it in the broad category of soft water pitting corrosion. Pitting did not occur in the complete absence of aluminum in tests of a few weeks duration, but the authors observed pitting tendencies in the complete absence of aluminum if Cl_2 was maintained at high levels for an extended period of time (Rushing and Edwards, 2004; Marshall and Edwards, 2005).

Historically, thin carbonaceous films, derived from carbonization of the lubricant used in manufacture, have resulted in pitting of copper tubes, though it is not clear that this mechanism has operated for decades after changes in manufacturing processes. Films of manganese oxides, formed by slow deposition from soft moorland waters, can also cause localized attack. A review of the literature on pitting corrosion and an evaluation of reported field experience indicate that the presence of certain types of NOM apparently reduce the corrosion of copper in certain waters by promoting the formation of more protective scales, and also by reducing the tendency for pitting attack (Edwards et al., 1994b). This evaluation recommended that careful consideration be given to an increased Cu pitting incidence resulting from the removal of NOM for the purpose of controlling DBPs. Another study found similar effects of NOM. Initially, NOM promoted pitting in certain narrow water quality and NOM concentration ranges, but over long periods of time NOM reduced the tendency toward pitting at higher NOM levels (Korshin et al., 1996). Generally, the study concluded that NOM interacts with the copper through sorption, and it tends to increase the rate of copper leaching and the dispersion of the inorganic corrosion by-product scale materials.

Many instances of microbially mediated copper corrosion have been reported, though the mechanisms and differentiation from inorganic causes are not always clear (Geesey et al.,

1986, 1988; Iwaoka et al., 1986; Jolley et al., 1988; Bremer and Geesey, 1991a and b; Geesey and Bremer, 1991; Fischer et al., 1992; Arens et al., 1996; Camper, 1996; Murphy et al., 1997a-c; Reiber et al., 1997; Cantor et al., 2006; Cantor, 2009).

Brasses and Bronzes

Although many studies on factors involved in the corrosion and dissolution of brasses and bronzes have been conducted, a clear understanding of the role of water chemistry in these processes has not emerged (Schock and Neff, 1988). Even now, little has been published on normal corrosion scales which cover various brass components within a water system and which might give evidence for passivation against lead and copper release or of aggravation of metal release by galvanic reactions (Frenkel and Korshin, 1999; Korshin et al., 2000). Although lead contamination from brass has been well known for over 20 years, some recent studies implicate the brass corrosion as an important source of several other metals to tap water and wastewater metal loadings (Kimbrough, 2001, 2007, 2009).

Most studies on dezincification problems have mainly focused on materials longevity and economic implications. Several aspects of brass dezincification in water systems have been studied (Oliphant, 1978). There are also several useful reviews of important performance issues (Oliphant and Schock, 1996; Sadayappan, 2005), including investigations of the new generation of truly non-leaded brasses (Sandvig et al., 2007).

Corrosion causes the failure of mechanical devices such as valves and faucets made from brass or bronze, but it also contributes lead, copper, and zinc to the water. Metal leaching from the tap and other brass or bronze plumbing fittings can confound the interpretation of field studies for which the intent is to correlate metal levels at the tap to human exposure, corrosion rates, or the effectiveness of corrosion control treatment programs.

In the drinking water corrosion field, the contribution of brass fixtures to first draw lead levels in tap water monitoring programs is now well accepted (Lee et al., 1989; Dodrill and Edwards, 1995; Oliphant and Schock, 1996; Schock et al., 1996; Reiber et al., 1997; Kimbrough, 2001, 2007; Sandvig et al., 2008; Kimbrough, 2009). The effects of many water quality properties on lead release from brass have been reviewed, particularly, the interrelationships of lead content, pH, DIC concentration, and orthophosphate concentration (Schock and Neff, 1988; Lytle and Schock, 1996, 2000; Oliphant and Schock, 1996). Important variables in the performance of brasses and bronzes in potable waters include the pH, flow, temperature, lead content, surface area of lead and brass, alkalinity (or DIC), chloride concentration, orthophosphate concentration, and the presence of natural inhibitors. Several studies have implicated changes in chloride content or the ratio of chloride to sulfate resulting primarily from coagulant changes, as an aggravating cause of elevated lead release from brasses, particularly in the context of in-place galvanic connections (Dudi et al., 2005; Edwards and Triantafyllidou, 2007; Triantafyllidou and Edwards, 2007). Lead, zinc, and copper leaching vary greatly with the types of alloys used and the manufacturing and fabrication processes (Lytle and Schock, 1996, 2000; Oliphant and Schock, 1996; Dudi et al., 2005).

In the United States, the leaching of lead, cadmium, zinc, and other metals from brass and solders is regulated in an indirect way. The Safe Drinking Water Act (SDWA) Amendments of 1996 limit the content of Pb in solder and flux to be used in contact with drinking water to 0.2 percent (USEPA, Sec. 1417(d), 1996). Because the definition of *lead free* for pipes, well pumps, plumbing fixtures, and fittings under the original statute was a content of 8 percent or less, it was ineffective in controlling contamination from this source, as virtually all fixtures and fittings implicated in high levels of metal leaching contain much less than 8 percent Pb (Lytle and Schock, 1996; Oliphant and Schock, 1996; Kimbrough, 2001, 2007). Thus, the SDWA Amendments of 1996 incorporated a performance standard in Sec. 1417(e) requiring fixtures and fittings intended to dispense water for human consumption

to be certified under a voluntary standard established by the act (NSF/ANSI, 2007a). As of this writing, there is current research activity and marketing of several new lead-free brasses (Maas and Patch, 2004), which should help water systems develop specifications for materials that will reduce the amount of lead in contact with drinking water in the future. This activity is largely due to the reduction of leachable lead permitted under ANSI/NSF 61, including a new Annex G, which will take effect in 2012 (NSF/ANSI, 2007a and b).

Lead and Lead-Containing Solder

Regulatory requirements for the permissible lead levels in the drinking water of many countries are so low that the rate of lead corrosion is of no practical concern. Even only slightly aggressive water standing for a brief time in contact with lead pipe or lead-containing materials will pick up lead levels that are considered a public health risk; see Chap. 2 for health effects.

Particulate Lead. Lead release is a significant problem whether released as dissolved lead species, associated with particulate material like dislodged pipe deposit solids, or sorbed on other particulate matter present in the water. The relative contribution of dissolved lead to particulate matter almost certainly varies with the water chemistry, the configuration of the sampling site, and the history of the plumbing materials containing the lead. Numerous studies have investigated different aspects of the occurrence of particulate lead in drinking water (Harrison and Laxen, 1980; Sheiham and Jackson, 1981; Walker, 1983; de Mora and Harrison, 1984; Colling et al., 1987; de Mora et al., 1987; AwwaRF, 1990; Hulsmann, 1990; Breach et al., 1991; Fuge et al., 1992; AwwaRF-TZW, 1996; Reiber et al., 1997; AwwaRF, 1998; Edwards and Dudi, 2004; Cantor, 2006, 2009; Triantafyllidou et al., 2007). Aggravation of solder corrosion by galvanic stimulation has been implicated as an important contributor to elevated lead levels after disinfectant or coagulant changes (Edwards and Dudi, 2004; Edwards and Triantafyllidou, 2007; Nguyen et al., 2008; Stone et al., 2008). Comparisons among studies of the significance of lead particle release are difficult, because the analytical schemes (such as filtration) developed to differentiate dissolved from particulate lead species are very prone to both negative and positive biases. Regardless of its prevalence, when it occurs, the release of particulate lead makes achieving regulatory standard objectives for lead levels very difficult. Utilities should make every effort to minimize all types of lead release by the selected corrosion control treatment approach as much as possible.

Divalent Lead. Historically and currently in most drinking water utilities, passivation of lead usually results from the formation of a surface film composed of a Pb(II) hydroxycarbonate or orthophosphate solid. These protective minerals include $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$ (hydrocerussite), $\text{Pb}_{10}(\text{CO}_3)_6(\text{OH})_6\text{O}$ (plumbonacrite), $\text{Pb}_5(\text{PO}_4)_3(\text{OH}, \text{Cl}, \text{F})$, $\text{Pb}_9(\text{PO}_4)_6$, or some combination of these forms. The soluble oxide PbO (litharge or massicot) is sometimes a component of the lowest level of a pipe scale, or may exist as a transitory breakdown product of some other solid phase, such as $\beta\text{-PbO}_2$ (plattnerite) or hydrocerussite. Though present historically on many lead pipes and though it forms a physically adherent passivating film, the solid PbCO_3 (cerussite) is not desirable, because its equilibrium solubility is dangerously high from a health standpoint. The formation of these passivating compounds depends primarily on pH, the concentrations of DIC, and orthophosphate. These interrelationships are complicated and occasionally misunderstood (Schock, 1980, 1981, 1989; Sheiham and Jackson, 1981; Schock and Gardels, 1983; Trussell, 1985; LeRoy, 1993; LeRoy and Cordonnier, 1994; Dodrill and Edwards, 1995; Schock et al., 1996). The carbonate containing films are usually off-white, pale bluish-grey, or light brown, are usually slightly chalky when dry, and are frequently mistaken for coatings of calcium carbonate.

FIGURE 20-21 Effect of DIC on the solubility of Pb(II), $I = 0.01$, 25°C , assuming both hydrocerussite and cerussite can form.

The Pb(II) solubility diagram shown as Fig. 20-21 shows four critically important aspects of plumbosolvency behavior. First, as the DIC level is increased, the domain of lead carbonate stability is extended to a higher pH limit (approximately pH 8.5 instead of approximately pH 7) and the solubility of lead is decreased within the lead carbonate stability domain. Second, the aqueous carbonate complexes compete successfully for lead primarily at the expense of $\text{Pb}(\text{OH})_2^{\circ}$ and PbOH^+ . Third, lead solubility is enhanced in part of the region where basic lead carbonate is the controlling solid, primarily around pH 8.5, brought about by carbonate complexation. Fourth, for the pH range of approximately 7.2 to 8.2, the lead solubility is nearly independent of the DIC concentration, particularly when DIC is in the range of approximately 15 to 100 mg C/L. This clearly explains why many corrosion control field studies and many corrosion control optimization studies performed by large- and medium-sized utilities required by the Lead and Copper Rule failed to find a significant relationship between lead release and alkalinity. Low lead levels at modest to high DIC were also found to be attributable to the discovery that many of these moderate- to high-alkalinity water systems are likely protected by PbO_2 deposits, and not the Pb(II) carbonates that have been commonly assumed to be the protective solids (Schock et al., 2001, 2005a).

The divalent lead solubility model appears to be accurate in predicting plumbosolvency trends on the basis of many years of experience with carbonate passivation to meet the Lead and Copper Rule. However, it seems to be inaccurate for cases with either dissimilar material coating the pipe surface or for pHs above approximately 9.7. This is likely caused by some combination of inaccurate formation constants for key hydroxide, carbonate, or hydroxycarbonate complexes that dominate at high pH, uncertainty in hydrocerussite formation kinetics with respect to pH and DIC, and uncertainty of unusual plumbonacrite solid phase solubility (Rego and Schock, 2007).

Few systematic studies have been performed that have adequately identified or isolated the effect of various cations, such as calcium, magnesium, sodium, and zinc, on lead corrosion in potable waters (LeRoy, 1993; Schock et al., 1996). Existing data and a consideration of corrosion thermodynamics suggest that in the absence of a uniform diffusion barrier of calcium carbonate or other solids, the significance of the cations will be minor. One study indicated an increase of lead release in the presence of higher concentrations of calcium (LeRoy, 1993). It has been hypothesized that the greatest (and perhaps only) effect would be on new surfaces, where metals could function as inhibitors of cathodic site reactions (Schock and Clement, 1998), which would rarely be the case with lead piping in drinking water plumbing installations. Calcium is also a common substituting cation in the pyromorphite ($\text{Pb}_5(\text{PO}_4)_3(\text{Cl},\text{OH})$) mineral structure, and therefore, it could be incorporated into protective films in orthophosphate-treated systems.

As noted in the previous section on metallic deposits on pipe surfaces, lead leaching has been shown to be reduced by some of these kinds of surficial deposits. A mixed postprecipitate, probably composed of some combination of calcium, iron, and aluminum, was noted to cause turbidity when orthophosphate application was begun in the Washington, D.C., water system (Tesfai et al., 2006). This precipitation event coincided with rapid reduction in lead release, and therefore, is also likely to be responsible for augmenting the formation of simple Pb(II) orthophosphate solids from PbO_2 breakdown that would occur over time.

Generally, studies have also shown the effects of sulfate, chloride, and nitrate on plumbosolvency in potable waters to be negligible (Schock et al., 1996). However, these anions could have an assortment of kinetic effects on the rate of lead release, or effects on the physical structure of the scale minerals. Sudden increases in chloride levels or ratios of chloride to sulfate resulting primarily from changes in types of coagulant have been implicated in several episodes of increased lead release and failures to meet the lead Action Level in the United States (Edwards and Triantafyllidou, 2007; Triantafyllidou et al., 2007). Metz et al. (2006) showed conclusively that when the key water chemistry variables were accurately controlled, neither sodium fluoride nor fluosilicic acid added at a normal utility dosage (1 mg/L as fluoride) as either sodium fluoride or fluosilicic acid, had any adverse impact on lead levels, as predicted by lead complexation models (Urbansky and Schock, 2000a and b).

Organic acids apparently increase lead solubility, and some complexation of dissolved lead by organic ligands has been determined. In the United Kingdom, NOM is considered to be a major aggravating factor for plumbosolvency control (Colling et al., 1987; Hayes et al., 1997, 2006, 2008). Some organic materials, however, have been found to coat pipe walls and reduce corrosion. The effect of the organic material on lead release or passivating film stability may depend on the chemical and physical nature of the NOM in the particular water supply; this will make a broad generalization about the effect of various natural organic substances impossible.

Orthophosphate has been shown in field and laboratory tests to greatly reduce lead solubility through the formation of Pb(II) orthophosphate films. However, the effectiveness depends on the proper control of pH and DIC concentration, and a sufficient orthophosphate dosage and residual in the distribution system through the premise plumbing (Gregory and Jackson, 1984; Schock, 1989; Colling et al., 1992; Schock et al., 1996; Schock and Clement, 1998; Hayes et al., 2008; Cardew, 2009). The conventional wisdom of using orthophosphate versus pH adjustment to reduce plumbosolvency is summarized for a water with DIC of 5 mg/L in Fig. 20-22.

From solubility considerations alone, considerably higher dosages of orthophosphate are needed in waters with higher carbonate contents, as is illustrated in Fig. 20-23. The dosages of orthophosphate applied throughout the United Kingdom that have been convincingly shown to be highly effective for plumbosolvency control are generally 2 to 4 times the dosages commonly applied in the United States (Hayes et al., 2008; Cardew, 2009). Cardew

FIGURE 20-22 Solubility of Pb(II) with and without orthophosphate, assuming DIC = 5 mg C/L, 25°C, $I = 0.005$.

FIGURE 20-23 Computed solubility for $Pb_5(PO_4)_3OH$ (hydroxypyromorphite) at $I = 0.01$ and 25°C showing strong dependence of the solubility on both orthophosphate and carbonate concentrations. Note the distinct minimum dose thresholds for the high DIC condition, and higher dosages needed for optimal plumbosolvency reduction.

(2009) clearly points out the success of long-term application of high orthophosphate dosages to mitigate both particulate Pb release and plumbosolvency in difficult waters. The low lead levels resulting from the higher orthophosphate dosage from the Cardew (2009) and Hayes et al. (2008) studies argue that the lead release in most U.S. water systems is not truly optimized as intended by the Lead and Copper Rule.

In the United States, several water systems typically having low DIC levels, have reported difficulty with achieving good lead release control at pH over 8 using phosphate. Though the mechanism of the phenomenon is not fully understood, the phenomenon has been observed in USEPA laboratory experiments with low DIC waters and approximately 1 mg PO₄/L orthophosphate dosage (Fig. 20-24) (Schock, 1989; Schock et al., 1996, 2008b). Whether this difficult pH range remains with higher levels of carbonate or orthophosphate has not been tested.

FIGURE 20-24 Soluble and total Pb release versus pH for test systems with new pipe, DIC = 5 mg C/L, orthophosphate = 1.0 mg PO₄/L. (Source: Schock et al., 2008.)

The rate of formation of lead orthophosphate passivating films seems to be slower than the rate of carbonate or hydroxycarbonate film formation. There is field and mineralogical evidence that they undergo an aging process similar to the cupric hydroxycarbonate and oxide films. Slow conversion from the hydroxide form of pyromorphite to the chloride form, with accompanying reduction in solubility, is inferred from pipe analysis data from several water systems in the United States. Considerable time must be allowed for the reactions to take place. Some studies have shown that many months to several years are needed to reduce the rate of lead release down to essentially constant levels (Lyons et al., 1995; Cook, 1997). The speed and amount of reduction appear to be proportional to the applied dosage of orthophosphate (Wagner, 1989; Colling et al., 1992; Schock et al., 1996; Schock and Clement, 1998). No systematic and quantitative information exists on the rate of film formation on new versus used pipe.

Most polyphosphate treatment chemicals are strong complexing agents for lead and calcium, and would be expected either to directly enhance lead solubility or to interfere with the formation of calcareous films. In both theory and practice, polyphosphate chemicals have been shown to be detrimental to lead control when all the important factors have been isolated in the tests (Schock, 1989; Holm and Smothers, 1990; Holm and Schock, 1991a and b; Schock et al., 1996; Cantor et al., 2000). Some of the apparently successful applications of polyphosphate-lead corrosion control may actually be caused by pH adjustment or the reversion of a fraction of the polyphosphate to a protective orthophosphate form.

Silicate may also reduce lead solubility or release, especially at levels exceeding 10 to 20 mg SiO₂/L (Lytle et al., 1996; Schock et al., 1995b, 2006). Little is known about the nature of films formed, except that reaction rates may be slow, similar to the case of orthophosphate, and that the use of fresh surfaces (such as commonly employed in pipe loop, coupon, and similar studies) may give a false prediction of poor performance.

Research has also shown that the rate of oxidation of lead is fast and that stagnation curves for lead showing the concentration increases in pipes with time can often be modeled accurately with a diffusion-based model (Kuch and Wagner, 1983), indicating that levels tend to approach equilibrium conditions within about 8 to 12 hours (Schock and Gardels, 1983; AwwaRF, 1990; Schock et al., 1996).

A study in Portland, Oregon, observed that the use of chloramines for disinfection had the effect of decreasing the rate of lead corrosion compared to the use of free chlorine although the final pH values of the two alternatively treated waters were approximately equal (Trussell, 1985). This could be attributed to a lower redox potential in the system with combined chlorine, and lead corrosion being controlled by Pb(II) chemistry in both cases. The addition of ammonia to chlorinated water to generate chloramines, however, tended to increase the concentration of lead by-products in solution. The role of ammonia in possible complexation of metal ions and its effect on corrosion rates are poorly understood, but the effect (if any) must be greater at high pH where Pb-NH₃ complexation is favored. Several recent research studies have shown detrimental impacts of chloramines on the release of Pb(II) from pipe, brass, and soldered joints under some circumstances (Edwards and Dudi, 2004; Zhang et al., 2008a and b).

The leaching of lead from soldered joints, unlike lead pipe dissolution, has a strong galvanic corrosion component. Lead is essentially a diluent in the solder and does not appear to affect how the solder alloys with the copper pipe when the joint is made (Parent et al., 1988). Lead release from solder is somewhat variable, over time and across different sites in a distribution system of similar general age and construction. This is likely caused by differences in exposed surface areas and their locations relative to water samples being collected. Particles of solder can also be eroded or otherwise released, creating the occurrence of random spikes of high lead levels in some samples (Lytle et al., 1993). Lyon and Lenihan (1977) found that the quality of workmanship and the presence of excess flux on the pipe interior enhanced lead release. Though decreasing reduced the lead release from this source, higher levels of copper dissolution were then seen (Lyon and Lenihan, 1977). Several other researchers have investigated lead release and the electrochemistry of soldered joints (Gregory, 1990; Reiber, 1991; Singley, 1994; Dudi and Edwards, 2005; Edwards and Triantafyllidou, 2007; Nguyen et al., 2008, 2009), and mineralogical evidence has recently been presented confirming low pH conditions in the proximity of galvanic connections between lead pipe and solder, brass, or copper (DeSantis et al., 2009). Two studies of lead release from soldered joints, in particular, have attempted to assess the contribution of the different plumbing components to lead levels at the tap (Lee et al., 1989; Sandvig et al., 2008).

Oliphant (1983) did several electrochemical studies of solder corrosion and concluded that even if the exposed area of solder were small, considerable contamination would be possible for years. He suggested that lead leaching from solder is not affected by conductivity, carbonate hardness, or pyro and orthophosphate concentration (Oliphant, 1983; Oliphant and Schock, 1996). Lead leaching was increased by decreasing pH, increasing chloride, and increasing nitrate levels. Leaching rates were decreased by increasing sulfate and silicate concentrations. The effectiveness of sulfate in reducing the rate of Pb release was related to the ratio of sulfate to chloride, with a 2:1 ratio allowing the formation of good crystalline corrosion product layers. Numerous studies of municipal corrosion control treatment in the United States since the promulgation of the Lead and Copper Rule have affirmed that proper control of pH, DIC, orthophosphate, and sometimes blended phosphate levels have been able to achieve considerable reduction in lead release from soldered joints in building and domestic plumbing systems.

Tetravalent Lead. Tetravalent lead, which usually occurs in drinking water pipes as the solid polymorph β - PbO_2 (plattnerite), has been an integral feature of known potential-pH and Pourbaix diagram solubility relationships in potable waters, dating back at least to the original work of Pourbaix (1966), if not earlier. In this regard, lead parallels iron (in contrast to copper) in that the highly insoluble valence state is the most oxidized form. The well-publicized incident of the high lead release caused by conversion from free chlorine disinfection to chloramine that surfaced in 2004 was the first noted instance of this logical reductive dissolution phenomenon by many water systems and regulators (Renner, 2004; Schock and Giani, 2004), though it should not have been surprising. In laboratory corrosion experiments in 1983, Schock and Gardels (1983) observed the formation and accumulation of PbO_2 in the apparatus, away from the pipe sections, where high-ORP conditions were maintained. PbO_2 was a major scale component in an EPA field study on partial lead service line replacement that revealed surprisingly low lead concentrations in service lines in a water supply with high pH and alkalinity (Wysock et al., 1991), and its presence in several pipe scales was further documented in the 1996 edition of the AwwaRF-TZW *Internal Corrosion of Water Distribution Systems* manual (Schock et al., 1996). The low lead levels throughout most of the Cincinnati distribution system were found to be the result of almost pure PbO_2 passivating films (Schock et al., 2001).

Results of solids analysis of pipe scales from the Washington, D.C., Water and Sewer Authority distribution system confirmed the reductive dissolution pathway for the breakdown of PbO_2 (Schock et al., 2001), and many research projects have now subsequently explored various aspects of the kinetics of PbO_2 formation and breakdown (Lytle and Schock, 2005; Switzer et al., 2006; Rajasekharan et al., 2007; Lin and Valentine, 2008a and b; Liu et al., 2008; Lytle et al., 2009b). A representation of the phenomenon of reductive dissolution of PbO_2 with respect to Pb - E_h -pH relationships is shown in Fig. 20-25. The reversibility of this reaction (in the absence of phosphate) over time frames of only weeks has also been shown (Giani et al., 2005; Lytle and Schock, 2005). Tetravalent lead deposits

FIGURE 20-25 Potential-pH diagram for 0.015 mg/L Pb and 18 mg C/L showing conceptually the two major pathways by which Pb(II) can be resolubilized to high release levels from a protective low-solubility passivating PbO_2 scale.

have turned out to be relatively common, and they can be categorized generally into three modes (Schock et al., 2005a): (1) complete, relatively uniform PbO_2 scale, often much thinner than normal lead carbonate and hydroxycarbonate deposits; (2) distinctly layered scale, PbO_2 occurring as an upper water contact layer on top of typical Pb(II) carbonate or hydroxycarbonate deposit; and (3) in patches or comingled with divalent lead and other scale minerals. As of this writing, the presence of PbO_2 has been confirmed in 1/3 of the 43 water systems from which USEPA has received over 230 individual lead and lead-lined service line specimens from the United States and one Canadian province.

Persistently high concentrations of chlorine have been observed to alter divalent lead carbonate or hydroxycarbonate under drinking water conditions to form PbO_2 in a matter of weeks to months in recent USEPA field research (Fig. 20-26), which supports the hypothesis that the conversion reaction of Pb(II) (hydroxyl)carbonates to PbO_2 is faster at

FIGURE 20-26 X-ray diffraction patterns of lead pipe scale samples showing growth of $\beta\text{-PbO}_2$ (plattnerite) over time, following pH adjustment to over 9, implemented in early 2005 for a soft, low-alkalinity surface water system in the United States. (Source: USEPA.)

higher pH. This further suggests that some water systems that presume they have achieved plumbosolvency control through carbonate passivation are actually achieving it through PbO_2 formation. The implications for the impacts of future changes become radically different in these cases.

Notably, no tetravalent lead compounds other than $\alpha\text{-PbO}_2$ (scrutinyite) or plattnerite have been reported thus far in drinking water pipe scales. For water systems having large numbers of lead service lines, stable and abundant PbO_2 scales appear to be both theoretically and practically of comparable or superior effectiveness to orthophosphate dosing for the control of lead release. Ephemeral or inexplicable episodes of slightly elevated lead levels during Lead and Copper Rule (LCR) monitoring, without apparent correlation to pH fluctuations, temperature changes, alkalinity changes, DIC changes, or other major water quality changes, may actually be caused by cycles of deposition and dissolution of PbO_2 scales.

Little specific information is available that would allow solubility modeling for Pb(IV) of the type successfully applied to copper, divalent lead solubility, or iron corrosion control. Data from Pourbaix (1966) and limited thermodynamic data tabulations only hypothesize the existence of two hydroxide complexes that are only relevant at pH well above those normally encountered by drinking water systems. Carbonate, bicarbonate, chloride, sulfate, and orthophosphate complexes for Pb^{4+} have not been reported, but they would be hard to measure because of the low PbO_2 solubility and extreme ORP conditions. Mixed oxidation state oxides (Pb_3O_4 and Pb_2O_3) have been observed in some artificial conditions (Pourbaix, 1966), but are very uncommon in drinking water pipes. Existing solubility constant and Gibbs free energy of formation values (ΔG_f°) result in solubility predictions that are considerably lower than are observed in practice. This may also cause the pH/E_h stability field for PbO_2 in the diagrams to be slightly overestimated. Largely unpublished sequential sampling data from at least three water systems and bench-scale experimental data, all point to upper-bounds equilibrium plumbosolvency in the range of 0.001 to 0.01 mg/L in the pH range of 7 to 10. It is not currently possible to define a precise relationship to major water quality variables, other than the approximation with ORP. Orthophosphate has now been shown to inhibit the oxidation of Pb(II) to PbO_2 , though a threshold pH and phosphate concentration have not been established (Lytle and Schock, 2005; Lytle et al., 2009a).

There is enough occurrence information to be able to offer drinking water utilities some guidance for determining relative likelihood of PbO_2 deposits in lead service lines or pig-tails, and thus, the potential vulnerability for process or disinfection changes that would lower ORP (such as changing from free chlorine to chloramination).

- History of very low 90th percentile Pb levels in water systems having large numbers of lead pipes and a pH of below approximately 8.5, without the use of phosphate or silicate corrosion inhibitors
- Recent or historical use of high free chlorine dosages, such as 2 to 3 mg/L or more, to control biofilms or coliform or to ensure residual to the end of an old distribution system
- Systems with low distribution system chlorine demand that maintain near mg/L level free chlorine residuals, such as systems that are non-corrosive toward iron, have few unlined iron pipes, or have removed oxidant demand (including NOM) through optimized coagulation, filtration, GAC, or greensand (or similar Mn and Fe oxidative removal processes)
- Systems which have elevated pH (over 9) to optimize carbonate passivation and which concurrently notice stable free chlorine residuals that approach or exceed 1 mg/L
- Systems that supplement free chlorine with chlorine dioxide, particularly if a ClO_2 residual tends to persist into areas with lead pipes

There are several water chemistry, water treatment, and distribution system characteristics that make the formation and presence of tetravalent lead compounds (such as PbO_2)

unlikely. These include (1) absence of lead piping, (2) low or no free chlorine residual in large areas of the distribution network, (3) long-time use of monochloramine as secondary disinfectant, (4) somewhat frequent red or discolored water complaints, (5) long-term use of phosphate corrosion inhibitors, with higher phosphate residuals making PbO_2 formation progressively less likely, and (6) unchlorinated groundwater systems.

The best way to maintain the stability of tetravalent lead deposits is through optimal corrosion control and DBP precursor removal (i.e., NOM). The removal of the precursor material reduces DBP formation, reduces nutrient material (often a food source for biofilms), and thus reduces disinfectant demand translating into reduced chlorine dosage. Coupling with iron corrosion control is also important. This reduced disinfectant demand reduces needed chlorine dosage and potential for DBP formation. It also reduces microbial habitat, so less disinfectant is needed. A threshold ORP and pH must be maintained by a chlorine residual that is sufficiently high. It is hard to accurately and precisely determine those values, as there are utility-specific components to the amount of oxidant demand observed, but the trends follow those found in the E_h -pH diagrams. Additionally, complete removal of iron and manganese at the treatment plant is very desirable to reduce chlorine demand out in the distribution network.

Galvanized Steel

Galvanized steel pipe was the dominant material used to transport domestic drinking water for most of the twentieth century, only being replaced in the last several decades by copper and plastic. Galvanized plumbing is still the material choice in many developing countries (Trussell and Wagner, 1996). Galvanized pipe consists of a base steel layer, underlying a sequence of layers that are zones of iron-zinc alloy that successively approach pure zinc at the interior surface of the pipe (Trussell and Wagner, 1996). One of the complexities of this material is that once the zinc layer is corroded away, the pipe behaves as if it were black iron pipe. Therefore, the corrosion potential of the water and optimal corrosion inhibition strategies should change, depending on how much of the zinc layers are left.

Uniform corrosion, pitting, metal release, and tuberculation can all be important in galvanized pipe corrosion (Wagner, 1989; Trussell and Wagner, 1996; MWH, 2005). Mechanical failure because of uniform corrosion is rare but, when the zinc corrosion rate is high, failures are often induced by the tuberculation that follows rapid depletion of the zinc layer. When the pipe is new, the uniform corrosion depends strongly on pH. The nature of the film formed on the pipe changes in response to many chemical factors, and galvanized pipe corrosion seems to be sensitive to the type of scale produced. Some scales are voluminous, chalky, and relatively unprotective, even if the rate of metal release is not extremely high. Poor film protection can accelerate pitting or tuberculation. Field experience indicates that the effect of corrosion scales on the corrosion of galvanized pipe does not appear to be strictly proportional to zinc solubility and release. Moderate levels of DIC and high buffer intensity seem to produce good passivating films in cold water (MWH, 2005).

Studies have shown increases in the corrosion rate of zinc with increasing carbonate hardness, even in the presence of orthophosphate (Trussell and Wagner, 1996). This increase may be caused by the formation of aqueous carbonate complexes [ZnHCO_3^+ , ZnCO_3° , $\text{Zn}(\text{CO}_3)_2^-$] increasing zinc solubility (Schock and Buelow, 1981; Schock, 1985; Trussell and Wagner, 1996).

The calcium carbonate seen in deposits is often aragonite (Schock and Neff, 1982; Trussell and Wagner, 1996), and its role in galvanized pipe protection is not clear. Calcium carbonate, along with basic zinc carbonate [$\text{Zn}_5(\text{CO}_3)_2(\text{OH})_6$, hydrozincite], and forms of zinc hydroxide and zinc oxide, appear to be the most significant components of natural scale layers.

The effects of orthophosphate and silicate, and the tendency for galvanized pipe to fail through non-uniform corrosion have previously been reviewed in some detail (Trussell and Wagner, 1996; MWH, 2005). Orthophosphate effectiveness is a function of the pH, alkalinity, and the orthophosphate level in solution (Schock and Neff, 1982; Schock, 1985). Silicate has been shown to reduce galvanized pipe corrosion, but most studies have focused on hot water systems. Zinc silicate compounds are generally of low solubility; however, and theoretically should provide some protection in the slightly alkaline pH range.

Pitting failure of galvanized pipe is more common in hot than cold water systems. Pipe failures have been caused by poor pipe coating quality, the presence of dissolved copper, and the reversal of electrochemical potential of zinc and iron at high temperature (Trussell and Wagner, 1996; MWH, 2005).

There have been numerous anecdotal reports of drinking water contamination by impurities of lead and cadmium in the galvanizing layer. Usually, tap water samples have been involved, making it difficult or impossible to separate the probable contribution of brass faucets and shutoff valves.

Asbestos-Cement (A-C) Pipe, Cement-Mortar Linings, and Concrete Pipe

A-C pipes and cement-mortar linings (without seal coat or from in situ rehabilitation) behave similarly in drinking waters. The principal difference is the additional possibility of the release of asbestos fibers into the water by A-C pipe deterioration. Deterioration of cementitious materials causes substantial water quality degradation. Leaching of free lime from the cement causes considerable increase in pH of the water, especially in long lines or low flow areas and with poor to moderately buffered waters. Because the equilibrium pH for calcium hydroxide solubility is approximately 12.4 (note that calcium hydroxide is a common high-pH analytical buffer solution), there is a considerable driving force for pH increase. This pH increase, in turn, can cause reduced effectiveness of disinfectants and phosphate corrosion inhibitors, unwanted precipitation of a variety of minerals (causing cloudy or turbid water), and poor taste. In extreme cases of attack by aggressive water, the attack can result in reduced pipe strength and a roughened pipe wall that can cause increased head loss.

The cement matrix of A-C pipe is a complicated combination of compounds and phases (Schock et al., 1981; LeRoy, 1996; LeRoy et al., 1996). Several different types of cement can be used in the production of cement linings (LeRoy et al., 1996; Guo et al., 1998). The main components of the Portland cement used most frequently are tricalcium silicate, dicalcium silicate, and tricalcium aluminate, together with smaller amounts of iron and magnesium compounds. Free lime ($\text{Ca}(\text{OH})_2$) is also present, but it is limited by product standards to be less than or equal to 1.0 percent by weight in U.S. commercial type II auto-claved A-C pipe (LeRoy et al., 1996).

Groundwaters having high mineral content but low pH values, show accelerated rates of pipe leaching (LeRoy et al., 1996). In soft waters with low mineral content the mechanism of attack is believed to proceed as follows: First, the calcium hydroxide is removed, and if the water still possesses sufficient acid content, calcium carbonate is either dissolved or prevented from forming at the water-cement boundary. Because alkaline conditions cannot be maintained within the cement after the initial calcium hydroxide is removed, attack begins on the hydrated calcium silicates. These convert to calcium hydroxide, and the cycle of reactions can continue until sufficient calcium carbonate is formed to fill voids in the cement matrix and prevent lime leaching, the water is neutralized to the point at which the cycle stops, or no cementitious material remains to bind the aggregates together (LeRoy et al., 1996).

Waters with low pH (less than approximately 7.5 or 8, unless they contained high calcium, alkalinity, and silicate levels), and high sulfate concentrations are particularly destructive to A-C pipe, and probably to all concrete or cement-mortar-lined pipes. Strong

sequestering or complexing agents, such as polyphosphate chemicals, have been shown to attack the pipe by enhancing calcium, aluminum, iron, and magnesium leaching from the cement matrix (LeRoy et al., 1996). They tend to prevent the formation of protective coatings by metals such as zinc, manganese, iron, and calcium.

No simple chemical index exists that can directly predict the behavior and service life of A-C pipe. In addition to the use of CCPP or saturation indices to suggest chemistries where a porosity sealing process is unlikely to occur, Trussell and Morgan (2006) have proposed the use of the saturation index for calcium silicate (wollastonite) as providing several advantages over calcium carbonate. With A-C pipes, the primary drawback to calcium carbonate saturation treatment is that in the absence of the formation of an actual surface coating or the formation of protective coatings by naturally occurring substances such as iron and manganese, fibers are left exposed at the surface of the pipe where they are vulnerable to erosion.

Coatings containing iron have been found on many A-C pipe specimens exposed to a variety of aggressive to non-aggressive water. Iron coatings sometimes have a granular, porous structure that does not necessarily retard calcium leaching from the cement matrix. The iron frequently helps prevent the exposure of asbestos fibers at the pipe surface; however, the iron coatings may also become a habitat for the growth of biofilms or the retention of microorganisms.

Mn(IV) oxide can provide a similar protection to that provided by iron. Silica may also be beneficial as an agent that can help maintain the hardness of the pipe (Schock et al., 1981; LeRoy et al., 1996). In some cases, silicate dosing could enhance protection by the formation and adsorption of iron colloids on to the pipe surface.

Orthophosphate, sulfate, and chloride salts of zinc have been used in laboratory experiments to prevent the softening of A-C pipe specimens to slow calcium leaching (Schock and Buelow, 1981). These results should also apply to the preservation of any uncoated cementitious materials in a water supply system. Though often overlooked and misunderstood, the required dosage of zinc depends at least on the pH and DIC concentration of the system (Schock and Buelow, 1981). The utility of zinc addition for extending the potential lifetime of newly installed cement linings or A-C pipe lines or for increasing the service life of existing mains has not been established in the short field tests performed thus far, usually because of inadequacies in the maintenance of appropriate pH, alkalinity, and zinc concentrations. In the laboratory experiments, zinc, and not the anion of the compound, has been found to be the active agent (with the exception of the bicarbonate and carbonate ion role); this was also observed in a field investigation (Mah and Boatman, 1978). The reaction mechanisms to form the final long-term coating observed in tests have not been precisely delineated. The experiments suggest the hypothesis that zinc first reacts with the water to form a zinc hydroxycarbonate precipitate, which delivers zinc to the surface of the pipe (Schock et al., 1981; LeRoy et al., 1996). The zinc solid then reacts with dissolved silica released from the pipe surface to convert some or all of the coating to a harder zinc silicate solid phase. In parallel, dissolved zinc probably also will interact and sorb on the surface of the pipe to some degree.

The choice of zinc salt can be based on economics and the presence of materials benefiting from phosphate addition (e.g., unlined iron, lead, brass, copper). Considerations of wastewater discharge regulations could rule out phosphate-containing formulations. More research needs to be done to determine if the orthophosphate inhibits the calcium carbonate protection mechanism of the cement matrix or if the calcium orthophosphate solids help stabilize the cement material.

Polyphosphate use should be avoided or only done cautiously with A-C or cement-lined pipes (LeRoy et al., 1996). In an extreme case, aggressive water from a membrane desalination plant and containing polyphosphate was introduced into a water system in the Dutch Antilles with a mix of iron and cement-lined pipes. The water leached such high concentrations of aluminum unknown to the hospitals that it caused serious illnesses and several deaths of kidney dialysis patients (Berend and Trouwborst, 1999).

A potential for the leaching of metals such as barium, cadmium, and chromium from some cements has been reported (Guo et al., 1998). Care must be taken especially when cement is produced in kilns cofired with hazardous waste-derived fuel. It is not clear if there is a real problem in the United States, as manufacturing standards that will alleviate the potential for this kind of problem may be in place or developed soon.

DIRECT METHODS FOR THE ASSESSMENT OF CORROSION

Physical Inspection

Water treatment plant operators and engineering staff should be aware of the appearance of the interior of the distribution piping and how their water quality is affecting the materials in their system. Physical inspection is a useful inspection tool to a utility, and it can also be done routinely at a low cost. Both macroscopic (human eye) and microscopic observations of scale on the inside of the pipe are valuable tools for diagnosing the type and extent of corrosion, and digital photography provides a flexible and convenient means to maintain good historical documentation of pipe condition. Macroscopic studies can be used to determine the amount and type of tuberculation, postprecipitation accumulation (Fe, Mn, Al, and others), pitting, corrosion at joints, and possible crevice corrosion. A record of historical observations of pipes in different parts of a distribution system and exposed to different water treatments over time could yield insights into slow corrosion or passivation reactions.

Utility personnel should try to obtain pipe sections from the distribution or customer plumbing systems whenever possible, such as when old lines and equipment are replaced. This is important even when there are no active complaints, because the pipe scale information may be important to determine if future treatment changes that are contemplated for regulatory or other reasons would be feasible. When lines are tapped, the cookies generated can be an excellent record and history of water quality impacts on the scaling or corrosion of mains. An examination of the pipe wall can yield valuable information about the type and extent of corrosion and corrosion-product formation (such as pitting or tubercles), though it may not indicate the most probable cause. Pipe sections of small diameter may be conveniently examined by sawing them lengthwise.

Examination under a microscope can yield even more information, such as hairline cracks and local corrosion too small to be seen by the unaided eye, mineralogical layering of the scale, scale porosity, or associations of particular solid phases in the scales. Such an examination may provide additional clues to the underlying cause of corrosion by relating the type of corrosion to the metallurgical structure of the pipe.

Photographs of specimens should be taken for comparison with future visual examinations. High-magnification photographs should also be taken, if possible.

Corrosion Rate Measurements

Corrosion rate measurements are another method frequently used to identify and monitor corrosion. Corrosion rate measurements rarely correlate well with metal release into the water. The mechanisms involved in the attack on the metal are not necessarily the same reactions as those that result from the interaction of the water with a developed scale on the pipe surface. The corrosion rate of a material is commonly expressed in mils (0.001 in) penetration per year (mpy). Common methods used to measure corrosion rates include (1) *weight-loss methods* (coupon testing and loop studies) and (2) *electrochemical methods*.

Weight-loss methods measure corrosion over a period of time. Electrochemical methods measure either instantaneous corrosion rates or rates over a period of time depending on the method used.

Coupon Weight-Loss Method. Four important criteria for corrosion tests are (1) the metal sample must be representative of the metal piping, (2) the quality of the water to which the pipe sample is exposed should be the same as that transported in the plumbing system, (3) the flow velocity and stagnation times should be representative of those in the full-scale system, and (4) the duration of the test must allow for development of the pipe scales that have an important effect on corrosion rate and on the quality of the water passing through the pipes (Reiber et al., 1996).

Coupons are often employed in *planned interval tests*, which are often useful and desirable if the test duration is to be 12 months or longer. The test duration can then be modified on the basis of the results obtained (Thompson, 1970). Planned interval tests can also be used with removable pipe sections for scale examination, not just weight-loss coupon studies.

Coupon preparation, handling, and examination are relatively time consuming and exacting operations that usually require a trained laboratory analyst or corrosion specialist to provide reproducible results (Kuch et al., 1985; Reiber et al., 1988, 1996). Several ways have been developed to improve the processing of coupons for corrosion rate determination, and the statistical validity of the results (Reiber et al., 1988; USEPA, 1993). Contamination during the manufacture of the coupons has also been identified in some studies, and careful examination, cleaning and data evaluation may need to be used to overcome that problem (Lytle et al., 1992).

Electrochemical Rate Measurements. These methods are based on the electrochemical nature of corrosion of metals in water, and they have been widely discussed in the drinking water corrosion literature (Silverman, 1995; Reiber et al., 1996). The primary types of techniques try to determine corrosion rates through the measurement of the electrical resistance, linear polarization, corrosion current, or galvanic current of test specimens. Although the techniques have been used widely, often successfully, there are limitations inherent to all of them, and the user must be cautious that fundamental mathematical or chemistry assumptions behind the analytical and data analysis procedures are not violated or the results biased by the technique itself (Reiber, 1989; Vitins et al., 1994; Silverman, 1995; Reiber et al., 1996, 1997). Frequently, the experiments and studies focus only on electrochemical parameters and neglect corroboration and simultaneous acquisition of metal release and water chemistry data, to ensure that results and interpretations aren't biased or misleading when applied to their ultimate purpose. In addition to corrosion rate information, some of the techniques can yield valuable information on corrosion mechanisms, such as whether a given variable can act as an anodic site or cathodic site inhibitor and what concentrations lead to protection or adverse behavior. It is also important to realize that only sometimes do electrochemical measurement techniques correspond well to metal release to solution and metal solubility.

Pipe Rig Systems

Another method for determining water quality effects on materials in the distribution system, metal release, or both, is the use of sections of pipe (AwwaRF, 1990, 1994; AwwaRF-TZW, 1996; Eisnor and Gagnon, 2003; Cantor, 2009). The pipe sections can be used to measure the form and extent of corrosion and the effect of corrosion control methods. Pipe loop sections can be used also to determine the effects of different water qualities on a specific pipe material. The advantage is that actual pipe is used as the corrosion specimen. The loop may be made, or a rig made from long or short sections of pipe. For direct monitoring of

dissolved constituent levels or changes in background water parameters, such as chlorine residual depletion, or pH changes, longer pipe sections are required (Reiber et al., 1988; AwwaRF, 1990, 1994; AwwaRF-TZW, 1996; Cantor, 2009). Pipe rig systems can also be useful as part of an overall holistic corrosion control optimization strategy, incorporating water quality, scale development, and corrosion treatment monitoring. The effectiveness of this integrated approach has been shown for several water systems (Cantor, 2009).

Excavating and removing existing pipe invariably causes the disturbance of the deposits in the pipe. Special precautions, which have rarely been studied, may be needed to improve the probability of success and restabilization time. Such precautions may include continual contact with water until reinstallation, attachment to cushioned rigid frameworks for transport without damaging vibration, and maintenance of original shape to prevent scale cracking. Hence, a long period of stabilization (many months to years) may be necessary to reestablish equilibrium in the scales and regain consistency of metal release before introducing the test treatment changes to the designated loops. Systematic comparisons between the length of restabilization time necessary for exhumed pipes versus the development of representative characteristic scales on new pipe surfaces have not been reported. For studies involving comparisons among potential treatment changes, stabilization and comparability likely need to be determined among all loops to be used for the study. Substantial disagreement with in situ performance may be a clue that the operating mechanisms are not comparable between the experimental pipe rig conditions and actual distribution system conditions. All of the physical and chemical factors involved with exhumation of pipes and their reinstallation into pipe rig systems are not completely understood. Whereas in many water systems, consultants and researchers have successfully employed exhumed copper, unlined iron, A-C, and lead pipes with Pb(II)-based scales for experimental treatment studies, one area where there has been inadequate investigation is whether the same considerations apply to lead pipes with nearly complete PbO₂ scales on them. Anecdotal evidence from some largely unsuccessful attempts, including one published study (Wysock et al., 1991, 1995), suggests that there may be additional complications with these kinds of scales.

The question of how to make proper statistical comparisons is a difficult problem in using pipe loop data for treatment evaluation or other interpretations of water quality effects. This has been addressed in different ways in many practical studies, but some major considerations and suggested approaches have been given in some recent publications (AwwaRF, 1994; Wysock et al., 1995; Cantor, 2009).

Immersion Testing in the Laboratory

Immersion tests are sometimes useful to make an *initial* appraisal of the effectiveness of inhibitors (Kuch et al., 1985; Reiber et al., 1996), but it is only truly valid for plumbing materials that are being currently installed and have new surfaces. Immersion tests use metal coupons in batch jars of water to evaluate inhibitors, dosages, and pH control. The procedures of ASTM Standard 631-72 should be utilized for immersion tests.

Limitations of all immersion tests are that accurate representation of flow and water chemistry conditions in the field situation are sacrificed for testing simplicity and efficiency. Important parameters like pH, DIC concentration, DO, chlorine, and chloramine residuals may frequently be difficult or impossible to control, leading to incorrect results. Thus, results of immersion tests might not prove to be accurate simulations when extrapolated to practice at the treatment plant and in the whole distribution system. They should only be used as a general screening tool, and results contrary to expectations from chemistry theory or experience of utilities with similar pipe materials and water quality should be critically examined for possible experimental problems or errors.

Chemical Characterization of Deposits

Valuable information about probable corrosion causes or inhibition mechanisms can be found by chemically analyzing the corrosion by-product material on the pipes. Analytical approaches to characterization may be broadly separated into three categories: elemental/functional group characterization, optical/visual characterization, and compound-based characterization. Only several of the most common methods proven widely useful in solving practical drinking water corrosion and scaling problems are described in this section.

Scraping off a portion of the corrosion by-products, dissolving the material in acid, and qualitatively analyzing the solution for the presence of suspected metals or compounds can sometimes suffice to indicate the type or cause of corrosion. These analyses are relatively quick and inexpensive. If a utility does not have its own laboratory, samples of the pipe sections can be sent to an outside laboratory for analysis. The numerical results of these analyses cannot be quantitatively related to the amount of corrosion occurring because only a portion of the pipe is being analyzed. However, such analyses can give the utility a good overview of the type of corrosion that is taking place. Whenever possible, analytical techniques should be specified that can determine the abundance of anionic constituents (carbonate, phosphate, sulfate, chloride, silicate) as well as major metals, toxic and regulated trace metals, and other constituents (such as oxygen, silica, and others). Assumptions based on physical appearance and only data on metal composition can often be misleading (Schock and Smothers, 1989). For complex scales, especially when silicates or organic materials may be a significant component of the deposits, a laboratory should be consulted to advise on the most appropriate digestion technique and analytical methods for the deposit constituents. If samples come from distribution systems fed by water sources likely to have radionuclides based on geologic setting, those should be included in the analysis, along with radon if radium is present. Some useful guidance is given by ASTM procedures (ASTM, 2003a and c).

Comparing sampling data of scales from various locations within the distribution system can isolate sections of pipe that may be corroding. Increases in levels of metals such as iron or zinc, for instance, indicate potential corrosion occurring in sections of iron and galvanized iron pipe, respectively. The presence of cadmium, a minute contaminant in the zinc alloy used for galvanized pipe, also indicates the probable corrosion of a galvanized iron pipe. The presence of zinc, copper, lead, and nickel are often indicative of corrosion of brass plumbing devices. Corrosion of cement-lined or A-C pipe is generally accompanied by an increase in pH, aluminum, and calcium throughout the system, sometimes in conjunction with an elevated asbestos fiber count.

Elemental Spectroscopy after Decomposition. The most common analytical tools for the analysis of total recoverable metal concentrations in environmental samples are flame or graphite furnace atomic absorption spectroscopy (F/ or GF/AAS) and inductively coupled plasma-atomic emission spectrometry (ICP-AES) or mass spectrometry (ICP-MS). The ICP methods add a greater degree of selectivity and sensitivity in elemental analysis.

For total recoverable elemental content determination, solid samples must be prepared for analysis by extraction of the solid-phase metals into solution. This is accomplished through digestion or fusion. Table 20-1 is a list of a few method references for preparation procedures. It should be stressed that while all of the references below are considered acceptable methods, methods should be chosen on the basis of the target constituents and the nature of the information the data user seeks. Because different preparation methods are not necessarily equivalent, the method used must remain a consideration when evaluating data, and preparation and analytical methods should be referenced in any forum in which the data is presented.

It is imperative that digestion efficiency and analytical performance be monitored through the use of appropriate standard reference materials, which can be obtained through

TABLE 20-1 Common Standard Procedures for Accurate Analyses of Solid Materials Related to Pipe Scales and Distribution System Deposits

Method reference	Brief method description
EPA SW846 3050B	Strong hot plate, block, or microwave acid digestion. Applicable to soils, sediments, and sludges. Will recover most elements that could become environmentally available. It is not a total digestion technique. There are two versions, depending on the analysis method that will follow.
EPA SW846 3052	Microwave-assisted acid digestion. Applicable to difficult matrices (siliceous and other complex matrices). It is a total digestion technique. It is not appropriate for regulatory applications that require use of leachate preparations.
<i>Standard Methods for the Analysis of Water and Wastewater</i> , Method 3030D (E, F, G, H, and I) 21st edition	3030D is an introduction to five methods (E through I; K is not for solid samples). All five methods are variations of hot plate acid digestions, each using a different combination of acids. In addition to water; these are applicable to solid samples and liquid sludges. At the end of 3030D, four other references that may be more suitable for solid sample digestions are recommended.
USGS	Very strong hot plate acid digestion. Applicable to most rock types, soils, sediments, and ashed botanical samples. The sections describing Interferences list examples of specific minerals for which complete digestion of certain metals is not achieved.

ASTM D 4698-92	Fusion and digestion procedures are described. Both are applicable to suspended and bottom sediments of natural waters. Both recover >95% of the metals listed in each procedure.

the National Institute of Standards and Technology (Gaithersburg, MD), the U.S. Geological Survey (Denver, CO), or international organizations with equivalent programs. It is not always necessary to achieve complete digestion for all purposes, but the objective of the analytical work needs to be carefully considered and methods chosen accordingly.

X-Ray Fluorescence. For surficial deposits, *X-ray fluorescence spectrometry* (XRF) is helpful for elemental analyses (Rose, 1983; Schock and Smothers, 1989; Miller et al., 1995; ASTM, 2003c; Sandvig et al., 2008; Cantor, 2009). The sample is ground finely into a powder and is either compressed into a flat discoidal pellet under high pressure or fused with a compatible flux into a glass bead (Buhrke et al., 1998; SPEX CertiPrep Inc., 2005). X-ray fluorescence can be done quickly in comparison to wet chemical analysis (including flame or flameless atomic absorption spectrophotometry), because of the relative simplicity of sample preparation and processing. Quantitative analysis can be performed with proper sample preparation precautions, calibration techniques with corrections for matrix chemistry

and interelemental effects, and suitable mathematical processing of the raw intensity data. For most major constituents and for most metals down to the order of high ppm levels by weight, the accuracy is comparable to dissolution and analysis techniques. The drawback to XRF is that it usually requires a large amount of scale relative to the amounts typically found in lead and copper pipes.

Electron Microscopy Methods. The scanning electron microscope (SEM) has been widely applied to the evaluation of A-C pipe deterioration (Schock and Buelow, 1981; Schock et al., 1981; LeRoy et al., 1996). Studies have also attempted to directly relate the morphology of corrosion product crystals of lead carbonate, basic lead carbonate, or a lead phosphate to the protectiveness against corrosion (Colling et al., 1987, 1992; Breach et al., 1991).

On the microscale, *energy-dispersive X-ray analysis* (EDXA) is useful for elemental identification and qualitative analysis, and *wavelength-dispersive X-ray analysis* (WDXA) is also possible with some electron microscopes. WDXA is generally better for quantitative analysis and lighter elements in the scale. Theoretically, electron diffraction using a transmission electron microscope should be capable of identifying specific solid phases, analogous to X-ray diffractometry. However, the difficulty in applying the technique and isolating sufficient particles in the scale to be representative usually make it impractical for this application.

For all electron microscopic analysis methods, observing representative sections of the pipe is important because the same pipe might vary in color and texture. Often, many small areas on several sections of the same pipe must be analyzed.

Compound Analysis and Visual Techniques. The field of analysis of pipe scales and inhibitor films can make use of a variety of sophisticated instrumental analysis techniques, in addition to the traditional *wet chemical procedures* (ASTM, 2003a). Often, no single technique will provide all the answers in film identification and interpretation of corrosion and corrosion control data. Judicious use of a combination of methods, however, can give invaluable insight into the problems and solutions. A plethora of advanced instrumental analysis techniques exist, which have been or can be applied to scale analysis. For example, techniques such as secondary ion mass spectrometry (SIMS) have been applied to the elemental analysis of pipe scales in Scotland (Davidson et al., 2004). Infrared spectroscopy has been employed extensively by many investigators (Hogan and Jackson, 1981; Sheiham and Jackson, 1981; Boireau et al., 1997). A full description of the many surface and compound analysis techniques available to modern laboratories and their relative merits is beyond the scope of this section. Overviews are available of several useful scale analysis approaches and their applicability to different materials have been given by many authors (Schock and Smothers, 1989; Miller et al., 1995; Scheetz et al., 1997; Davidson et al., 2004; Rego and Schock, 2007; Borch et al., 2008; Cantor, 2009).

Mounting a pipe sample with scale in place using an epoxy resin can be employed to get a cross-sectional analysis, which can reveal detailed information, layer by layer. Sometimes this can reveal important structural features of the scale. Techniques such as WDXA, EDXA and laser-ablation ICP spectrometry can be used to do the scans or elemental maps. The major challenge to such an approach is physically obtaining a flat, contamination-free surface for analysis.

Optical and Photomicroscopy. Optical microscopic techniques have been used widely for the evaluation of A-C pipe corrosion and have been summarized and described (Schock et al., 1981; LeRoy et al., 1996). They have also been employed in the examination of particulates in drinking water (Walker, 1983) and in the examination of films on iron pipe (Singley et al., 1985; Benjamin et al., 1996). Photomicrographs have been extremely useful in examining the structure of the alloy and zinc layers on galvanized pipe (Trussell and Wagner, 1996).

X-Ray Diffraction. X-ray diffraction (XRD) is a procedure with which actual crystalline compounds can be identified in the scales, or aggregates of particulates. The fundamental principle behind the method is that when a highly collimated beam of X-rays of a particular wavelength strikes a finely ground, randomly oriented sample of material, the X-rays are diffracted in a pattern that is characteristic of the crystalline structure of the compound (Gould, 1980; Schock and Smothers, 1989; ASTM, 2003b). Mixtures of compounds give a pattern that is a sum of those compounds present. The analyzed patterns are compared to a reference library of known patterns for various solids, minerals, metals, and alloys. Particularly when used in conjunction with other analytical techniques to reduce the amount of pattern-searching necessary (by identifying the combinations of elements present or probable class of compounds—phosphates, silicates, oxides, and so forth—XRD provides a tremendous insight into pipe corrosion and corrosion inhibitor effects. For very crystalline materials, XRD can often detect down to 2 to 5 percent by weight, but it often fails to detect or identify solids that frequently occur as amorphous material, such as iron and manganese oxyhydroxides and aluminum phosphates. Microcrystallinity causes peak broadening which can hinder identification. Because XRD relies on crystallography, there are some minerals that have overlapping significant analytical peaks, making identification in mixtures of certain concentration combinations difficult (Schock et al., 2005a). An example is the misinterpretation of a combination of PbCO_3 and tetragonal PbO as appearing to be a trace to minor amount of $\beta\text{-PbO}_2$ (plattnerite). Sometimes solution chemical context is needed to accurately confirm identifications.

Figure 20-27 shows the easy differentiation between a dominantly $\beta\text{-PbO}_2$ (plattnerite) pipe scale from Newport, Rhode Island, and a dominantly $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$ (hydrocerussite) pipe scale from the Boston, Massachusetts area.

FIGURE 20-27 Comparison of powder X-ray diffraction patterns for a city with predominantly $\beta\text{-PbO}_2$ scales with a trace of $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$ (Newport, *top*) with the XRD pattern for a scale where $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$ is the dominant solid phase (Boston, *bottom*).

Several studies have reported many analyses of lead pipe by X-ray diffractometry (Elzenga and Graveland, 1981; van den Hoven, 1987; Schock and Smothers, 1989; van den Hoven and van Eekeren, 1990; Schock et al., 1996, 2001, 2005a; Lytle and Schock, 2005; Rego and Schock, 2007), and corroboration of copper solubility models and analysis of pitting phenomena by scale analyses using XRD have also been described (Schock et al., 1995; Lytle and Schock, 2008).

Synchrotron Methods (XANES, XAFS). Recently, powerful compound identification methods have been developed, that have excellent capability for valence state determination, compound determination, and even quantitative analysis. *X-ray absorption fine structure* (XAFS) refers to the interaction of how X-rays are absorbed by an atom at energies near and above the core-level binding energies of that particular atom. XAFS spectra are especially sensitive to the formal oxidation state, coordination chemistry, and the interatomic distances, coordination number, and species of the atoms in the surrounding proximity of the selected element of interest. As a result, XAFS provides a practical and simple way to determine the chemical state and local atomic structure for a selected atomic species. There is significant chemical data in the spectral region near the absorption edge, particularly the formal valence and coordination environment. The valence is identifiable by the position of the maximum edge energy by taking the derivative in this region, which is referred to as *X-ray absorption near-edge spectroscopy* (XANES). Employing a statistical spectral analysis methodology (linear combination fitting) facilitates a quantitative analysis capability with appropriate reference standards (Scheckel et al., 2005).

While environmental applications are voluminous, these analytical methods have only been infrequently applied to drinking water (Frenkel and Korshin, 1999; Schock and Giani, 2004; Schock et al., 2005a; Gerke et al., 2009). They are likely to achieve more use in the future, however, because of common ambiguities in the interpretation of X-ray diffraction, IR, and Raman spectra in pipe scales.

CORROSION CONTROL ALTERNATIVES

The complete elimination of corrosion is difficult if not impossible. Technologies generally exist to reduce or inhibit corrosion, though the determination of feasibility may depend mostly on economics or risk/aesthetic trade-offs. Corrosion depends on both the specific water quality and pipe material in a system, and a particular method may be successful in one system and not in another or even show different results in different parts of a distribution system of a single utility or water supplier. The most common ways of achieving corrosion control are to (1) properly select system materials and adequate system design, (2) modify water quality, (3) use inhibitors (may require pH or DIC adjustment as well), (4) provide cathodic protection (mainly for external corrosion), and (5) use corrosion-resistant linings, coatings, and paints.

Materials Selection

In many cases, corrosion can be reduced by properly selecting system materials and having a good engineering design (Singley et al., 1984; AWWA, 1986). When selecting materials for replacing old lines, putting new lines in service, or rehabilitating existing pipes (e.g., cement lining), the utility should select a material that will not corrode in the water it contacts. Putting a freshly cleaned cast-iron line or a freshly cleaned and cement-relined pipe back into service in a soft and poorly buffered water can cause serious water quality

problems. It also undermines the rehabilitation investment just made. To protect sizable investments in rehabilitation, the utility should always evaluate the cost on the basis of integrating distribution system corrosion control adjustments with the cleaning, relining, or replacement. A realistic assessment of the impact of the water quality and the resources available to appropriately modify treatment to protect the newly installed materials in the future is often neglected, but is a wise strategy for long-term economy.

First and foremost, the water chemistry must be examined to determine which material or materials are appropriate. For example, many high-alkalinity waters with high sulfate and neutral to slightly acidic pH is incompatible with copper pipe. Many soft waters are basically incompatible with galvanized pipe, although it provides excellent performance in many hard water situations that are problematic for copper pipe.

The drinking water utility may not have control over the selection and installation of the materials for household plumbing, but should not overlook the possibility of working to influence plumbing codes to be most compatible with the water treatment options available.

Engineering Considerations

Some of the important design considerations for plumbing systems of all sizes include (1) avoiding dead ends and stagnant areas, (2) providing adequate drainage where needed, (3) selecting an appropriate flow velocity, (4) selecting an appropriate metal thickness, (5) eliminating shielded areas, (6) reducing mechanical stresses, (7) avoiding uneven heat distribution, (8) avoiding sharp turns and elbows, (9) providing adequate insulation, (10) choosing a proper shape and geometry for the system, (11) providing easy access to the structure for periodic inspection, maintenance, and replacement of damaged parts, and (12) eliminating grounding of electrical circuits to the system (Singley et al., 1984; AWWA, 1986).

Many plumbing codes are outdated and allow undesirable situations to exist. Such codes may even create problems, such as with grounding (Bell et al., 1995a and b) and in the allowance or requirement of materials which could be readily corroded by a given water, but for which corrosion control by central water treatment could be difficult. Water utilities seeking to specify low-lead or genuinely lead-free materials for distribution system devices (pressure reducers, control valves, meters, etc.) may not be able to find them currently permitted by applicable state or local codes and industry standards.

Water systems need to be actively engaged with the responsible government agencies and plumbing code bodies to modify outdated codes, to tailor them to reduce treatment costs and protect the health of consumers, and to enforce voluntary standards in the sale and distribution of plumbing materials, such as NSF/ANSI 61, Secs. 8 and 9, as well as the enforcement of the lead solder ban. Surveys since 2001 in Pennsylvania have uncovered a rising number of occurrences of sale of prohibited lead solders (Goss, 2008), and it is widely known that plumbing inspectors rarely examine household and building plumbing devices to determine certification with passing the metal leaching requirements of NSF/ANSI 61.

On a larger scale, a poorly designed distribution system can produce areas of locally poor water quality, loss of disinfection, turbidity, taste, and odor problems. Renovation and rerouting of pipe lines may be more effective in solving water quality problems than treatment in some cases. Consolidating multiple distribution entry points can enable much better consistency and control of water quality. Many references review and discuss construction and design issues that relate to corrosion control (Singley et al., 1984; James M. Montgomery Consulting Engineers, 1985; AWWA, 1986; Medlar and Kim, 1993a and b; Schock et al., 2002; MWH, 2005).

Water Chemistry Modification

Water chemistry adjustment most commonly consists of the feeding single or combinations of solid, liquid, or gaseous chemicals to achieve desired target levels of parameters, such as pH, alkalinity, corrosion inhibitor residual, or buffer intensity, in the finished water and throughout the distribution system. Details of how to properly set-up and operate such processes are beyond the scope of this chapter.

Numerous corrosion control studies have identified mixing zones, or areas of a distribution system where water quality continually shifts, sometimes back and forth, as particularly problematic. Stable passivating films cannot form in these areas, as they are constantly being deposited and redissolved by the water quality changes. Employing any water chemistry adjustment requires a commitment to continually maintaining a consistent operation and prior investigation to ensure the absence of unintended detrimental side effects.

Two treatment approaches that have found growing successful application for the control of corrosion and metal release and that do not consist of the feeding of chemicals are *aeration* and *limestone contactors*. To be more precise, limestone contactors belong to a family of processes that can better be termed to be *neutralization*, as any of several similar natural and solid media can be used. In the United States, the concept of neutralization using filter beds consisting of or amended with limestone has been widely presented since the 1930s. Often mistakenly considered primarily a technology only for small water systems, some use of neutralization beds for acidic waters has been applied to a diverse size array of water systems (Cox, 1933; Letterman et al., 1987; Benjamin et al., 1992; Smith and Bager, 1995; Mackintosh et al., 1998; Spencer, 1998; Kettunen and Keskitalo, 2000; de Souza et al., 2002; Jalil et al., 2002; Rooklidge and Ketchum, 2002; Hammarstrom et al., 2003; Withers, 2005). An additional important application is to provide substantial pH and carbonate adjustment posttreatment for demineralizing processes, such as nanofiltration or reverse osmosis. Supplementing the product water with either orthophosphate or additional pH adjustment to ensure low corrosivity may be necessary. Nonetheless, it is an effective and relatively low-maintenance type of process that can provide a simplified consistent background that is amenable to minor chemical additions. Several good sources are readily available to the design engineer to provide computational support for sizing, final water quality, and contact time considerations (Letterman et al., 1987, 1991; Letterman, 1995; Letterman and Kathari, 1996; Jalil et al., 2002; Robinson and Carmical, 2005).

Aeration offers an excellent option for systems with low source water pH and an abundance of dissolved CO_2 in the water, though it is historically associated more with VOC or radon removal than with its usefulness for corrosion control (Lytle et al., 1998a–c). Typically, pH can be raised to the range of 7.8 to 8.2 without scaling, and DIC can be held at a level compatible with plumbosolvency and cuprosolvency control. For water systems with source water radon, it offers a particularly useful dual treatment option (Spencer, 1998; Schock et al., 2002), and the final pH achievable is automatically in a nearly ideal range for combining with orthophosphate addition. Aeration systems most commonly come in four configurations, all of which can be useful depending on the amount of CO_2 removal needed: Venturi injector systems, tray systems, packed tower systems, and diffuse bubble systems. The effectiveness of radon removal can concurrently be ensured and conveniently monitored by controlling the final pH (Spencer and Brown, 1997). In field application, particularly for smaller water systems, diffuse bubble aeration systems are relatively inexpensive to operate and more robust with respect to pH and DIC consistency than chemical feeds (Lytle et al., 1998a–c; Schock et al., 2002).

Secondary Effects of Treatment for Corrosion Control

A utility must meet a broad spectrum of regulatory and aesthetic water quality goals, aside from those associated with corrosion and corrosion by-products. Therefore, the potential

effects of different corrosion control strategies must enter into the determination of the best course to follow. There are both positive and negative effects of corrosion control with respect to other regulations (Schock, 1999b).

Adjustment of pH may affect the ability of coagulation to remove turbidity or organic matter effectively, as can the adjustment of alkalinity or the addition of phosphate. The pH will also affect the formation of disinfection by-products. Consideration must be given to the impact of changes in water quality on industrial processes, building heating and cooling systems, wastewater loadings of metals (such as copper and zinc) and nutrients (such as phosphates), and on algal or plant growth in open storage reservoirs.

Certain treatment processes cause mineral imbalances in the water that can exacerbate corrosion control, without substantial posttreatment. Examples are nanofiltration, reverse osmosis, ion exchange, ozonation, sequestration, enhanced coagulation, enhanced softening optimized for NOM removal (insufficient hardness, and insufficient DIC for buffering), and possibly oxidative processes for iron and manganese removal.

On the other hand, there are particular benefits to a holistic corrosion control approach for the entire distribution system. Good corrosion control throughout the distribution system is necessary to optimize many aspects of distribution system water quality and performance, even aspects targeted by different specific regulations (Schock, 1999b). Examples are improved (1) aesthetic characteristics, (2) longevity of infrastructure, (3) disinfection and biofilm control through reduced chlorine demand and NOM sorption, (4) DBP formation through reduced chlorine demand, and (5) reduction of noxious constituents like Cu, Fe, Zn, and Pb in wastewater and sludges.

These multiple objectives can be achieved with proper attention to the broad view of treatment optimization throughout the whole distribution system. Although not necessarily simple and inexpensive, achieving good lead and copper corrosion control can be made chemically compatible with protecting the other distribution system piping materials. Further, this can be done while also meeting both other regulatory and aesthetic water quality requirements throughout the distribution system.

Linings, Coatings, and Paints

Another technique to keep corrosive water away from the pipe wall is to line the wall with a protective coating. These linings are usually mechanically applied, either when the pipe is manufactured or in the field before it is installed. Some linings can be applied even after the pipe is in service, though this method is much more expensive. The most common pipe linings are coal-tar enamels, epoxy paint, cement mortar, and polyethylene. The use of coatings must be carefully monitored, because they can be the source of several water quality problems, such as support of microbiological growth, taste and odor, and solvent leaching, and only coatings meeting ANSI/NSF and AWWA standards should be used. Although coal-tar based products have been widely used in the past for contact with drinking water, concern exists about their use because of the presence of polynuclear aromatic hydrocarbons and other hazardous compounds in coal tar and the potential for their migration in water.

The process of cement-mortar lining is historically the most common rehabilitation approach in the United States, but it can have important detrimental water quality impacts (LeRoy et al., 1996; Water Research Foundation, 2010). Like calcium carbonate films, the cement linings are far from inert. To protect the investment in time, money, and materials, as well as to avoid water quality degradation, a utility must critically examine alternative materials and not automatically select cement. In Europe, the use of in situ epoxy and polyurethane coatings is becoming far more widespread. A recent study has compared some of the water quality impacts of different lining materials (Water Research

Foundation, 2010). For some applications, in-situ lining products have been developed, consisting of collapsed tubing that can be inserted through even small-diameter pipes, and then expanded with heat and pressure to seal the pipe interior surface against water contact.

WATER SAMPLING FOR CORROSION CONTROL

The effects of corrosion may not be evident without monitoring. The effects can be expensive, and in the case of corrosion by-products such as lead, copper, and cadmium, they can be injurious to the health of segments of the population (see Chap. 2).

The first concern for a utility is to meet regulatory sampling requirements, in terms of the number of sampling sites, the location and frequency of the samples, and the use of approved and generally accepted analytical methods. Beyond these requirements, monitoring programs may address other questions. Some recent reviews discuss several aspects of investigating and monitoring for corrosion control and system studies (AwwaRF-DVGW Forschungsstelle, 1985; Schock et al., 1988; Schock and George, 1991; AwwaRF, 1994; Wysock et al., 1995; AwwaRF-TZW, 1996; AwwaRF, 1998).

Defining the Problem

Many factors are responsible for variability in metal concentrations that can limit the accurate assessment of exposure levels, treatment performance, and regulatory compliance. The goal of a sampling program must be to control as many of the analytical, chemical, and physical factors as possible, so that proper exposure assessments and decisions on the existence of water quality problems or the performance of a treatment program can be made.

The variability represents the actual range of exposures that occur routinely in the population. A monitoring system designed to accurately reflect exposure to lead or any other metal in drinking water must simultaneously capture that diversity while providing adequately reliable information to critically evaluate exposure. A monitoring program for corrosion control effectiveness must address similar concerns, although the criteria for sample size based on the desired levels of confidence in the mean values could be different. A study done in France obtained both good exposure estimates and good correspondence of lead levels to predictions of solubility models by a program of proportional sampling at many household sites (Anjou Recherche, 1994).

Another important piece of information that would be helpful in diagnosing and solving corrosion or metal release problems is determining the extent to which release of particulate corrosion by-products contributes to the observed metal levels (Cantor, 2006).

Human exposure evaluations require sampling considerations that have been frequently overlooked in health-effects studies. The sampling and monitoring structure under the U.S. drinking water regulations were never intended to represent human exposure estimates. To guard against a worst-case scenario, sampling locations and sampling collection protocols that are likely to coincide with occurrences of elevated by-product levels in drinking water to which consumers are likely to be exposed must be established. Several studies have investigated these factors (Schock et al., 1988; Schock, 1990; AwwaRF, 1994; Wysock et al., 1995; Reiber et al., 1996; AwwaRF, 1998), and research continues in that area.

Careful thought must be given to the selection of sites within the target groups. For example, when lead is of concern, sites can be lead interior plumbing or service lines, the most recent construction before the lead solder ban, or faucet replacements when lead-containing brass is used (remembering that lead-free was defined as no more than 8 percent). Aerators should be checked for the presence of trapped particulate material.

For copper, the age of the scale plays a major role in copper solubility. Hence, the most dangerous copper exposures would be in the newest construction, not covered as targeted monitoring sites under the Lead and Copper Rule.

The nature of exposure varies depending on the configuration of the plumbing system involved (e.g., single-family dwelling, apartment building, office building, school, etc.), as well as water usage pattern, contact time of the water with the plumbing, and water chemistry. Different sampling strategies are essential, and they must be carefully oriented toward the layout of the customer's system. At this time, the best sampling program design which adequately addresses this objective is proportional sampling, reported in studies from Canada, the Netherlands, and France (Meranger and Khan, 1983; van den Hoven, 1987; Anjou Recherche, 1994). The age of the plumbing materials, fittings, and devices in which the sampled water is in contact is important information, especially for copper and brasses (see the section, Corrosion of Specific Materials).

To determine whether the contamination is from a particular part of the plumbing system (e.g., faucets, soldered joints, parts of a service line, or pig-tail connector), sequential sampling can be conducted via the collection of small sample volumes, one immediately following the other. The isolation of a specific area of plumbing in question may also be obtained by selectively wasting an appropriate volume of water to get to the water parcel in contact with the area of interest, although it creates the complication that the water contacts other materials during flow to the sampling tap (Schock and Neff, 1988; AwwaRF, 1990; Wysock et al., 1995; Edwards et al., 2004; Sandvig et al., 2008). Guidelines were developed by USEPA, which are applicable to many other corrosion problems as well, to isolate locations of contamination in building (USEPA, 1988) or school (USEPA, 1989) drinking water systems. Table 20-2

TABLE 20-2 Distance-Volume Relationships for Some Common Residential Piping, Useful for Planning, Sampling, and Diagnosing Lead Sources

Material	Type	Nominal size (in)	ID (in)	ID (mm)	mL/ft	mL/m	ft/L	m/L

[†]For old galvanized steel pipe, corrosion usually reduces the ID and volume considerably.

[‡]For plastic pipe, wall thickness can vary slightly, changing exact ID.

provides some translations of water volume to length of plumbing that is helpful in designing accurate sampling programs.

For schools, there are particularly difficult sampling issues, because of complex usage patterns and the considerable variability in age and configuration of plumbing from room to room, and often poor recording of the origin and model of the plumbing products installed. Multiple lead-containing devices may be located within one sample volume of an end-point tap, and they may have been installed over a long time period. There is essentially no such thing as a representative sampling site for most schools, necessitating sampling at virtually every location where drinking water could be obtained, to ensure adequate protection against lead contamination. Additionally, drinking water could be obtained from non-intuitive locations, such as showers or janitor closets, when large containers of drinking water are filled for activities such as sporting events.

A final aspect to water quality sampling is ensuring the complete chemical characterization of the water. Many direct and indirect reactions govern the corrosivity of the water and metal release, and the lack of complete water characterization causes several problems that are potentially more expensive than the cost of the analyses themselves. This fact has been lamented by Davis (1988) for groundwater studies, and his principles are equally applicable to drinking water problems. Background analyses of parameters that often are not covered directly in the regulations are important in defining the applicability of certain treatment processes and the selection of appropriate treatment. Because of the cost, it is tempting to wait to undertake these kinds of assessments until a specific regulation has been promulgated and a deadline set for initial monitoring. However, selection of appropriate treatment combinations for a water system requires as much information as possible about the raw water to be treated, to anticipate secondary impacts. A few hundred (or even in extreme cases, a few thousand) dollars in analytical costs at the beginning of a project are likely to pay huge dividends in terms of tens to hundreds of thousands of dollars or more saved in the long run by avoiding costly treatment choice mistakes and enabling a good integration of current and future treatments at one time. This benefit needs to be emphasized. Recommendations for analyses to be considered in corrosion and treatment evaluations are given in Table 20-3.

A corollary of obtaining sufficient analytical information for water characterization is that the data must be sufficiently accurate for the purposes. Even seemingly simple measurements, such as pH, alkalinity, and carbon dioxide concentrations are fraught with opportunities for analytical error, particularly with the training available for and instrumentation commonly employed by smaller water systems and many of their consultants. Errors of more than 0.5 pH units are common, in the experience of the authors. Poor data quality can mislead design engineers and regulators in determining and selecting the most economical and appropriate treatment scenarios for the water system. Thus, considerable emphasis should be put on determining and ensuring the quality of the data used for making expensive optimization or design decisions. If necessary, engineers should consult with aquatic chemists to help spot data that might be of dubious quality on the basis of known chemical interrelationships.

Statistical Considerations

The number of sites to be monitored for exposure evaluation or corrosion control must be related to the level of constituent or corrosion by-product variability over the proposed range of sites, and the relationship of that variability to the population mean (mean of all sites) (Schock et al., 1988; AwwaRF, 1990; Wysock et al., 1991, 1992, 1995; AwwaRF, 1994; Cantor, 2009). A good before-sampling program must be developed to obtain a baseline of data. The baseline is used to get a handle on the required number and frequency

TABLE 20-3 Recommended Analyses for a Thorough Corrosion Monitoring Program

General parameters for all investigations	
In situ measurements	pH, temperature, CO ₂ if low-pH groundwater
Dissolved gases, oxidants	Oxygen, hydrogen sulfide, [†] free chlorine residual, total chlorine residuals (if ammonia present or used)
Parameters required to calculate CaCO ₃ -based indices [‡]	Calcium, total hardness (or magnesium), alkalinity (or DIC), total dissolved solids (or conductivity) [‡]
Parameters for A-C pipe	Add to general parameters: Fiber count, iron, zinc, silica, polyphosphate, aluminum, manganese
Background parameters for metal pipe	Add to general parameters:
Iron or steel pipe	Iron, chloride, sulfate
Lead pipe or lead-based solder	Lead, copper, chloride, sulfate
Copper pipe	Copper, lead, sulfate, chloride
Galvanized-iron pipe	Zinc, iron, cadmium, lead, chloride
Brass (faucets and valves)	Zinc, copper, lead, sulfate
All metal pipes	Add to background parameters:
Corrosion inhibitor constituents (all metal pipes)	Orthophosphate, polyphosphate, [§] silica
Biofilm-related inorganics	Nitrate, nitrite, ammonia (if ammonia is present in source water or if chloramination is used)

[†]It only needs to be analyzed when suspected.

[‡]If a complete water analysis is done, TDS and conductivity can be neglected because ionic strength can be directly computed.

[§]For most potable waters; derived from analyzing total phosphate and subtracting orthophosphate.

[¶]When no inhibiting agents are present.

of sampling for the rest of the program and to enable valid comparisons to be made of water characteristics before and after changes in the system (e.g., treatment changes, design changes, source water changes). A multistage sampling design can sometimes be used to obtain information more economically (AwwaRF, 1990; Schock, 1990; Cantor, 2009).

One problem that arises is the practical issue of the proper statistical tests and the confidence levels for establishing whether two or more treatments or water chemistry conditions are showing equivalent effects on corrosion rates or metal release. Automatically using common statistical criteria, such as 90 or 95 percent confidence limits, may lead to misleading conclusions because of the nature of metal release (and possibly other corrosion test) data. A small episode of high variability or periodic episodes of widely different metal release may bias the statistical calculations of parametric or even nonparametric tests to indicate there is no difference in effect between or among test conditions (Wysock et al., 1991, 1992, 1995; AwwaRF, 1994). Simple examination of the data may show very consistently different behavior, except for the periodic excursions from what is clearly the most characteristic behavior. Therefore, purely statistical testing must be tempered with careful interpretation.

Chemical and Physical Considerations

Many important decisions are likely to be made on the basis of the sampling and chemical analyses performed by a utility or contract laboratory. Therefore, care must be taken during the sampling and analysis to obtain the best data. Handling of samples for pH, alkalinity, and CO₂ analyses often requires special precautions (Schock and Schock, 1982). Samples

should be collected without adding air and with minimal agitation, as air tends to remove CO_2 and also affects the oxygen content in the sample. To collect a sample without additional air and to minimize the exchange of volatile gases (such as CO_2 in waters that are frequently out of equilibrium with the atmosphere), fill the sample container to the top so that a convex dome is formed at the opening and no bubbles are present. If possible, the sample bottle should be filled below the surface of the water using tubing, so that the water is not contaminated by the faucet material. Cap the sample bottle as soon as possible. For general purposes, high-density linear polyethylene bottles are very suitable for metals and most other water quality constituents. For pH measurements off-site, the bottles should be glass or a material ensured to be impermeable, especially toward carbon dioxide, and to a lesser extent, oxygen. Most plastic bottle manufacturers can provide tables of gas permeabilities for the plastics used in their products, which will be helpful for the selection of the proper bottles for the purpose.

When available, a direct analysis of DIC concentration (or TIC concentration, if unfiltered) is generally more accurate than computing DIC from pH and alkalinity measurements, unless particular care is taken in the analyses and sophisticated equivalence point and pH stabilization point techniques are employed (Schock and George, 1991; Schock and Lytle, 1994). Glass, or other material impermeable to CO_2 , must be used for the container, and the cap must allow no air space.

To determine if metal release is primarily particulate or dissolved, frequently filtration is used. This is a deceptively difficult procedure, as there are numerous opportunities for erroneous data and biases that can significantly affect conclusions. Losses of dissolved metals to container walls, filters, and filtration apparatus will cause an overestimation of the contribution of particulates to the total metal release levels observed. Sorption losses are especially acute on glass materials and with cellulose acetate membranes, so polycarbonate, Teflon, or stainless steel apparatus and filter supports are preferable. Polycarbonate filter membranes have generally been shown to cause less bias than membranes made of most other materials, as have nylon syringe filters. Some cleaning and filter apparatus preparation precautions have been described in some studies (Schock and Gardels, 1983; Schock et al., 1995). Before using data from sample filtration, a careful laboratory and field test evaluation should be conducted of all materials used and all steps in the procedure to determine if there is a potential for losses of dissolved constituents or contamination from the materials.

When corrosion control studies obtain good baseline data and have a comprehensive, well-designed monitoring program in place throughout their corrosion control effort, the data are invaluable to other utilities and corrosion scientists. They can then work with a larger body of drinking water chemistry and treatment knowledge to implement future corrosion control and public health protection strategies much more effectively and efficiently.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the extensive contributions of all of the writers of the AWWA publication *Corrosion Control For Operators*, the AwwaRF/DVGW-Forschungsstelle/TZW manual *Internal Corrosion of Water Distribution Systems*, and the late Dr. T. E. Larson, who originated this chapter and whose works guided much of the evolution of the contents. The authors are also indebted to the late Dr. Heinrich Sontheimer for inspiration for much of the copper research, Dr. Vernon Snoeyink for inspiration on the iron research, and to Dr. Marc Edwards for many interesting ideas, editorial comments, and discussion on lead, copper, corrosion, and historical perspectives. Michael K. DeSantis of

Pegasus Technical Services provided several illustrations and photographs, as well as many useful presentation ideas. John Consolvo of the Philadelphia Water Department contributed review and information for the solids analysis sections. Many improvements were brought about by the editorial and technical reviews from Dr. James Edzwald and France Lemieux (Health Canada). Robert N. Hyland of Pegasus Technical Services assisted greatly in the editorial review, equations, and layout of the chapter.

DISCLAIMER

The U.S. Environmental Protection Agency through its Office of Research and Development funded and managed the production of this chapter. It has not been subject to agency review and, therefore, does not necessarily reflect the views of the agency. Mention of trade names of commercial products and companies does not constitute endorsement or recommendation for use.

ABBREVIATIONS

A-C	asbestos-cement (pipe)
ANSI	American National Standards Institute
ASTM	American Society for Testing of Materials
AwwaRF	Awwa Research Foundation
CCPP	calcium carbonate precipitation potential
DIC	dissolved inorganic carbon, equivalent to C_{TC} in Chap. 3
DO	dissolved oxygen
LR	Larson ratio
LSI	Langelier saturation index
MCL	maximum contaminant level
NOM	natural organic matter
NSF	NSF International
ORP	oxidation-reduction potential
TALK	total alkalinity
TDS	total dissolved solids
USEPA	U.S. Environmental Protection Agency
WHO	World Health Organization

NOTATION FOR EQUATIONS

{ }	braces denote the <i>activity</i> of an aqueous species
[]	brackets denote the concentration of an aqueous species
β	buffer intensity, (mmol/L)/pH unit

- E potential generated by an electrochemical reaction
 $S_{T,X}$ total solubility for species X

**MICROBIAL RISKS FROM DISTRIBUTION
 SYSTEM CONTAMINATION**

Waterborne Disease Outbreaks

Since the mid-1980s, the number of waterborne outbreaks in the United States has declined (Fig. 21-1), largely attributed to the promulgation of more stringent drinking water standards, including the Surface Water Treatment Rule (SWTR), the Total Coliform Rule (TCR), and other regulations; see Chap. 1 for a discussion of these and other regulations. In addition, many water utilities have made voluntary improvements, such as the Partnership for Safe Water Program, to reduce the risk of waterborne cryptosporidiosis. The Partnership program involves a comprehensive evaluation of treatment practices with a focus on achieving filtered

*Excludes outbreaks of Legionnaires disease.

FIGURE 21-1 Number of drinking water disease outbreaks in the United States, 1971–2002. (Source: Adapted from Blackburn et al., 2004.)

drinking water turbidities of less than 0.1 ntu. The number of reported community- and non-community-reported outbreaks decreased sharply in the 1984–1986 reporting period, largely in anticipation of promulgation of the 1989 SWTR and TCR regulations. In contrast, the increase in outbreaks reported during 1999–2001 was attributable primarily to individual home owner systems, comprising 40 percent of the waterborne outbreaks during the period (see Fig. 21-1). Among the seven outbreaks associated with community water systems in 2001–2002, four (57.1 percent) were related to problems in the water distribution system. Investigations conducted in the late 1990s suggested that a substantial proportion of waterborne disease outbreaks, both microbial and chemical, was attributed to problems within distribution systems (Craun and Calderon, 2001).

In 2001, there were significant changes in the reporting of outbreaks by the U.S. Centers for Disease Control and Prevention (CDC) and the U.S. Environmental Protection Agency (USEPA) with the inclusion of *Legionella* outbreaks (Blackburn et al., 2004). Additionally, in 2003, there were changes to the classification of system deficiencies that resulted in the outbreaks (Liang et al., 2006). Importantly, the number of deficiency classes increased from 5 to 13 categories with a total of 23 subcategories and distinguished between contamination under the control of the water utility and events outside the jurisdiction of the utility. Examples of contamination outside the jurisdiction of the utility include plumbing deficiencies, deficiencies in the building/home-specific treatment systems, contamination at the point of use, and contamination during the bottling or shipping of water. Outbreaks of *Legionella* typically are outside the jurisdiction of the utility (Liang et al., 2006).

The result of this reclassification was a more detailed understanding of waterborne disease outbreaks, particularly those associated with distribution systems. Prior to 2003, all outbreaks associated with any piping, even those internal to buildings or homes, were categorized as “distribution system.” Since 2003, it has been clear that the majority of “distribution system” outbreaks have been due to problems in premise plumbing and other problems outside the jurisdiction of the utility, and relatively few have been due to contamination of community water system pipelines. Since its categorization in 2001 as a waterborne disease agent, *Legionella* has emerged as the most commonly identified pathogen (Fig. 21-2).

† Beginning in 2003, mixed agents of more than one etiologic agent type were included in the surveillance system. However, the first observation is a previously unreported outbreak in 2002.

§ Beginning in 2001, Legionnaires' disease was added to the surveillance system, and *Legionella* species were classified separately in this figure.

FIGURE 21-2 Number of waterborne-disease outbreaks associated with drinking water by year and etiologic agent—United States, 1971–2006. (Source: Yoder et al., 2008.)

FIGURE 21-3 Reclassification of 27 waterborne disease outbreaks caused by distribution system deficiencies for community and noncommunity systems, 1974–2004. *Legionella* is not included in these outbreaks. (Source: USEPA, 2007b.)

The USEPA and the CDC are in the process of reclassifying outbreaks from 1971 through 2004 to better understand the underlying deficiency that caused the outbreak. This process is somewhat subjective because it requires interpretation of historical accounts, and the results do not include outbreaks owing to *Legionella*. Cross-connections or backsiphonage (where low pressures in the distribution system draw in contaminants) accounted for 40 percent of the reported outbreaks (Fig. 21-3). Contamination of mains during construction or broken or leaking mains accounted for 26 percent of the outbreaks. Low-pressure events were associated with 19 percent of the outbreaks, whereas contamination of storage tanks was the cause of 15 percent of the reported deficiencies. Attention to these routes of contamination was the focus of the research agreement formed as part of the 2008 revisions to the TCR (USEPA, 2008b). The importance of cross-connections and backsiphonage is supported in a separate compilation by the USEPA of backflow events that revealed a total of 459 incidents resulting in 12,093 illnesses from 1970 to 2001 (USEPA, 2002a). For the period 1981–1998, the study found that only 97 of 309 incidents were reported to public health authorities, suggesting that the magnitude of the public health concern due to cross-connections is an underestimated.

Epidemiological Studies of Distribution System Risk

Epidemiological studies also point to potential risks in distribution systems. Payment and colleagues (1991, 1997) conducted two epidemiological studies that examined the health of people who drank tap water compared with people receiving water treated by reverse osmosis. For the 1991 study, reverse osmosis units were installed in 299 households (1206 persons), and another 307 households (1202 persons) were followed as controls with no device installed. Both groups were monitored for a 15-month period for episodes of highly credible gastrointestinal illness

(HCGI). The water source for the study area was a river that was contaminated by human sewage discharges, including combined sewer overflows. The community had a single water treatment plant with predisinfection, alum coagulation, flocculation, rapid sand filtration, ozonation, and final disinfection with chlorine or chlorine dioxide. The overall incidence of highly credible gastroenteritis was 0.66 episode/person per year and was highest in children 5 years of age and younger. The authors concluded that approximately 35 percent of the self-reported gastrointestinal illnesses were attributed to tap water consumption. Although not designed to evaluate the source of contamination, the study suggested that contamination could come from the distribution system because those living closest to the treatment plant (or point of rechlorination) had some of the lowest illness rates.

The 1997 study was designed to examine a number of hypotheses as to the possible source of illnesses; however, it should be noted that between the time of the first and second studies, the water treatment plant was upgraded significantly with higher disinfection doses and better filtration. The study included groups receiving (1) regular tap water, (2) tap water from a continuously purged tap, (3) bottled plant effluent water, or (4) bottled plant effluent water purified by reverse osmosis. The difference in gastroenteritis rates between groups 2 and 3 was assumed to be due to pathogens breaking through the treatment process. The average turbidity of the finished water was 0.1 ntu and never exceeded 0.5 ntu. The study found no statistical difference in illness rates between groups 2 and 3, suggesting that no observable pathogens were in the treated effluents, although the authors acknowledged the possibility that "microbursts" would not be observed. The difference in gastroenteritis rates between groups 1 and 2 versus group 3 was assumed to be due to changes in water quality that occurred between the time the water left the treatment plant and the time it reached the household. The water ingested by group 1 represented tap water that had gone through the distribution system and also had residence time in the household plumbing. The water ingested by group 2 represented tap water quality in the distribution system without any significant residence time in the household plumbing. The 1997 study by Payment and colleagues attributed 14 to 40 percent of the gastrointestinal illness to the consumption of tap water and concluded that the distribution system played a role in waterborne disease because the rates of HCGI were similar for group 3 (ingested purified bottled water) and group 4 (ingested bottled water from the treatment plant), but groups 1 and 2 (ingested water from the distribution system) had higher HCGI rates than group 4. Interestingly, there appeared to be no correlation between the relatively short residence time of the water in the distribution system (which varied from 0.3 to 34 hours) and the incidence of HCGI in a family. Furthermore, microbiological testing of the water in the distribution system did not reveal any bacterial indicators of contamination, but these water samples were not tested for viruses or protozoa. Contrary to their expectation, the investigators observed higher HCGI rates in families that ingested water from the continuously purged taps compared with families with regular tap water that may be subject to bacterial regrowth in household pipes. The investigators suggested that the shorter residence time for water from the continuously purged taps may have transported pathogens in the distribution system to the household sooner than regular tap water and that there may have been inadequate contact time with residual chlorine in the distribution system to inactivate pathogens introduced by intrusion.

Subsequent studies by Kirmeyer and colleagues (2001) and Besner (2007) and Besner et al. (2010) examined the susceptibility of the Laval system to intrusion of contaminants during low-pressure events. Transient pressure modeling conducted by Kirmeyer and colleagues (2001) suggested that the distribution system was particularly prone to negative pressures, with more than 90 percent of the nodes within the system drawing negative pressures under certain modeling scenarios (e.g., power outages). During the 1997 study by Payment and colleagues, the system reported some pipe breaks, particularly during the fall and winter, when temperature changes placed added stresses on the distribution system. Although the system employed state-of-the-art treatment, the distribution network

maintained low disinfectant residuals, particularly at the ends of the system. Low disinfectant residuals and a vulnerability of the distribution system to pressure transients could account for the viral-like etiology of the illnesses observed.

A double-blinded, randomized trial completed in Melbourne, Australia (Hellard et al., 2001), examined the contribution of drinking water from an unfiltered surface water supply with a protected forested watershed to the rates of gastroenteritis in the distribution system. The rates of HCGI ranged from 0.79 episodes/person per year for those with functional treatment units to 0.82 episodes/person per year with the placebo device (a sham unit that looked the same but provided no additional treatment). The study concluded that the water was not a source of measurable gastrointestinal disease (the ratio of illness rates between the group drinking treated water and those drinking normal tap water was 0.99, with a 95 percent confidence interval of 0.85–1.15; $p = .85$). There was no difference between the groups despite the rather poor water quality in the distribution system. Total coliform bacteria were detected in 18.9 percent of 1167 routine 100-mL distribution system water samples, but fecal coliform bacteria were not detected. Distribution system samples were positive for *Aeromonas* spp. (50 percent of 68 weekly samples), *Campylobacter* (one occasion), and *Giardia* (two positive samples by reverse-transcriptase polymerase chain reaction (RT-PCR)). Although the study was not designed specifically to examine the risks from the distribution system, the results call into question traditional measures of water quality (e.g., total coliforms and *Aeromonas* spp.) with respect to predicting the risks of gastrointestinal illness.

A study conducted in Davenport, IO, was designed to determine the incidence of gastrointestinal illness associated with consumption of drinking water meeting all U.S. federal and state treatment guidelines (LeChevallier et al., 2003; Wade et al., 2004; Colford et al., 2005). The municipal water system used a single source (the Mississippi River) and was treated at a single plant with conventional treatment consisting of coagulation, flocculation, sedimentation, filtration (dual filters with granular activated carbon and sand), and chlorination. A total of 456 households with 1296 participants were randomized into two groups. One group received a household water treatment device with a 1- μm absolute ceramic filter and ultraviolet (UV) light with 35,000 to 38,000 $\mu\text{W} \cdot \text{s}/\text{cm}^2$ output. The other group received a placebo (sham) device that was identical to the active device but had an empty filter chamber and a UV light that was shielded to block transmission of radiation but still generated the same light and heat as the active unit. Each study household had an active device for 6 months and a sham device for 6 months and was blinded to the status of their device during the study. Overall, the rate of HCGI for households with the sham device was 2.12 and 2.20 episodes/person per year for households with the active device. Multivariate analyses showed no effect of the household water treatment device on illness rates during the 12-month study period. The overall conclusion was that fewer than 11 percent of the gastrointestinal illnesses observed in this community were due to drinking water.

During the Davenport study in April and May 2001, the Mississippi River experienced a 1 in 300-year flood that swamped upstream sewage treatment plants and elevated raw water levels of *Giardia* cysts, total and fecal coliforms, and male-specific coliphage. Average turbidity exceeded 40 ntu over a 6-week period and peaked at 197 ntu. However, treatment plant performance remained good, with individual filter and combined filter effluent turbidities below 0.1 ntu. The flood period was associated with significantly increased rates of gastrointestinal illness for people (especially in children) with direct contact with flood water and flood cleanup activities; however, drinking water quality was not a factor in the increased illness rate (Wade et al., 2004).

A study conducted in Wales and northwest England in 2001–2002 found a very strong association (a probability $p < .001$) between self-reported diarrhea and reported low water pressure at the home tap based on a postal survey of 423 subjects (Hunter et al., 2005).

This study was part of a larger case-control study of risk factors associated with sporadic cryptosporidiosis. The study populations were drawn from two large regions that include both heavily industrialized areas and rural areas and about 240 water treatment plants. The overall microbiological water quality for the utilities in these regions was described to be excellent, with less than 0.05 percent of water samples positive for *Escherichia coli* during this study period. Four risk factors for diarrhea in the control group remained significant: feeding a child under 5 years old, contact with another person who had diarrhea, loss of water pressure at home, and how often the subject ate yogurt. The first three risk factors had a positive association with diarrhea [odds ratios (ORs) of 2.5, 7.0, and 12.5, respectively, after adjusting for the effects of the other variables in the model]. The investigators hypothesized that most of the reported episodes of pressure loss were due to main breaks in which contamination entered the distribution system. The investigators concluded that up to 15 percent of gastrointestinal illness may be associated with consumption of drinking water that was contaminated from main breaks or other pressure-loss events.

Nygård and colleagues (2007) examined 626 households that lived downstream from main breaks or planned maintenance that resulted in loss of pressure in seven distribution systems and 549 control families that lived outside the affected area. A total of 88 low-pressure episodes were examined, varying from 2 to 24 events per system. Only one system chlorinated the affected areas, but flushing was done in 87 of the cases. No boil-water notice was provided in any of the systems, and none maintained a disinfectant residual in the distribution system. The interview questionnaires were administered 1 week after the low-pressure event. Gastrointestinal illnesses occurred in 22.7 percent of the affected households compared with 8 percent of the controls, with an attributed fraction among exposed households of 37 percent. Households with higher average daily water consumption (>2 glasses per person per day) had higher [relative risk (RR) of 4.9, with a 95 percent confidence interval (CI) of 1.6–15.2) compared with a lower average daily water consumption (≤ 2 glasses per person per day). The authors concluded that breaks and maintenance work in the water distribution systems increased the risk of gastrointestinal illness among exposed households and that the public health burden caused by contamination of drinking water within the distribution network may be larger than previously anticipated.

MICROBES IN DISTRIBUTION SYSTEMS

Differentiation between Suspended and Biofilm Microbes

The microbiology of distribution systems essentially consists of two different environments—microorganisms suspended in the bulk water column and those in biofilms attached to the surfaces of pipes, sediments, and other materials. Microorganisms in the bulk water column originate from either the source water, bacterial growth within the treatment process (e.g., within the treatment filters), biofilms within the distribution system, or recontamination of the water from cross-connections, intrusion, pipe breaks, or other external sources. The presence of a disinfectant residual will have an important selective effect for suspended microorganisms in treated systems. Organisms that are most resistant to disinfectants include those with spores, cysts, and waxy or thick peptidoglycan cells walls. In general, gram-positive bacteria and acid-fast or partially acid-fast bacteria are more resistant to disinfection than gram-negative bacteria (Norton and LeChevallier, 2000).

Biofilms can form by attachment of microbes from the bulk water or can originate from organisms present on pipe surfaces when the system was installed. A biofilm is a collection of organic and inorganic, living and dead material collected on a surface (Characklis and Marshall, 1990). It may be a complete film or, more commonly in water systems,

FIGURE 21-4 Examples of biofilm bacteria. (Source: LeChevallier, 2005.)

a small patch on a pipe surface. Microorganisms in biofilms can include bacteria [including coccoid (round), rod-shaped, filamentous, and appendaged bacteria] (Fig. 21-4), fungi, and higher organisms, such as nematodes, larvae, and crustaceans. The nature of the surface material can have a strong influence on the composition and activity of the attached microbial community.

Studies have shown that biofilms developed more quickly on iron pipe surfaces than on plastic polyvinyl chloride (PVC) pipes despite the fact that adequate corrosion control was applied, that the water was biologically treated to reduce assimilable organic carbon (AOC) levels, and that chlorine residuals were consistently maintained (Haas et al., 1983a; Camper, 1996). Iron pipes supported a more diverse microbial population than did PVC pipes (Norton and LeChevallier, 2000). Part of the reason that certain bacteria associate with certain pipe types is because materials may leach compounds that support bacterial growth. For example, pipe gaskets and elastic sealants (containing polyamide and silicone) can be a source of nutrients for bacterial proliferation. Colbourne and colleagues (1984) reported that *Legionella* were associated with certain rubber gaskets. Organisms associated with joint packing materials include populations of *Pseudomonas aeruginosa*, *Chromobacter* spp., *Enterobacter aerogenes*, and *Klebsiella pneumoniae* (Schoenen, 1986). Coating compounds for storage reservoirs and standpipes can contribute organic polymers and solvents that may support regrowth of heterotrophic bacteria (Schoenen, 1986; Thofern et al., 1987). Liner materials may contain bitumen, chlorinated rubber, epoxy resin, or tar-epoxy resin combinations that can support bacterial regrowth (Schoenen, 1986). Kilb and colleagues (2003) identified the source of coliforms in a number of nonchlorinated distribution systems in Germany as originating from biofilms grown on rubber-coated valves and concluded that usable carbon compounds leached from the coating material. PVC pipes and coating materials may leach stabilizers that can result in bacterial growth. Studies performed in the United Kingdom reported that coliform isolations were four times higher when samples were collected from plastic taps than from metallic faucets (Geldreich and LeChevallier, 1999). The purpose of these studies was not to indicate that certain pipe materials are preferred over another but to demonstrate the importance of considering the type of materials that come into contact with potable water. Although procedures are available to evaluate the growth-stimulation potential of different materials (Bellen et al., 1993), these tests are not applied in the United States. In parts of the distribution system where there is a large surface-to-volume ratio (such as smaller-diameter pipes), biofilm bacteria will have a greater impact on bulk water quality. The greater surface area of small pipes also increases reaction rates that deplete chlorine residuals. Because smaller-diameter pipes are found in buildings and homes, premise plumbing is particularly prone to growth of biofilm bacteria and the resulting water quality problems.

Pathogen Occurrence in Distribution Systems

Excluding opportunistic pathogens that grow in distribution system biofilms (e.g., *Legionella*, *Mycobacterium*, amoebae, etc.), pathogenic microbes in drinking water networks can be considered transitory (USEPA, 2002b), resulting from failures of the treatment process or subsequent pipeline contamination. Contamination events, however, can lead to transitory accumulation of pathogens within distribution system biofilms. For example, researchers have shown that viruses and parasites such as *Cryptosporidium* can be trapped in biofilms after a contamination event (Quignon et al., 1997; Piriou et al., 2000; Lehtola et al., 2007). Bacterial pathogens such as *Helicobacter pylori* (Mackay et al., 1998; Gião et al., 2008), enterotoxigenic *E. coli* (Szewzyk et al., 1994), *Salmonella typhimurium* (Armon et al., 1997), and *Campylobacter* spp. (Buswell et al., 1998) can persist within biofilms formed in experimental laboratory systems. How long these microbes persist in actual full-scale distribution systems is unknown, but it is thought that microbial competition, predation, and detachment from the biofilm eventually dissipate their numbers. For example, *E. coli* O157:H7 did not persist in biofilms after 20 days, but cells of *S. typhimurium* were detected by fluorescent antibody methods throughout the 60-day experiment (Camper et al., 1998). After this prolonged exposure, no *S. typhimurium* were recovered by culturing methods, but the organism was recovered after incubation in a dilute nonselective broth, indicating that low levels of viable cells still were present. Wolyniak et al., (2009) reported that the number of oocysts adsorbed to a biofilm surface was related to the thickness of the biofilm, with increased adsorption during the summer when biofilms were thicker than in the winter.

These findings are most important for rehabilitation of distribution systems after intentional or unintentional contamination events or after prolonged depressurization (e.g., following flooding or natural disaster), and extensive flushing and disinfection is recommended—even after samples from the water column are clean. A study of decontamination protocols for distribution system infrastructure (Welter et al., 2008) showed that the presence of biofilm and pipe tuberculation/scale tended to increase contaminant attachment to pipe surfaces. Decontamination protocols varied depending on the nature of the contaminant material, but flushing and chlorination may not be sufficient if the pipe is heavily tuberculated. In these cases, mechanical cleaning of the pipe may be necessary to remove both the tubercles and the contaminants.

Identification of Bacteria in Distribution Systems

Identification of microorganisms typically relies on culture methods that do not detect all microbes that may exist in water, and typically such methods recover only a fraction (10 percent or less) of viable organisms. In addition, most culture methods detect only relatively rapidly growing heterotrophic bacteria, whereas slowly growing organisms and fastidious or autotrophic organisms generally are not detected. Diagnostic kits are unreliable for many heterotrophic bacteria because the methodology often requires the analyst to perform a Gram stain, which is difficult because of the slow growth and acid-fast or partially acid-fast nature of bacteria surviving in disinfected drinking water.

Fatty acid profiling has been used to identify organisms from drinking water (Briganti and Wacker, 1995; Norton and LeChevallier, 2000), but the organisms were cultured prior to identification, and therefore, the limitations associated with culturing are still present. Additionally, for identification, the lipid profile must match an established profile in a database; these databases are predominated by clinical isolates. The use of fatty acid profiles has been further developed by Smith and colleagues (2000), who used biofilm samples without prior culturing to demonstrate that predominantly gram-negative bacteria were present,

but no further identification was accomplished. A similar approach was taken by Keinanen et al. (2004), who compared profiles from two drinking water systems and showed that they differed, but again, no identifications were obtained.

Molecular methods offer the promise of a more complete determination of the microbiology of drinking water. DNA extraction and polymerase chain reaction (PCR) amplification and analysis of RNA sequences can be used to identify waterborne microbes (Amann et al., 1990; Amann et al., 1995; Liu and Stahl, 2006). These procedures can be combined with quantitative real-time PCR, fluorescence in situ hybridization, or flow cytometry to provide quantitative assessments of bacterial populations. However, careful quality assurance is necessary to ensure complete extraction and recovery of environmental DNA. In an early study in which fluorescence in situ hybridization (FISH) was used along with a redox dye to assess activity, probes specific for the domains Eucarya and Bacteria, the α , β , γ , and δ subclasses of Proteobacteria, the flavobacteria-cytophaga group and Legionellaceae were used. The research demonstrated that the β subclass of the Proteobacteria predominated (Kalmbach et al., 1997), although no further characterization of the individuals in this subclass was done. Another investigation used terminal restriction fragment length polymorphisms (T-RFLPs) to identify members of a biofilm consortium over a 3-year time period (Martiny et al., 2003). In this study, several organisms were identified (*Pseudomonas*, *Sphingomonas*, *Aquabacterium*, *Nitrospira*, *Planctomyces*, and *Acidobacterium*), but for the majority of peaks, no sequence match could be made. This group was unsuccessful in applying FISH probes to visualize the identified species. Other methods for developing microbial fingerprints include denaturing gradient gel electrophoresis (DGGE), PCR–amplicon-length heterogeneity (ALH), single-strand-conformation polymorphism (SSCP), and DNA microarray (Liu and Stahl, 2006).

The point of this section is to illustrate that any discussion of the types of microbes present in distribution systems should be taken with a bit of caution because all methods have some drawbacks and give an imperfect picture of the ecology of drinking water networks.

Heterotrophic Bacteria

Heterotrophic bacteria (a broad classification that takes into account all bacteria that use organic carbon) are commonly found in distribution systems because they readily form biofilms in such systems. They are measured by using heterotrophic plate counts (HPCs). As noted earlier, the composition of the HPC population changes as the water goes through treatment. Phylogenetic analysis of rRNA genes amplified from bulk water and biofilms samples were significantly different and included isolates of *Acidobacterium*, *Nitrospirae*, *Planctomyces*, and *Verrucomicrobium* (Martiny et al., 2005). Identification of bacteria using fatty acid analysis (Norton and LeChevallier, 2000) showed that chlorination resulted in a rapid shift from predominately gram-negative bacteria (97 percent) in the raw water to mostly gram-positive organisms (98 percent) in the chlorinated water (Table 21-1). Bacteria in the raw water were diverse, with *Acinetobacter* spp., *Pseudomonas* spp., and *Klebsiella* spp. predominant among the 20 genera identified. Ozonation of the raw water reduced the microbial diversity to 13 genera, dominated by *Pseudomonas* spp. and *Rhodococcus* spp. However, following biologically active granular activated carbon filtration, 19 genera were identified in the filter effluent, the majority of which (63 percent) matched isolates observed in the raw water. The predominant genera were *Pseudomonas* spp. and *Sphingomonas* spp., which are known to grow attached to the carbon fines of the filter while using natural organic compounds found in the aquatic environment. Final chlorination of the filtered water resulted in a shift to *Nocardia* spp. as the water entered the pipe system. *Nocardia* spp. possess characteristic fatty acids that are closely related to *Rhodococcus*, *Mycobacterium*, and

Corynebacterium. Its partially acid-fast cell wall and possession of the catalase enzyme, which breaks down hydrogen peroxide, are important factors that enable the organism to survive disinfection. Other gram-positive bacteria found in chlorinated drinking water include *Bacillus* spp. and *Staphylococcus* spp. *Bacillus* spp. form environmentally resistant spores that can withstand prolonged contact with chlorine. Some strains of *Bacillus* and *Staphylococcus aureus* can produce toxins when contaminated water is used in food preparation (LeChevallier and Seidler, 1980).

Treated drinking water will include a mixture of gram-negative and gram-positive HPC bacteria. In the absence of a disinfectant residual, gram-negative bacteria typically will out grow gram-positive bacteria and dominate the bacterial population. These organisms typically include *Pseudomonas*, *Acinetobacter*, *Flavobacterium*, and *Sphingomonas* spp. Figure 21-5 shows the microbial populations grown on PVC and iron pipe surfaces. *Stenotrophomonas* spp. dominated on plastic pipe, but *Nocardia*, *Acidovorax*, *Xanthobacter*, and *Pseudomonas* spp. were most dominant on iron pipe (Norton and LeChevallier, 2000). For the most part, these organisms have limited public health significance, except for *P. aeruginosa*, which is a possible opportunistic pathogen in drinking water and in the biofilms of water systems. The organism has been known to colonize point-of-use carbon

PVC Pipe

filters in drinking water systems (de Victoria and Galvan, 2001; Chaidez and Gerba, 2004). *P. aeruginosa* is of concern in bathing waters, especially in swimming pools and spas, where skin infections may result owing to exposure. In the case of drinking water, there are a few studies that suggest a relationship between the presence of this organism in the water and disease. In one hospital setting, 5 of 17 patients with a *Pseudomonas* infection carried a genotype also detected in the tap water (Trautmann et al., 2001). In another outbreak of pediatric *P. aeruginosa* urinary tract infections, two isolates had genotypes similar to those in the water. The outbreak was resolved when the taps in the unit were changed (Ferroni et al., 1998). In another instance, *P. aeruginosa* was used as an indicator of long storage and the potential for the presence of bacteria causing gastroenteritis in drinking water from a neighborhood in Mexico (de Victoria and Galvan, 2001).

With regard to the public health significance of HPC bacteria generally in drinking water, a workgroup convened by the World Health Organization (WHO) addressed this issue (Bartram et al., 2003). The WHO concluded that HPC bacteria were not associated with any

adverse health effect: “In the absence of fecal contamination, there is no direct relationship between HPC values in ingested water and human health effects in the population at large” (Bartram et al., 2003). HPC levels can be high in foodstuffs, but there is no evidence of a health effect in the absence of pathogen contamination. One of the difficulties in interpreting the significance of HPC data is that test methods involve a wide variety of conditions that lead to a wide range of quantitative and qualitative results. Nonetheless, the USEPA recommends that HPC levels be maintained at or below 500 colony-forming units (CFU)/mL so as to not interfere with the detection of total coliform bacteria (USEPA, 1989).

Coliform Bacteria

Total coliform bacteria (a subset of gram-negative bacteria) are used primarily as a measure of water treatment effectiveness and occasionally can be found in distribution systems. The origins of total coliform bacteria include untreated surface and groundwater, vegetation, soils, insects, and animal and human fecal material. Typical coliform bacteria found in drinking water systems include *K. pneumoniae*, *Enterobacter aerogenes*, *E. cloacae*, and *Citrobacter freundii*. Other typical species and genera are shown in Table 21-2, although

Sources: From Geldreich et al., 1977; LeChevallier, Seidler, and Evans, 1980; Olson and Hanami, 1980; Herson and Victoreen, 1980; Reilly and Kippin, 1981; Clark et al., 1983; Staley, 1983.

the range of genera and species that can be recovered by various total coliform methods is expansive. Although most coliforms are not pathogenic, they can indicate the potential presence of fecal pathogens and thus may be a measure of public health risk. Indeed, the presence of coliforms in the distribution system usually is interpreted to indicate an external contamination event, such as injured organism passage through treatment barriers or introduction via water line breaks, cross-connections, or uncovered or poorly maintained finished water storage facilities (Geldreich et al., 1992; Clark et al., 1996). Biofilms within distribution systems can support the growth and release of coliforms, even when physical integrity (i.e., breaches in the treatment plant or distribution system) and disinfectant residual have been maintained (Characklis, 1988; Haudidier et al., 1988; Smith et al., 1990) such that their presence may not necessarily indicate a recent external contamination event.

Thermotolerant coliforms (capable of growth at 44.5°C), also termed *fecal coliforms*, have a higher association with fecal pollution than total coliforms. *E. coli* is considered to be even more directly related to fecal pollution because it is commonly found in the intestinal track of warm-blooded animals. Although most fecal coliform and *E. coli* strains are not pathogenic, some strains are invasive for intestinal cells and can produce heat-labile or heat-stable toxins (AWWA, 1999). *E. coli* and most of the thermotolerant coliforms do not grow in biofilms, although they most likely can be trapped and retained within biofilms (see below).

Stressed and Viable but Nonculturable Bacteria

Although most of the attention on stressed organisms has been on indicator bacteria (especially total and fecal coliforms), all organisms can become stressed. Stressed organisms are present under ordinary circumstances in treated drinking water and may be associated with partial or inadequate disinfection or the presence of metal ions or other toxic substances. These and other factors, including extremes of temperature and pH and solar radiation, may result in significant underestimations of the number of viable bacteria. In addition, laboratory manipulations following sample collection also may produce injury or act as a secondary stress to the organisms (McFeters et al., 1982; McFeters, 1990). These include excessive sample storage time, prolonged holding time (>30 minutes) of diluted samples before inoculation into growth media and of inoculated samples before incubation at the proper temperature, incorrect media formulations, incomplete mixing of sample with concentrated media, and exposure to untempered liquefied agar media. Excessive numbers of nonindicator bacteria also interfere with detection of indicators by causing injury (LeChevallier and McFeters, 1985b).

Coliforms also may enter the distribution system as injured organisms that pass through treatment barriers or by introduction into water line breaks, cross-connections, uncovered finished water storage, or low water pressure [<140 kPa (20 psi)]. For these reasons, more attention should be paid to the search for injured coliforms in an effort to provide a more sensitive measurement of water quality (LeChevallier and McFeters, 1985a; McFeters, 1990; Bucklin et al., 1991). To increase the sensitivity of detection of injured bacteria, the utility may process high-volume samples (≥ 500 mL) and use methods designed to detect stressed coliform bacteria (LeChevallier and McFeters, 1985a; McFeters, 1990) or HPC bacteria (Reasoner and Geldreich, 1985). For chloraminated water, inclusion of sodium sulfite in the media can reverse the oxidation of bacterial enzymes and increase microbial recoveries significantly (Watters et al., 1989).

The *viable but nonculturable* (VBNC) *response* is a temporary state during which organisms are not culturable using conventional nonselective culture conditions. The VBNC state has been reported for a wide variety of bacteria (Table 21-3). Whereas entrance into the VBNC state is easily demonstrated, proving resuscitation has been difficult for most bacterial species. In some cases, a simple temperature upshift allows for cellular resuscitation, whereas in other cases (such as *Legionella pneumophila*), where induction into the VBNC state was caused by nutrient depletion, resuscitation occurred when co-incubated with an *Acanthamoeba* host (Steinert et al., 1997; Oliver, 2005). Other mechanisms for the loss of culturability are likely to exist for other bacteria, but they are frequently unknown or not rigorously examined.

Organisms not well adapted to survival in a low-nutrient drinking water environment might persist in the VBNC state. Juhna and colleagues (2007) placed coupons made of cast iron, polyvinyl chloride, and stainless steel into 15 locations at six distribution networks in France and Latvia and examined them after 1 to 6 months of exposure to the drinking water. *E. coli* was detected in 56 percent of the coupons using a peptide nucleic acid (PNA) 15-mer probe in the fluorescence in situ hybridization (PNA FISH), but no *E. coli* was detected using culture or enzymatic methods (detection of β -D-glucuronidase). PCR analyses confirmed the presence of *E. coli* in samples that were negative according to culture-based and enzymatic methods. The viability of *E. coli* cells in the samples was demonstrated by cell elongation after resuscitation in low-nutrient medium supplemented with pipemidic acid, suggesting that the cells were present in an active but nonculturable state but unable to grow on agar medium.

Legionella

Legionella is regulated through the Surface Water Treatment Rule, with the maximum contaminant level goal (MCLG) set at zero (USEPA, 1999b). However, there is little evidence

TABLE 21-3 Bacteria Described to Enter the Viable but Not Culturable State

that filtration and disinfection of surface water prevent the growth of *Legionella* spp. in distribution systems or premise plumbing. In 2001–2002, six drinking water outbreaks were attributed to *Legionella* spp. (19.4 percent of the total), caused illness in 80 persons, and resulted in 41 hospitalizations. All these outbreaks occurred in large buildings or institutional settings and were related to multiplication of *Legionella* spp. in the respective plumbing systems. In 2003–2004, *Legionella* was responsible for 8 of the 17 (61.5 percent) outbreaks with known etiologies, and in 2005–2006, *Legionella* was responsible for 10 of the 20 (50 percent) drinking water outbreaks (see Fig. 21-2). In fact, all 12 fatalities associated with drinking water from 2001 to 2006 were due to *Legionella*.

Chloramines appear to be more effective than free chlorine in reducing the risks from *Legionella*. Kool et al., (1999) examined 32 hospital-acquired (*nosocomial*) outbreaks of legionnaires' disease from 1979 to 1997 where drinking water was implicated and tabulated the characteristics of the hospital (i.e., size, transplant program) and the primary disinfectant treatment, disinfectant residual, water source, community size, and pH of the water. The researchers found that the odds of a nosocomial *Legionella* outbreak were 10.2 (95 percent CI 1.4–460) times higher in systems that maintained free chlorine than in those using a chloramine residual. Heffelfinger and colleagues (2003) reported that 25 percent (38) of 152 hospitals surveyed had reported cases or outbreaks of hospital-acquired legionnaires' disease during the period 1989–1998. However, hospitals supplied with drinking water disinfected with monochloramine were less likely (OR = 0.20, 95 percent CI 0.07–0.56) to have hospital-acquired legionnaires' disease than other hospitals. Cunliffe (1990) reported that suspensions of *L. pneumophila* were more sensitive to monochloramine disinfection, with a 99 percent level of inactivation when exposed to 1.0 mg of monochloramine per liter for 15 minutes compared with the 37-minute contact time required

for *E. coli* inactivation under similar conditions. Donlan and colleagues (2002) reported that monochloramine was significantly more effective than free chlorine at eradicating laboratory-grown biofilms of *L. pneumophila*.

Legionella spp. have been shown to proliferate in biofilms in institutional and domestic plumbing and can be found in water heaters, shower heads, and cooling towers (Pryor et al., 2004; Thomas et al., 2006). There is evidence that the organism must be taken up by protozoa to proliferate (Murga et al., 2001). Epidemiological studies have linked water contaminated with both *Legionella* and protozoa to outbreaks of legionellosis (Moore et al., 2006). Flannery and colleagues (2006) showed a 93 percent reduction in the occurrence of *Legionella* spp. in building plumbing systems in San Francisco after the utility converted from free chlorine to chloramines. Amoebae at sampled sites were associated with *Legionella* spp. colonization predominately when chlorine was used for residual disinfection. *Legionella* spp. were cultured from 61 (36 percent) of 169 samples in which amoebae were present versus 291 (24 percent) of 1236 samples without amoebae ($p = .01$). After conversion to monochloramine, *Legionella* were found in 1 (1 percent) of 78 samples containing amoebae and 8 (1 percent) of 866 samples without amoebae ($p = .75$). The prevalence of amoebae decreased from 169 (12 percent) of 1405 samples when chlorine was the residual disinfectant to 78 (8 percent) of 944 samples collected after conversion to monochloramine ($p = .006$). *Legionella* occurrence in Pinellas County, FL, was reduced when the system converted from chlorine to monochloramine disinfection (Moore et al., 2006). Water samples were collected from 96 buildings (public buildings and individual homes) for a 4-month period when chlorine was the primary disinfectant and from the same sampling sites for a 4-month period after monochloramine was introduced into the municipal water system. When free chlorine was used, 20 percent of the buildings were colonized with *Legionella* in at least one sampling site. *Legionella* colonization was reduced by 69 percent within a month after chloramination. Monochloramine appeared to be more effective in reducing *Legionella* in hotels and single-family homes than in county government buildings perhaps because of more consistent water usage.

Aeromonas

Aeromonas spp. are gram-negative bacteria comprised of 19 recognized DNA groups, are found in fresh and salt waters, and cause a wide variety of human infections, including septicemia, wound infections, meningitis, pneumonia, respiratory infections, hemolytic-uremic syndrome, and gastroenteritis (Carnahan and Altwegg, 1996; Alavandi et al., 1999; Moyer, 2006). The ability of these microorganisms to grow at low temperatures and low levels of organic carbon [total organic carbon, AOC, or biodegradable dissolved organic carbon (BDOC)] is an important factor in their occurrence in drinking water supplies. Through the Unregulated Contaminant Monitoring Rule, USEPA examined the occurrence of *Aeromonas* spp. in 308 drinking water systems and found detectable concentrations in 2.6 percent of 5060 samples and in 13.6 percent of the systems. In a 16-month study conducted on the presence of *A. hydrophila* in drinking water in Indiana, 7.7 percent of the biofilm samples were positive for *A. hydrophila* (Chauret et al., 2001). The health significance of detecting aeromonads in drinking water is not well understood. Chopra (2008) examined 242 *Aeromonas* isolates obtained from water and clinical samples and concluded that both bacterial factors and host responses were responsible for virulence. Chopra (2008) identified both water and clinical isolates with a specific pulsotype based on pulse-field gel electrophoresis that possessed the same set of virulence factors. The European Community has set standards for aeromonads in drinking water leaving the treatment plant (<20 CFU/200 mL) and in the distribution system (<200 CFU/100 mL). Canada has an *Aeromonas* maximum contaminant level (MCL) of 0 CFU/100 mL for bottled drinking

water (Moyer, 2006). *Aeromonas* are effectively controlled by disinfection practices used by public drinking water supplies to low levels that do not represent a threat to public health (USEPA, 2006a).

Mycobacterium

The genus *Mycobacterium* comprises both the pathogenic species that are transmitted by human or animal reservoirs (*M. tuberculosis* and *M. leprae*) and the so-called environmental nontuberculous mycobacteria (NTM) that are associated with soil and water. Although some of the NTM are increasingly reported as opportunistic pathogens, the primary risks in drinking water typically are associated with the *M. avium* complex (MAC), comprised of *M. avium* and *M. intracellulare* (Pedley et al., 2004). Studies have detected MAC organisms in drinking water distribution systems with concentrations ranging between 0.08 and 45,000 CFU/mL (LeChevallier, 2006). *M. avium* are resistant to disinfectants, especially free chlorine (Taylor et al., 2000). It is postulated that they may in fact be selected for in distribution systems as a result of their resistance to chlorine (Briganti and Wacker, 1995). However, there is also evidence that MAC organisms are susceptible to chlorine dioxide and chloramine (Vaerewijck et al., 2005). In fact, additions of compounds that cause oxidative stress have been shown to stimulate the formation of biofilms by mycobacteria (Geier et al., 2008).

Falkinham et al., (2001) examined eight well-characterized drinking water systems and reported that 20 percent of the water isolates and 64 percent of the biofilm isolates were identified as *M. avium* or *M. intracellulare*. Additionally, 8 percent of the water isolates were identified as *M. kansasii*. Most of these isolates were detected in raw water samples, with MAC organisms detected in five of six surface water sites ranging from 6 to 35 percent of the organisms isolated. MAC organisms were not detected in any plant or well effluent sample but were detected occasionally at low levels (<1 CFU/mL) in drinking water samples. However, *M. avium* and *M. intracellulare* were recovered frequently from drinking water biofilm samples, indicating that *M. avium* levels were growing in the distribution system. Increases in *M. avium* levels in drinking water were correlated with levels of AOC ($r^2 = 0.65$, $p = .029$) and BDOC ($r^2 = 0.64$, $p = .031$) (Falkinham et al., 2001; LeChevallier, 2004).

MAC organisms were the second most common opportunistic infection among children with human immunodeficiency virus (HIV) infection in the United States (second to *Pneumocystis pneumoniae*) prior to the availability of highly active antiretroviral treatment (HAART), but the incidence of MAC infections has decreased from 1.3 to 1.8 episodes/100 person-years to 0.14 to 0.2 episodes/100 person-years with the availability of HAART for HIV-infected individuals (Mofenson et al., 2009). MAC organisms are ubiquitous in the environment and presumably are acquired by routine exposures through inhalation, ingestion, or inoculation. Evidence for environmental transmission, especially in immunocompromised individuals, includes the following (Pedley et al., 2004):

- The frequency of gastrointestinal colonization increases as the stage of HIV advances.
- Isolation of MAC organisms from the gut occurs more often than from the respiratory tract.
- Gastrointestinal symptoms (e.g., nausea, vomiting, and diarrhea) are common with MAC infections.

Because MAC organisms are ubiquitous in the environment, the CDC does not recommend any actions to avoid exposure from water, soil, or air. Instead, prophylactic HAART is recommended when levels of immunity (CD4 white blood cells) decline in HIV-infected individuals (Mofenson et al., 2009).

Free-Living Protozoa

Naegleria spp. and *Acanthamoeba* can be pathogenic, but these infections are usually associated with recreational rather than drinking waters. However, cysts also have been isolated from drinking water distribution systems in France (Jacquemin, Simitzia, and Chaneau, 1981). *Acanthamoeba* is an opportunistic pathogen affecting contact lens wearers (USEPA, 2003a). A study in Arizona detected *Naegleria fowleri* DNA by PCR in 11 (7.7 percent) of 143 wells, and of 185 total samples, 30 (16.2 percent) tested positive for *N. fowleri* (Blair et al., 2008).

Of the genera of protozoa present in distribution systems, *Acanthamoeba*, *Hartmanella*, and *Naegleria* are known to feed on bacteria and biofilms by grazing. Transient association with amoebae has been reported for a number of different bacteria, including *L. pneumophila* (Abu Kwaik, 1996; Bozue and Johnson, 1996), *M. avium* (Adékambi et al., 2006), and other *Mycobacterium* spp. such as *M. leprae* (Adékambi et al., 2004; Yu et al., 2007). *Acanthamoeba* also can support intracellular growth of *Francisella*, the agent of tularemia (Abd et al., 2003), the enteric pathogens *Listeria monocytogenes* (Ly and Müller, 1990) and *Helicobacter pylori* (Winięcka-Krusnell et al., 2002), *E. coli* O157, and the respiratory pathogen *Chlamydia pneumoniae* (Molmeret et al., 2005). Since most of these bacteria are human pathogens, amoebae have been suggested to represent environmental reservoirs for infection (Molmeret et al., 2005). However, some *Legionella*-like amoebic pathogens (LLAPs) appear to occur exclusively as endosymbionts of protozoa (Adeleke et al., 1996, Birtles et al., 1996, La Scola et al., 2004).

Specific PCR-mediated amplification of bacterial rRNA genes in free-living amoebae, comparative sequence analysis, and fluorescence in situ hybridization led to the identification of five novel evolutionary lineages of bacterial endosymbionts of free-living amoebae. These lineages have been found to be affiliated with (1) Alphaproteobacteriae, (2) Betaproteobacteriae, (3) Gamaproteobacteriae, (4) Bacteroides, and (5) Chlamydiales (Molmeret et al., 2005). Interestingly, co-occurrence of phylogenetically different endosymbionts in a single amoeba isolate has never been observed, and significant differences regarding the host range have been shown for the different endosymbionts. The observation by Flannery and colleagues (2006) that *Legionella* spp. were predominately associated with amoebae when chlorine was used for residual disinfection—36 percent of 169 samples in which amoebae were present) versus 1 (1 percent) of 78 samples containing amoebae when chloramines were used—suggested that the colonization of amoebae by *Legionella* spp. can be influenced by the type of disinfectant used. Understanding the relationship between opportunistic pathogens and free-living amoebae is clearly important in understanding the ecology of distribution system and the factors that contribute to human health risks.

Fungi

Although many fungi have been found in drinking water systems, their levels are typically low (<10 organisms/100 mL), and the organisms have not been directly associated with disease (Kelley et al., 2003). The origin of fungi in drinking water systems has not been well characterized, but it is assumed that they come from environmental sources, including surface water and groundwater, soils, and vegetation. Fungi occurrences in distributed water are more frequent during summer water temperature conditions. *Aspergillus fumigatus* was the predominant species detected in the distribution system water supplies in Finland (Niemi et al., 1982). A variety of fungi (*Cephalosporium* spp., *Verticillium* spp., *Trichodorma sporulosum*, *Nectria veridescens*, *Phoma* spp., and *Phialophora* spp.) were identified from water service mains in England (Bays et al., 1970; Dott and Waschko-Dransmann, 1981).

Nagy and Olson (1982) compared the distribution of fungal isolates in two distribution systems, one chlorinated and the other unchlorinated. In the unchlorinated system, *Penicillium* and *Acremonium* represented approximately 50 percent of 538 colonies identified among 14 genera, whereas *Sporocybe* and *Penicillium* accounted for 56 percent of 923 fungal strains distributed within 19 genera that occurred in the chlorinated supply. The mean densities of fungi from the unchlorinated and chlorinated systems were 18 and 34 organisms/100 mL, respectively.

The conidia of *A. fumigatus*, *A. niger*, and *P. oxalicum* isolated from distribution systems of three small water supplies in Pennsylvania showed a greater resistance to chlorine inactivation than yeast (Rosenzweig et al., 1983). The resistance of yeast to free available chlorine is primarily a result of the thick and rigid cell wall, which presents a greater permeability barrier to chlorine. Specific species identified in distribution waters include *Candida parapsilosis*, *C. famata*, *Cryptococcus laurentis*, *C. albidus*, *Rhodotorula glutinis*, *R. minuta*, and *R. rubra* (Hinzelin and Block, 1985; Engelbrecht and Haas, 1977). Densities of yeasts reported in finished drinking water average 1.5 organisms per liter.

Yeasts specialized research studies, potable water supplies are not tested routinely for fungi. Most of the focus on these organisms in water supplies has been related to their degradation of gasket and joint materials and taste and odor complaints by consumers (Burman, 1965; Bays et al., 1970; Niemi et al., 1982). Water supplies with fungal densities of 10 to 100 organisms/100 mL are frequently responsible for customer complaints of bad taste and odor (Burman, 1965).

Actinomyces and Other Related Organisms

These microorganisms create some of the objectionable tastes and odors reported in water supplies (see Chap. 3). *Actinomyces* in source waters of temperate climates may be reduced by approximately 10-fold with storage in holding basins prior to other treatment measures. Some drinking water treatment process configurations that include slow sand filtration or granulated activated carbon (GAC) filter adsorbers may support an increase in density and species that enter the distribution network. *Nocardia* spp. were predominant in finished water from water treatment trains consisting of aeration and filtration or aeration, sand filtration, ozonation, and activated carbon adsorption. *Micromonosporium* made up the greatest percentages in finished water from treatment trains consisting of flocculation, settling, and slow sand filtration or aeration and granular bed filtration. Some growth also may be expected on PVC-coated walls in finished water reservoirs (Dott and Waschko-Dransmann, 1981) and in the distribution lines where organic material accumulates in sediments (Burman, 1965; Bays et al., 1970). In addition to their presence in cold tap water, thermophilic *Actinomyces* and mesophilic fungi were found in several hot-water samples in three municipalities in Finland (Niemi et al., 1982). A 2004 study of 450 waterworks revealed that 10 percent had odor or taste problems related to the growth of fungi/*Actinomyces* in their distributed water (Miettinen et al., 2007). *Thermoactinomyces vulgaris* was the predominant actinomycetes found in 11 of 15 water distribution systems examined. In two studies of treated water supplies in England, chlorination alone was not effective in eliminating *Streptomyces*. Median densities were 2 streptomycetes per 100 mL of distributed water. Taste and odor complaints involving *Actinomyces* often were from waters that had *Streptomyces* or *Nocardia* spp. counts of more than 10 organisms per 100 mL (Bays et al., 1970).

Nitrifying Bacteria

Nitrification is a potential problem for utilities that use chloramines as a disinfectant residual, especially where there is an excess level of free ammonia. Nitrification is a microbial process by which ammonia is sequentially oxidized to nitrite and nitrate. The process is

accomplished principally by two groups of chemolithotrophic bacteria (bacteria that obtain carbon and energy from inorganic sources), the ammonia-oxidizing bacteria (AOB) and the nitrite-oxidizing bacteria (NOB). Various groups of heterotrophic bacteria and fungi also can carry out nitrification, although at a slower rate than chemolithotrophic organisms (Verstraete and Alexander, 1973). In the first step of nitrification, ammonia is oxidized to nitrite:

In the second step of the process, nitrite is oxidized to nitrate:

Nitrosomonas is the most frequently identified genus associated with the ammonia oxidation step, although other genera, including *Nitrosolobus*, *Nitrosococcus*, *Nitrosovibrio*, and *Nitrosospira* also can oxidize ammonia autotrophically (Watson et al., 1989). Recent development of molecular methods for the characterization of ammonia-oxidizing bacteria have shown that *Nitrosomonas oligotropha* is the commonly identified ammonia oxidizer in full- and pilot-scale chloraminated distribution systems (Regan et al., 2002, 2003). The molecular analysis also suggests that the currently identified species of ammonia-oxidizing bacteria are not representative of the sequences observed in environmental samples, indicating that many species are yet uncharacterized. Recently identified are the ammonia-oxidizing archaea (AOA), a novel microbial group that also catalyzes the aerobic autotrophic oxidation of ammonia to nitrite (Francis et al., 2005; Konneke et al., 2005), and these organisms have been detected in treatment processes and distribution systems where they were responsible for the removal of ammonia (van der Wielen et al., 2009).

Nitrobacter is the most frequently identified genus associated with nitrite oxidation, although other genera, including *Nitrospina*, *Nitrococcus*, and *Nitrospira*, also can oxidize nitrite autotrophically (Watson et al., 1989). Molecular analyses have identified *Nitrospira* and *Nitrobacter* as ubiquitous nitrite oxidizers in full- and pilot-scale chloraminated systems (Regan et al., 2002, 2003).

Iron-, Manganese-, and Sulfur-Using Bacteria

Other autotrophs (organisms that produce complex organic compounds from simple inorganic molecules using energy from inorganic chemical reactions) that occur in drinking water supplies include those which use iron, manganese, or sulfur as sources of energy. Iron bacteria derive energy by oxidizing dissolved ferrous iron, resulting in an insoluble ferric oxide that appears as a brown gelatinous slime. Iron bacteria can grow at levels as low as 0.1 $\mu\text{g/g}$ of iron but require at least 0.3 mg/L of dissolved oxygen. Common genera of iron-oxidizing bacteria include *Gallionella*, *Sphaerotilus*, *Crenothrix*, *Sidelocapsa*, and *Leptothrix*.

Deposits of manganese can collect in distribution or plumbing systems as black sediments, and manganese-oxidizing bacteria often will be present in such sediments. A number of microorganisms have been reported to oxidize manganese, including isolates belonging to the genera *Pseudomonas*, *Comomonas*, *Cytophaga*, *Flexibacter*, *Arthrobacter*, *Bacillus*, *Corynebacterium*, *Rhodococcus*, *Leptothrix*, and *Metallogenium*, among others. *Metallogenium* can form star-shaped manganese oxide minerals (called *metallogenium*) through the action of manganese oxide precipitation along its surface. The USEPA (1979) has set a recommended limit of 0.05 mg/L for manganese for aesthetic reasons (i.e., taste, discoloration, and staining of laundry or plumbing), but a much lower limit is recommended to prevent chronic problems (see Chap. 7).

Sulfur is a compound that can be either oxidized or reduced by bacteria in drinking water systems. Sulfur-oxidizing bacteria can produce gelatinous, filamentous growths that can be white, yellow, or gray-brown. Sulfur-oxidizing bacteria include species of *Thiobacillus*, *Thiothrix*, and other sulfur-oxidizing bacteria within the e-Proteobacteria class. Sulfur-reducing bacteria live in oxygen-deficient environments such as deep wells, distribution system biofilms, water softeners, and water heaters and usually flourish at the higher temperatures in the hot-water system. Sulfur-reducing bacteria produce hydrogen sulfide, which produces an objectionable “rotten egg” smell and is corrosive to most metals. More than 130 species of sulfur-reducing bacteria have been described, and they comprise a phylogenetically diverse assemblage of organisms consisting of members of at least four bacterial phyla and one archaeal phylum. Most sulfate-reducing bacteria also can use other oxidized sulfur compounds such as sulfite and thiosulfate or elemental sulfur. In drinking water, *Desulfobulbus* and *Desulfovibrio* are the genera most commonly associated with sulfate-reducing bacteria in drinking water.

FACTORS CONTRIBUTING TO MICROBIAL OCCURRENCES IN DISTRIBUTION SYSTEMS

To ensure delivery of a high-quality potable water supply to each consumer, managers of public water supply systems must be continually vigilant for any occurrence of microbial degradation that may occur as a result of inadequate treatment or treatment upsets, microbial growth, or direct intrusions of contamination into the distribution network. This job is complicated by the very nature of a distribution system—a network of mains, fire hydrants, valves, auxiliary pumping, chlorination substations, storage reservoirs, standpipes, and service lines. After a microbial contamination event, any of these component parts may serve as a habitat suitable for colonization by certain microorganisms in the surviving flora. The persistence and potential growth of organisms in the pipe network are influenced by a variety of environmental conditions that include physical and chemical characteristics of the water, system age, type of pipe materials, and the availability of sites suitable for colonization, often located in slow-flow sections, dead ends, and areas of pipe corrosion activity.

Treatment Processes

Water supplies using a single barrier (disinfection) for surface water treatment will not prevent a variety of organisms (algae, protozoan, and multicellular worms and insect larvae) from entering the distribution system (Allen et al., 1980). While many of these organisms are not killed immediately by disinfectant concentrations and contact times ($C \times T$ values) that control coliforms and viruses (USEPA, 1999a), they die eventually because of the lack of sunlight (algae) or adverse habitat (multicellular worms and insect larvae). Disinfection is also less effective on a variety of environmental organisms that include spore-forming organisms (*Clostridium*), fungi, yeast, and protozoan cysts. All these more resistant organisms can be found in the pipe environment (NRC, 2006).

Clarification and filtration are important treatment barriers for protozoan cysts (*Entamoeba*, *Giardia*, and *Cryptosporidium*) and are more effective than the usual disinfectant concentration and contact times applied in processing raw water (Logsdon, 1987). Improperly operated filtration systems have been responsible for releasing concentrated numbers of entrapped cysts (*Giardia* and *Cryptosporidium*) as a result of improper filter backwashing procedures or filter bypasses and channelization within the filter bed (Amirtharajah and Wetgstein, 1980). Filter sand may become infested with nematodes from

stream or lake-bottom sediments that shed into the process water and pass into the distribution system. Nematodes, rotifers, and protozoa have been observed in treatment plant effluent (van Lieverloo, 1997; Schreiber et al., 1997). While nematodes are not pathogenic, they can shelter viable bacteria ingested from source water or filter media beds and, if these food-chain organisms are not digested quickly, provide a passage for escaping survivors to reach the distribution system by offering the ingested bacteria a protection against disinfection (Locas et al., 2007; Ding et al., 1995).

Application of powdered carbon or granular activated carbon (GAC) adsorption/filtration or biologically activated carbon treatment (BAC) introduces other opportunities for bacteria to enter the microbial community of processed water. Highly adsorptive activated carbon (in either granular or powdered form) is often used in specific situations for removal of organic matter, including taste- and odor-causing substances, but the granular carbon must be changed periodically when the carbon bed reaches near saturation for expected removal rates. In contrast, the biologically activated carbon (BAC) process depends on the establishment of a permanent biofilm for degradation of conversion products created by ozonation of recalcitrant organics in process water, as well as biodegradable organic matter already in the water. Significantly higher heterotrophic bacterial densities were reported in distributed water from a full-scale treatment train using GAC (Symons et al., 1981) in comparison with a similar full-scale treatment train that did not employ GAC (Haas et al., 1983b).

Several coliform species (*Klebsiella*, *Enterobacter*, and *Citrobacter*) have been found to colonize GAC filters, grow during warm-water periods, and discharge into the process effluent (Stewart et al., 1990; Camper et al., 1987). Activated carbon particles also have been detected in finished water from several water plants using powdered activated carbon (PAC) or GAC treatment. Over 17 percent of finished water samples examined from nine water treatment facilities contained activated carbon particle fines colonized with coliform bacteria (Ridgway and Olson, 1981). These observations confirm that activated carbon fines provide a transport mechanism by which microorganisms penetrate treatment barriers and reach the distribution system. Other mechanisms that could be involved in transport of bacteria into the distribution system include release of aggregates or clumps of organisms from colonization sites in GAC/BAC filtration and by passage with unsettled coagulants. The particulate matter that embeds bacteria offers the microorganisms protection against disinfection (Gauthier et al., 1999a; Morin et al., 1999; Stringfellow et al., 1993).

The use of new and improved (molecular-based) microbial detection methods is suggesting that pathogenic microorganisms may be present in treated water following conventional treatment. Monitoring studies for the detection of specific microorganisms in treated drinking water meeting prescribed water quality regulations (absence of indicators) have shown that viable enteroviruses could be detected in treated water. Using an integrated cell culture/nested PCR approach followed by restriction enzyme analysis, Vivier and colleagues (2004) detected coxsackie B viruses in 11 and 16 percent of water samples from two surface water treatment plants (of a total of 172 samples). Infectious *Cryptosporidium* was detected in 1.4 percent of 1690 100 L finished water samples collected from 22 of 82 surface water treatment plants using cell culture–polymerase chain reaction (Aboytes et al., 2004). Water quality and treatment plant characteristics were no different for the positive sites than for the sites that had no oocyst detections. Consequently, the use of molecular techniques for the detection of pathogenic organisms is gradually confirming that the acceptable water quality indicators may not necessarily reflect the virus and parasitical content of treated water.

Microbial Growth in Distribution Systems

Microbial growth can be defined as the increase in bacterial numbers in the distribution system owing to cell reproduction. Significant growth always occurs at the expense of an organic

or inorganic substrate. Most microbial growth is thought to occur in biofilms on distribution pipe surfaces. Key factors in the establishment of microbial colonization within a distribution system include water temperature, the ineffectiveness of disinfectant residuals, the availability of nutrients, corrosion and sediment accumulation, hydraulic effects, and nitrification (NRC, 2006; Besner et al., 2002; LeChevallier et al., 1996; LeChevallier, 1990).

Impact of Treatment. The types of processes used to treat source water are likely to affect the biological stability of drinking water supplies (biologically stable water does not promote the growth of microorganisms). Given the natural percolation of water through the soil environment, groundwaters typically are stable with little change in bacterial levels. However, the presence of methane, ferrous iron, reduced sulfur compounds, hydrogen gas, manganese, ammonia, and nitrite can serve as either carbon or energy sources that promote the growth of certain microbes. In some cases, excess ammonia levels have been related to serious bacterial growth problems (Wolfe et al., 1988; Rittmann and Snoeyink, 1984).

For surface waters, some treatment processes (including the type of coagulant, clarification process, filter media, and disinfection regime) can alter the biological stability of treated water (Volk and LeChevallier, 2000). Essential nutritive substances, including those naturally occurring and human-made, containing phosphorus, nitrogen, trace metals, and carbon are introduced in varying concentrations from source waters. These organics are discharged through municipal wastewater effluents, industrial wastes, and agricultural activities. While some of the nutrient content in dissolved organic carbon may be removed (20–80 percent) through conventional treatment, more attention to treatment refinements is needed to further reduce trace organic residuals. Applying ozone coupled with GAC or other equivalent biological treatment processes (e.g., for improved disinfection by-product precursor control) also can minimize the available organic materials and thereby provide fewer opportunities for microbial biofilm development and coliform growth. For water utilities with a relatively clean surface water source that rely only on disinfection treatment, a seasonal threat of organic contributions from humic substances, natural lignins, algal blooms, and recirculating bottom sediments during lake destratification always will exist. These organic materials pass into distribution pipe networks, where they stimulate growth of a wide range of aquatic bacteria. Unfiltered surface water supplies were found to be particularly susceptible to coliform growth by LeChevallier and colleagues (1996). Application of nanofiltration membranes can be effective for removal of many inorganic and large-molecular-weight carbon molecules, but small-molecular-weight substances may serve as nutrients for coliform growth downstream in the distribution system (Escobar and Randall, 1999).

Temperature. Water temperature affects all processes involved in microbiological water quality—microbial growth rate, disinfection efficiency, decay of disinfectant residual, corrosion rates, and distribution system hydraulics (increased water velocity from increased consumer demand) (LeChevallier, 1990). Water temperature above 10°C accelerates the growth of adapted organisms with slow generation times. On average, the occurrences of coliform bacteria in distributed water are significantly higher when water temperatures are greater than 15°C (Besner et al., 2001; Volk and LeChevallier, 2000; LeChevallier et al., 1996; Volk and Joret, 1994) and during summer months when water temperatures are at their highest. However, the minimum temperature at which coliform activity is observed may vary from system to system. Strains of coliform bacteria that are better adapted to grow at lower temperatures (psychrophiles) may be found in systems experiencing cold water.

Disinfectant Type and Residual. The maintenance of a disinfectant residual in distribution systems is recommended to control microbial regrowth and to act as a barrier against any contamination resulting from the loss of integrity of the system. Such a management

approach is widely accepted in North America and the United Kingdom and is endorsed by the World Health Organization (Ainsworth, 2004; Bartram et al., 2003). However, in several European countries, distribution systems are operated with low or no secondary disinfectant mostly because of concerns about the formation of disinfection by-products and low tolerance of chlorine taste and odor. For example, some utilities located in The Netherlands and Germany are successfully producing and distributing hygienically safe and biologically stable drinking water without a disinfectant residual (van der Kooij et al., 1999; Fokken et al., 1998). However, in order to adopt a low, or no, secondary disinfectant residual strategy, water suppliers apply extensive treatment to limit microbial regrowth and care to prevent distribution system contamination, which could be difficult for all water systems considering the age and vulnerability of some distribution infrastructures.

It is known that free chlorine is less efficient for the inactivation of biofilm bacteria than for bacteria present in bulk water (Parent et al., 1996; Van der Wende and Characklis, 1990). However, relatively low chlorine concentrations (0.05–0.5 mg/L) have, in some cases, been successful in controlling the presence of coliform bacteria in distribution systems (Besner et al., 2001; Volk and LeChevallier, 2000; Volk and Joret, 1994), especially when combined with a good biological stability of the treated water (Gatel et al., 2000). By contrast, it has been reported that even high free chlorine doses (between 0.6 and 4.0 mg/L) were ineffective in controlling coliform occurrences in some cases (Schreppel and Geiss, 1996; LeChevallier et al., 1987; Wierenga, 1985). Even though increasing chlorine residuals have helped to control coliform occurrence in some cases, high chlorine may not always be an acceptable solution owing to the formation of potentially carcinogenic disinfection by-products. LeChevallier and colleagues (1996) recommended maintaining at the far ends of the distribution system at least 0.2 mg/L of free chlorine or 0.5 mg/L of chloramines to limit coliform occurrences.

Although free chlorine is a more effective disinfectant than chloramines, research has indicated that in some cases chloramines may penetrate and control coliform bacteria in biofilms better than free chlorine (LeChevallier, 1991; LeChevallier et al., 1990). The penetration of free chlorine into a biofilm has been shown to be limited by its fast reaction rate (DeBeer et al., 1994), with the consumption of the free chlorine residual before it can react with the bacterial components of the film (Chen and Stewart, 1996). Because chloramines react more slowly, they can diffuse into the biofilm and eventually inactivate attached bacteria. Stewart and colleagues (2000) showed that free chlorine did not penetrate alginate beads containing bacterial cells, but chloramines did penetrate into the alginate material and reduced bacterial levels nearly 1 million-fold over a 60-minute interval (2.5 mg/L chloramines, pH 8.9).

A case illustrating the effectiveness of a chloramine residual for controlling coliform occurrences attributed to biofilm regrowth in distribution pipelines was reported by Friedman and colleagues (2009). As shown in Fig. 21-6, the system experienced coliform occurrences even when free chlorine residuals averaged between 2 and 2.5 mg/L in the distribution system (about June 1991 through May 1993). When m-T7 medium, a technique that recovers injured bacteria (LeChevallier et al., 1983), was used, coliform occurrence rates ranged between 10 and 40 percent even during months when coliforms were not recovered on the standard m-Endo medium. Conversion of the disinfectant to chloramines in June 1993 resulted in dramatic decreases in coliform occurrences measured by both m-Endo and m-T7 media, and the bacteria were not detected in the finished drinking water for the 3 years following the change (results are shown until April 1994 in Fig. 21-6) (Norton and LeChevallier, 1997).

The ability of chloramines to penetrate biofilms also has led to a better control of *Legionella* in water systems (Flannery et al., 2006; Pryor et al., 2004). In San Francisco, a prospective study was conducted on 53 buildings to measure the impact of a conversion from chlorination to chloramination on the prevalence of *Legionella* in hot water systems.

FIGURE 21-6 Coliform occurrence in a system before and after conversion from free chlorine to chloramines (coliform bacteria were enumerated using either m-T7 or m-Endo medium). (Source: LeChevallier et al., 1996.)

A striking decrease in the colonization of hot water systems from 60 percent before conversion to 4 percent after conversion led the authors to conclude that chloramination of municipal water systems decreases the risk for legionnaires’ disease (Flannery et al., 2006). However, another study found higher levels of mycobacteria after chloramination (Pryor et al., 2004).

Because chloramines are less reactive, the residual can be carried and maintained at the ends of the system, which is another important advantage of chloramination, particularly if the system does not have a large network of storage tanks where stagnation and nitrification may become a problem. However, chloramines generally are less efficient for controlling a sudden pulse of contamination (Snead et al., 1980; Besner et al., 2008a) and also may have other inherent problems (nitrification, corrosion) and should be implemented after considering water quality and other potential unintended consequences.

Bacterial Nutrients. In drinking water, the limiting nutrient for the growth of heterotrophic bacteria is usually the biodegradable fraction of dissolved organic carbon (DOC), expressed in terms of AOC or BDOC concentrations. AOC is determined using a bioassay (Van der Kooij, 1990, 1992) and measures the microbial response to biodegradable materials in water, whereas BDOC is the difference in the concentration of DOC before and after bacterial growth in a sample and measures the amount of nutrient readily available for bacterial growth (Joret and Levi, 1986).

Studies have shown that AOC (LeChevallier et al., 1987) and BDOC (Servais et al., 1992, 1995) generally decrease with increased water residence time in the distribution system, which would suggest carbon use by bacteria and subsequent growth. Thus, decreasing the AOC and BDOC content of the water leaving the plant will help to limit bacterial regrowth in distribution pipes. Recommendations regarding the threshold concentration of biodegradable organic matter below which water can be considered biologically stable have been offered. van der Kooij and colleagues (1989) proposed an AOC value of 10 µg/L, and Servais and colleagues (1995) suggested a BDOC value of 0.15 mg of carbon per liter. Volk and LeChevallier (2000) determined that AOC levels in 94 North American distribution

systems ranged from 20 to 214 $\mu\text{g/L}$, with a median of 100 $\mu\text{g/L}$, and that levels of BDOC from 30 North American water systems ranged from 0 to 1.7 mg/L , with a median level of 0.38 mg/L . Coliform occurrences in distribution systems have been associated with AOC concentrations greater than 50 $\mu\text{g/L}$ (LeChevallier et al., 1991) and 100 $\mu\text{g/L}$ (Volk and LeChevallier, 2000) and BDOC consumption in the distribution system higher than 0.15 mg of carbon per liter (Volk and Joret, 1994). Levels of AOC alone do not dictate the occurrence of coliform bacteria in drinking water but are only one factor. High water temperature, high AOC/BDOC levels, and low disinfectant residuals especially may result in microbial growth problems (Volk and LeChevallier, 2000).

Because heterotrophic bacteria require carbon, nitrogen, and phosphorus in a ratio of approximately 100:10:1 (C:N:P), organic carbon is often a growth-limiting nutrient. However, limitation of bacterial growth because of the availability of phosphorus also has been demonstrated in some distribution systems (Lehtola et al., 2002). In such cases, the use of phosphate-based corrosion inhibitors could lead to a decrease in biological stability of the water and result in regrowth (Miettinen et al., 1997). For nitrogen, it is generally assumed that it is not a growth-limiting factor. Excess ammonia resulting from the use of chloramination may result in the growth of nitrifying bacteria and in water quality problems related to nitrification (e.g., accelerated loss of chlorine residuals, increased nitrite levels, and stimulated growth of HPC bacteria). Rittmann and Snoeyink (1984) found that ammonia concentrations in groundwater supplies frequently were high enough to cause biological instability.

Corrosion, Pipe Materials, and Sediment Accumulation. Water mains, storage reservoirs, standpipes, joint connections, valves, service lines, and metering devices have the potential to be sites suitable for microbial habitation. No pipe material is immune from potential microbial colonization once suitable attachment sites are established. Given sufficient time, aggressive waters or microbial activity will initiate corrosion of metal pipe surfaces, and water characteristics may change the surface structure of asbestos/cement mains. The nature of the water chemistry and continuous movement of water under high-velocity conditions helps to prevent the buildup of chemical and microbial species that contribute to corrosion and pitting. Therefore, not all pipe sections may show evidence of deterioration even after years of active service.

Corrosion of pipe surfaces provides not only a habitat for bacterial proliferation but also is a source of substrate and protection from chlorine disinfectant residuals. In drinking water systems, the occurrence of coliform bacteria in corrosion tubercles on iron pipes has been reported by a number of investigators (Clement and Snoeyink, 1998; Emde et al., 1992; LeChevallier et al., 1987). Laboratory studies showed that the densities of HPC and coliform group bacteria were 10 times higher when grown on mild steel coupons than on noncorroded polycarbonate surfaces (Camper, 1996). The increased surface area owing to tuberculation of the pipe walls, the concentration of organic substances within the tubercles, and the secretion of organic compounds by iron-using bacteria have been postulated as reasons why iron corrosion stimulates bacteria growth.

LeChevallier and colleagues (1990) showed that the disinfection of biofilm on galvanized, copper, or PVC pipes was effective at 1 mg/L of free chlorine or monochloramine, but disinfection of organisms on iron pipes was ineffective even at free chlorine residuals as high as 5 mg/L for several weeks. Follow-up studies showed that a combination of the corrosion rate, the ratio of the molar concentration of chloride and sulfate to bicarbonate (known as the *Larson index*), the chloramine residual, and the level of corrosion inhibitor could account for 75 percent of the variation in biofilm disinfection rates for microorganisms grown on iron pipes (LeChevallier et al., 1993). It is generally agreed that unlined iron pipes induce the highest level of attached bacterial densities (Laurent et al., 2005), although site-specific conditions (nature and quantity of organic material present) may

influence biofilm growth on various materials (Clement et al., 2003). The accumulation of fixed bacteria is also more rapid on iron than plastic surfaces [PVC and medium-density polyethylene (MDPE)] (Norton and LeChevallier, 2000; Kerr et al., 1999). Therefore, the choice of pipe material and the accumulation of corrosion products can have a dramatic impact on the ability to control the effects of biofilms in drinking water systems. Besides, biofilm bacteria also may play an important role in pipe corrosion. Iron-using bacteria (such as *Gallionella*) and sulfur-using bacteria (such as *Thiobacillus*) are the bacteria most often associated with pipe corrosion.

Coliform colonization of the pipe network also may occur in areas where porous sediments accumulate (Lu et al., 1997; Oliver and Harbour, 1995). These sediments may originate from the incomplete removal of particles from raw water, release of fines from filters, precipitation of metal oxides or calcium carbonate, external contamination in pipes and reservoirs, postflocculation, biological growth, and corrosion and then settle in low-flow and dead-end areas. Such sites are attractive to bacterial colonization because these deposits adsorb trace nutrients from the passing water and provide numerous surface areas for bacterial attachment against the flow of water. Although usually mostly mineral in nature, pipe and reservoir deposits include variable fractions of organic matter (Carrière et al., 2005; Gauthier et al., 1999b). The mineral fraction acts mainly as a support for bacteria, whereas the organic matter concentration drives the number of microorganisms (Gauthier et al., 1996). Sediments are problematic because they can shield microorganisms from disinfectants, exert a high disinfectant demand, and be the source of aesthetic problems when rapid changes in velocity, flow direction, or turbulence take place.

Residence Time and Hydraulic Effects. Various changes in water quality such as bacterial regrowth, loss of disinfectant residual, nitrification, formation of disinfection by-products, taste and odor problems, and water discoloration may result from high water age. Storage facilities and dead-end mains where water velocities and turnover can be very low are locations that are more susceptible to water quality degradations.

Long water retention time may result from the mixing characteristics prevailing in storage tanks (short circuiting, stagnation zones), their operation, and location in the distribution system. Water is often not drawn from the bottom of distribution storage tanks, so accumulations of sediments may occur. These sediments can contribute significant amounts of assimilable organic complexes that support bacterial colonization of the distribution network. Loss of disinfectant residuals has been observed in storage tanks (Gauthier et al., 2000; Rossman et al., 1995). Subsequent microbiological proliferation such as coliform occurrences (Gauthier et al., 2000) and nitrification episodes (Baribeau et al., 2000; Burlingame et al., 1995) have been linked directly to tank operation in distribution systems. Dead-end mains may be characterized by long water residence times, which may result in lower chlorine residuals, higher turbidity, and higher HPC and iron concentrations (Barbeau et al., 1999), although microbial levels are not always higher systematically. This could be due to settling of bacteria during stagnant or low-flow conditions in the water main (Carter et al., 1997) or to the limited amount of nutrients supplied to the biofilm because of low water usage or their consumption by upstream biofilm (Lu et al., 1997).

Abrupt changes in flow conditions may result in biofilm being detached from the pipe wall and may lead to microbial water quality variations. Increase in shear stress can lead to a significant increase in effluent suspended bacteria concentration (Choi and Morgenroth, 2003). Bacterial levels in an experimental system were found to increase 10-fold when flows were started and stopped (Opheim et al., 1988). Reversal of water flows within the distribution system also can shear biofilms, and water hammer can dislodge tubercles from pipe surfaces (Lehtola et al., 2006). Clumps of bacteria were observed (using epifluorescence microscopy and on-line particle counters) following flow changes in a 1.3-km experimental drinking water distribution system (Maier et al., 1999).

Nitrification. Nitrification is a microbial process by which reduced nitrogen compounds (primarily ammonia) are sequentially oxidized to nitrite and nitrate. Nitrification can result in rapid loss of chloramine residual and considerable microbial growth, among other water quality transformations, all of which can be problematic in potable water distribution systems that use chloramines for residual (secondary) disinfection. A nitrification episode typically begins with steadily decreasing total chlorine residuals, increased heterotrophic bacteria counts (HPCs), free ammonia decreasing to near zero milligrams per liter, and increasing nitrite levels up and above 0.05 mg/L of nitrogen. The rapid increase of AOB in the bulk water (or attached to sediments, in biofilms, on pipe walls, or on reservoirs liners) results eventually in complete or almost-complete loss of total chlorine residual, conversion of free ammonia to nitrite and nitrate, and often a decrease in pH (AWWA, 2006b).

There are numerous conditions that can contribute to nitrification in distribution systems. These include

- Inadequate chloramine dose, resulting in insufficient inactivation of nitrifying bacteria
- Improper chlorine-to-ammonia ratio, resulting in excess ammonia entering the distribution system
- Excessive chloramine demand, resulting in liberation of free ammonia and reduced total chlorine residuals
- Unstable chloramine residual, resulting in autodecomposition and liberation of free ammonia
- Increased temperature associated with seasonal variations or extended water age in storage facilities or low-flow areas of the distribution system
- Unstable finished water pH and alkalinity, which affect the stability of the monochloramine residual and AOB inactivation
- Other distribution system characteristics, such as biofilm and scale/sediment buildup that can exert a disinfectant demand
- Blending chlorinated and chloraminated sources, resulting in nonoptimal chlorine-to-ammonia ratios

The AWWA Manual M56, *Fundamentals and Control of Nitrification in Chloraminated Drinking Water Distribution Systems* (AWWA, 2006b), provides an in-depth discussion of nitrification causes and control strategies.

Recontamination of the Distribution System

Deteriorated and badly maintained infrastructure used for distribution of drinking water certainly may lead to intrusion of pathogenic microorganisms into the distribution system. Loss of a distribution system's integrity may result in waterborne disease outbreaks, as in the case of Gideon, Mo., where contamination originating from a poorly maintained storage tank resulted in the death of 7 people and 600 others being sick owing to a *Salmonella* outbreak (Clark et al., 1996). However, intrusion of pathogenic microorganisms may take place even in relatively well-maintained systems through four direct routes of entry that include (1) cross-connections, (2) transitory contamination events through water main leakage points and other orifices, (3) covered and uncovered storage facilities, and (4) water main installation and repair sites (Kirmeyer et al., 2001). External contamination events may result in the introduction of microorganisms (that can colonize the pipe system), nutrients, and sediments and decreased residual disinfectant concentrations.

Cross-Connections. A *cross-connection* is defined as a connection between the potable drinking water supply and a nonpotable, undesirable, or contaminated source. Cross-connections pose a threat to distribution system integrity if they are not protected or if the device used for protection fails. Contaminated water may be introduced into distribution pipes from the backflow of water through the cross-connections owing to a differential in pressure between the connected systems, especially during low-pressure events in the distribution system (backsiphonage) or increased pressure from a nonpotable source (backpressure).

In the United States, the USEPA has compiled data from 459 backflow incidents and estimated 12,093 illnesses owing to those incidents between 1970 and 2001 (USEPA, 2002a). Two outbreaks were reported in Finland with cross-connections involving sewage and seawater, both showing evidence of the presence of *E. coli* (Lahti and Hiisvirta, 1995). In the Netherlands, cross-connection incidents between the drinking water supply system and water supply for nonpotable use was one of the reasons leading to the termination of projects where a dual water supply was installed in some new housing estates (Oesterholt et al., 2007).

Cross-connections can result in either chemical or biological contamination of the drinking water supply. Some common types include irrigation, fire systems, garden/washdown hoses, and boilers. Different degrees of hazard may be associated with cross-connections depending on the type of fluid to which the pipe is connected. For example, Duranceau and colleagues (1998) showed that fire systems may be less of a risk in terms of microbial contamination. Total coliforms were mostly absent from the 84 wet-pipe fire sprinkler systems investigated. The situation could be quite different in a case where the plumbing fixture was mistakenly connected to sewage.

Biological contaminants introduced through cross-connections are reported most often as sewage or nonspecific microbes, but pathogens such as *Giardia* and some strains of *E. coli* have been associated with cross-connection contamination events (USEPA, 2002a). Because of the pressure drop induced (and some other site-specific favorable conditions), some maintenance activities (meter repair, main shutdown for valve replacement, and main break) may result in backflow of contaminated water into distribution systems.

Most cross-connections generally take place inside the private plumbing system of the customer. A survey compiled from 719 water utilities showed that 83 percent of documented cross-connections were in private buildings, whereas 16 percent were in areas under the direct control of the water utility (Lee et al., 2003). Although more than half (55.5 percent) of the cross-connections identified by utilities were connected to non-health hazards, 39 percent were connected to health hazards and 5.5 percent to sewage. In the United States, although the program requirements may vary widely between states, 50 states have a requirement for some control of cross-connections and/or backflow prevention (USEPA, 2002a).

Intrusion of Contaminants. Transitory contamination events are related to the intrusion of contaminants into drinking water distribution systems resulting from the occurrence of low or negative pressures in water mains. In comparison with backflow events through cross-connections, *intrusion events* refer to the flow of nonpotable water into mains through pathways such as leakage points, submerged air valves, faulty seals, or other openings (LeChevallier et al., 2002). Pressure transients (also referred to as *surges* or *water hammers*) are caused by abrupt changes in the velocity of water, and multiple factors may lead to their occurrence (Table 21-4).

In a distribution system, intrusion events will result from the combination of three conditions: (1) occurrence of low or negative pressure, (2) presence of a pathway for intrusion, and (3) availability of a contaminant in the soil or water surrounding a pipe. Intrusion events can take place even if the pressure in the pipe remains positive, provided that the external

TABLE 21-4 Causes of Transient Pressure Events in Distribution Systems

Cause	Example

pressure on the pipe is greater than the internal water pressure. Leaking pipes located in areas of high water table would be locations with a high potential for intrusion when negative-pressure events take place. Although no data are available on the actual measurement of intruded material owing to the occurrence of low/negative-pressure transients in full-scale distribution systems, the following observations are discussed next.

Low- and Negative-Pressure Transients Occur in Full-Scale Distribution Systems. One of the first occurrences of low-pressure transients to be reported was by Walski and Lutes (1994). These were found to be caused by pump and valve operation. More recently, the measurement of transient pressures has been facilitated with the use of high-speed pressure-transient data loggers. This type of equipment allows the recording of several pressure measurements per second, thus helping in the detection of short transient events (that can last only a few seconds) that likely would go unnoticed with standard pressure recorders. Since 2000, several Water Research Foundation (formerly Awwa Research Foundation or AwwaRF) studies have been published on the investigation of low/negative-pressure transients in distribution systems (Kirmeyer et al., 2001; Friedman et al., 2004; LeChevallier et al., 2003; Fleming et al., 2006). Transient null (zero) or negative-pressure events have been reported by Gullick and colleagues (2004), Hooper and colleagues (2006), and Besner (2007) and Besner et al. (2010). In these studies, the main cause of negative pressure was identified as a sudden shutdown of pumps (at a treatment plant or pump station) owing to either unintentional (power outages) or intentional (pump stoppage/startup tests) circumstances or as a pressure drop at the point of entry in the system.

Microbial Contamination Present in the Vicinity of Some Intrusion Pathways. Possible pathways for pathogen intrusion include the ones related to pipeline structural integrity: pipe fracture/leaks, deflections at flexible couplings, leaking joints, and deteriorating seals. Leakage rates corresponding to 10 percent of the water produced are not uncommon in distribution systems (with some systems having even higher values). Consequently, leak-detection programs usually are recommended to minimize the risk from transitory events as well as for other economical and operational considerations. Analyses of soil and water samples collected at sites immediately exterior to drinking water pipelines during pipe

repairs have shown various levels of microbial contamination. Karim and colleagues (2003) detected indicator microorganisms (total and fecal coliforms, *C. perfringens* spores, *B. subtilis* spores, and coliphage) and enteric viruses (detected by cell culture and RT-PCR) in more than 50 percent of the 65 samples examined from eight distribution systems. Fifty-six percent of the 32 sites investigated were positive by either cell culture or RT-PCR for one of the three viruses tested (enterovirus, Norwalk virus, and hepatitis A virus). A similar study by Besner et al. (2008b) showed lower evidence of fecal pollution and enteric viruses in the soil/water surrounding water mains in two Canadian distribution systems. In this case, *E. coli* was detected in only 1 soil sample out of 17, and no culturable enteric viruses were detected. The distance between the sewer and drinking water pipes, the conditions of soil saturation, and the geologic structure of the area are factors that can influence the level of fecal contamination detected. Leaking sewer mains certainly can contaminate the soil surrounding drinking water pipes because microorganisms can migrate significant distances in soil through macropores, worm holes, cracks, and fractures (Abu-Ashour et al., 1994). Transport mechanisms in soil involve advection and dispersion, which are influenced by the effects of filtration, adsorption, desorption, growth, decay, and sedimentation.

Submerged air-vacuum valves can be another pathway for microbial intrusion. These valves are specifically designed to exhaust large quantities of air when a pipe is being filled or to let air inside the main to prevent vacuum conditions from developing. Accordingly, the orifice may reach up to 600 mm (24 in) in some cases, providing a large entry point for contaminated water into the system if the orifice is completely flooded. In the United Kingdom, McMath and Casey (2000) measured subatmospheric pressures at one distribution system point downstream of a pumping station during surges. The authors observed that this point (an air-valve vault) was flooded with dirty water during wet weather, thus explaining the high coliform failure rate in the corresponding distribution system area. Flooded air-valve vaults may not be that uncommon. Besner (2007) and Besner et al. (2010) were able to collect water samples from 67 percent of 45 air-valve vaults in a distribution system, and 22 percent of these vaults had completely submerged air valves. In a survey of 26 water utilities, 12 utilities indicated that the number of flooded air-valve vaults in their system could vary between 0 to 80 percent of total vaults (Kirmeyer et al., 2001). The accumulated water found in air-valve vaults also may be contaminated with various microorganisms. Besner et al. (2010) found that the frequency and level of detection of various fecal indicator microorganisms (*E. coli*, *C. perfringens*, coliphages) were higher in the water from flooded air-valve vaults than in the soil and water from pipe trenches of a distribution system, although no enteric viruses were detected either by cell culture or by RT-PCR. The level of fecal contamination in the various sources investigated (soil and water from trenches and water from air-valve vaults) was more typical of that found in river water rather than in wastewater.

The evidence that intrusion of contaminated water may take place under negative-pressure transients has been demonstrated under pilot-system simulation conditions (Boyd et al., 2004a, 2004b). The use of a chemical tracer (cesium) method provided strong laboratory evidence that intrusion can occur during transient pressure events and that part of the intruded material remains in the pipe. Other information related to intrusion volumes has been obtained through the use of transient/surge analysis. Calculation of intrusion volumes under different scenarios such as power loss, main break, and fire flow have been performed, but the results were not field verified and served as a comparison purpose only (Kirmeyer et al., 2001; LeChevallier et al., 2003). It should be noted that there are many uncertainties involved in the modeling of intrusion volumes, and this is still a developing science.

Storage Facilities. The presence of open finished water reservoirs has been associated with microbial water quality problems (such as increased coliform occurrences) in distribution systems (LeChevallier et al., 1996). Such uncovered storage facilities are subject to

microbial contamination from fecal material from birds and small mammals that come in contact with the water, air contaminants, and surface water runoff. The health concern with bird excrement is that this wildlife may be infected with *Salmonella* and pathogenic protozoa. Within the wildlife population in every area (as is true for any community of people), a persistent pool of infected individuals exists that shed pathogenic organisms in their fecal excretions. Sea gulls are scavengers and often are found at landfill locations and waste-discharge sites searching for food that is often contaminated with a variety of pathogens. At night, birds often return inland to aquatic areas, such as source water impoundments and open finished water reservoirs, to roost, thereby introducing pathogens through their fecal excrement. Increased protozoa concentrations have been measured following open reservoir storage, although the organisms appeared to be nonviable (LeChevallier et al., 1997). Air pollution contaminants and surface water runoff can contribute dirt, decaying leaves, lawn fertilizers, and accidental spills to a water supply that is not covered. Such materials increase productivity of the water by providing support to food-chain organisms and nitrogen-phosphate requirements for algal blooms. This degrades the treated water quality.

For covered storage facilities, appurtenances such as access hatches, overflow pipes, vents, roofs, and poorly constructed sidewall joints are potential portals of entry for airborne microorganisms. Air movement in or out of the vents as a result of water movement in the structure could lead to occasional contamination. During air transfer, the covered reservoir is exposed to fallout of dust and air pollution contaminants from the inflowing air. Air vents with defective screen protection also may allow birds and rodents to gain access to the tank. Bird or rodent excrement around the vents may enter the water supply and become transported into the distribution system before dilution is able to dissipate and residual disinfection inactivate the associated organisms. Tears or rips in floating covers can lead to the loss of chlorine residual (Harvey and Kopansky, 2007) or to contamination of treated water with accumulated rain water, potentially contaminated by bird droppings (Kirmeyer et al., 1999). Inadequate maintenance of a municipal water storage tank was identified as the cause of a *Salmonella* outbreak reported in Gideon, MO, in 1993 (Angulo et al., 1997; Clark et al., 1996). Pigeons roosting in elevated storage tanks were believed to be the source of *S. typhimurium* that contaminated the water supply.

Main Installation and Repairs. Water main repairs have been associated with waterborne disease outbreaks. In Cabool, Mo., record low temperatures in December 1989 caused 43 outdoor service meters to freeze and two major distribution lines to break (Geldreich et al., 1992). The meters had to be replaced (some were found to be submerged under water) and the pipes repaired. It is believed that contaminated runoff from an undersized and deteriorating sewer collection system found to be overflowing through manholes could have entered the system while the repairs were conducted. An outbreak of hemorrhagic *E. coli* serotype O157:H7 resulted from this contamination and caused 243 known cases of diarrhea and 4 deaths in the population of 2090 inhabitants. In Sweden, a waterborne disease outbreak affecting 10,000 people was due to a pipeline containing stagnant raw water that was brought into use without first being flushed (Andersson and Bohan, 2001). In France, the servicing of a large transmission main [600 mm (24 in)] after several weeks of construction work corresponded with an increase in diarrhea among the population, although the number of affected people could not be evaluated (Deshayes et al., 2001). Approximately 60,000 people were without drinking water for a 15-day period because fecal coliforms and sulfite-reducing clostridial spores were detected in the water.

Corrosion, unstable soil, faulting, land subsidence, extreme low temperatures, and other physical stresses often cause line breaks and necessitate repair or replacement of pipe sections. To avoid possible bacteriologic contamination of the water supply during these construction projects, a rigorous protective protocol must be followed. Microbial contamination arising from pipe repair activities can take place prior to, during, and after construction/repair work. Some potential contamination sources are listed in Table 21-5.

TABLE 21-5 Potential Sources of Contamination During Water Main Repairs

Phase	Potential contamination source	Relative level of risk	
		Common	Higher risk
Preinstallation exposure	Soil/sediment entry	X	
	Animal/human wastes		X
	Dead animals		X
	Unsanitary human contact	X	
	Incidental dirty water (runoff, sprays)	X

Preinstallation contamination sources may deposit significant fecal material in the interior of pipe sections awaiting installation. Once introduced, this fecal material may become lodged in pipe fittings and valves. Thus such sites become protected habitats from which coliforms and any associated pathogens in the contaminated material may be released into the bulk flow of water supply. A case of contamination prior to installation has been reported by Haas and colleagues (1998). Although swabs of an internal surface of a 305-mm (12-in) pipe stored on the curbed side of the street and exposed to the local environment were negative for the presence of total coliforms, 75 percent of the swabs were positive for noncoliform bacterial growth on membrane filters, and 100 percent were positive for HPCs. The presence of noncoliform growth can be used as an indicator for contamination (as done by the Philadelphia Water Department), reflecting some impact of pipe storage conditions prior to installation. In Halifax, Nova Scotia, a new pipeline was found to contain pieces of wood used during construction work (Martin et al., 1982). Coliform bacteria from the wood were transported downstream, resulting in persistent positive bacteriologic results. Since the wood debris was difficult to remove, the problem was resolved by the addition of more than 5 mg/L of lime to the process water, which elevated the water pH to 9.1 in the distribution system. At this pH, *Klebsiella* were either inactivated or entrapped in the resulting carbonate scale, and the problem was eliminated.

During repair activities, the main points of concern are unsanitary construction practices and contamination from soil and trench water exposure [from a survey of 250 water utilities conducted by Haas and colleagues (1998)]. Soil and water found in main repair trenches may be contaminated with various levels of fecal indicators and pathogenic microorganisms (Karim et al., 2003; Besner et al., 2008b). Factors that may affect the potential for contamination during repair work include shutdown time, nature of the

excavation, method of repair, storage or cleanliness of materials, and size of the job. As such, to minimize the potential contamination, main repairs should be conducted *under pressure*, where the water main is not isolated or completely shut down by closing valves. However, this may not always be feasible, and many water utilities report that repairs of water mains under pressure are not conducted (Kirmeyer et al., 2001). Water quality changes also may take place in areas adjacent to construction or repair sites. Valves that are closed to isolate the section of main to be repaired may result in changes in flow direction and temporary dead ends in the network area still providing water to customers. In such areas, loss of chlorine residuals can take place (Besner et al., 2008b). When flushing of the repaired main is conducted, upstream distribution system areas also may see increases in turbidity, especially if the utility does not conduct a unidirectional flushing program. Increase in the water velocity may result in the resuspension of accumulated sediments.

After the repair is completed, flushing of the pipe, disinfection, and water quality testing are the recommended actions for contamination control (Pierson et al., 2001). Besner et al. (2008b) investigated 16 planned water main repairs to evaluate the risk of microbial contamination associated with this activity in two chlorinated distribution systems. Overall, 424 water samples were collected from customers' homes and flushed hydrants, and 4 percent of these were found positive for total coliforms. All but one positive sample were collected during the flushing step, suggesting that adequate pipe flushing was effective in removing potential contamination from the distribution system. In this study, *E. coli* was detected on one occasion in the water flushed from a hydrant. In the Netherlands, results of water quality testing after invasive distribution system operations provided by three water companies showed that 0.57 percent of 16,047 water samples collected after operations contained *E. coli* or thermotolerant coliforms (van Lieverloo et al., 2006). A study in Norway investigated the link between pipe breaks and maintenance work (with presumed loss of water pressure) in distribution systems and risk of gastrointestinal illness among water recipients (Nygård et al., 2007). Following 88 low-pressure episodes taking place in seven distribution systems, exposed and unexposed households were selected and interviewed. During a 1-week period after the episode, 12.7 percent of the exposed households reported HCGI compared with 8 percent in the unexposed households showing an increased risk of HCGI for households exposed to pressure-loss events. Unfortunately, little water quality data were available to correlate with the results obtained. Water samples were available for only 18 episodes, and one sample was found positive for *E. coli*. No information regarding the level of residual disinfectant used in the distribution systems was given.

MONITORING DISTRIBUTION SYSTEMS

Water quality in distribution systems depends on a series of complex reactions that vary in both space and time, making it difficult to accurately assess the true status of water quality. To maximize the value of the investment in monitoring, a carefully designed sampling program should be implemented.

Water utilities in the United States collect samples from distribution systems to meet the requirements of several different regulations, including the Total Coliform Rule (TCR) and the Disinfection By-Product Rule (DBPR). Yet utilities are given little guidance from regulatory agencies about the collection of samples from the distribution system, particularly regarding the time and location of sample collection. For example, the requirements for the selection of sampling sites for coliform monitoring vary widely from state to state

(Narisimhan et al., 2004). In addition to regulatory sampling, utilities often conduct operational monitoring and special sampling for a variety of different goals.

Regulatory Requirements

The USEPA regulates water quality in the distribution system for U.S. water utilities under several different rules. Utilities must meet regulatory requirements for disinfectant residual, disinfection by-products, lead and copper, and total coliform bacteria. The USEPA in 2007 and 2008 convened a Federal Advisory Committee to revise the total coliform rule (TCR), including provisions related to monitoring (USEPA, 2008b). Water utilities perform a significant amount of distribution system water quality monitoring to meet these regulatory requirements, as summarized in Table 21-6.

TABLE 21-6 Water Quality Parameters and Associated U.S. Federal Regulations for Water Distribution Systems

Parameter	Sample location	Regulatory limit	Reference	Comments
Disinfectant residual*	Entry point to distribution system	Minimum 0.2 mg/L on a continuous basis	Surface Water Treatment Rule (SWTR)	Only applies to systems using surface water supplies or groundwater supplies under the influence of surface water. In U.S., <i>Legionella</i> is also regulated by a treatment technique
Disinfectant residual	Distribution system	Maximum residual disinfectant level (MRDL) for chlorine of 4.0 mg/L; MRDL for chloramine 4.0 mg/L, running annual average	D/DBP Rule Stage 1	Applies to all public water systems that add a primary or secondary disinfectant to the water
Disinfectant residual or heterotrophic bacteria count	Throughout distribution system	Detectable level of disinfectant residual or heterotrophic bacteria count of 500 or less CFU/mL in 95% of samples collected each month for any two consecutive months	SWTR	Only applies to systems using surface water supplies
Total trihalomethanes (TTHMs)	Throughout distribution system	80 µg/L, locational running annual average based on quarterly samples	D/DBP Rule Stage 1	
Haloacetic acids (HAA5)	Throughout distribution system	60 µg/L, locational running annual average based on quarterly samples	D/DBP Rule Stage 1	

(Continued)

TABLE 21-6 Water Quality Parameters and Associated U.S. Federal Regulations for Water Distribution Systems (*Continued*)

Parameter	Sample location	Regulatory limit	Reference	Comments
Total coliform bacteriaw	Throughout distribution system	5% positive for systems collecting ≥ 40 samples per month. >1 positive for systems collecting < 40 samples per month	Total Coliform Rule	Number of samples determined by population served (generally 1 sample per 1,000 people served per month).
Lead and copper	At customer taps	Action levels: Lead 0.015 mg/L at 90% Copper 1.3 mg/L at 90%	Lead and Copper Rule	Number of samples determined by population served

*Disinfectant residual may be regulated for some systems using groundwater supplies under the forthcoming Groundwater Rule.

Source: Speight et al., 2009.

In addition to regulatory sampling, utilities often conduct additional sampling for specific projects. These projects may include assessment of the impact of operational adjustments and determination of compliance with future regulations. Water quality and pressure monitoring are used to help evaluate and optimize distribution system operational issues such as pressure maintenance, water age, nitrification, blending, storage tank operations, and emergency response. Water quality monitoring is also an important tool in planning and conducting maintenance activities. For example, color and turbidity data may be used to prioritize areas to be flushed and cleaned. Water quality testing can be viewed as a nonintrusive method for inspecting water mains and can be used to identify an underground leak by distinguishing between natural groundwater and treated water (Speight et al., 2009).

Measurement of Water Quality Parameters

The value of water quality data is influenced by the practices and procedures used to collect representative samples. Sample collection methods include grab sampling from taps or dedicated sampling devices and on-line continuous sample collection and analysis. Standard sample collection procedures are described in various AWWA publications (AWWA, 1985, 1990). Additional guidance can be found in American Society for Testing and Materials (ASTM) Standard D3370 for grab, composite, and continuous sampling and ASTM Standard D4840 for sampling chain-of-custody forms as well as in *Standard Methods for the Examination of Water and Wastewater* (APHA et al., 2005).

General Sampling Techniques. Water quality samples must be collected with care to minimize contamination and ensure meaningful results. Each test parameter that will be evaluated in the laboratory has a unique collection and storage requirement. Essential elements for the collection of good distribution system samples and associated field data include overall cleanliness of the sampling site, proper preparation of the sample collection container, adherence to aseptic sampling techniques, and proper transportation of samples (Kirmeyer et al., 2000).

Grab samples can be collected from sampling taps in a secure building, vault, or finished water storage facility. Ideally, the tap would be dedicated for water quality sampling only. Sample taps in a finished water storage facility can provide sample collection from several fixed depths and eliminate the time and safety concerns that may be involved in sampling through the access hatches. Dedicated sampling stations offer many advantages over the more traditional faucet or dedicated sampling tap. Burlingame and O'Donnell (1994) give examples of these advantages, which include the ability to sample water flowing in the mains without any potential impact from or interference with a sample site's internal plumbing, accessibility to areas where access to public buildings or residential sites is limited, as well as the ability to be disassembled, cleaned, and sanitized at regular intervals. Disadvantages of using dedicated sampling stations include a susceptibility to vandalism and the need to plan for the safe disposal and dechlorination of water flushed from these devices (Speight et al., 2009).

Burlingame and Choi (1998) explain why sampling from hydrants may not yield samples representative of the distribution system: "Hydrants are designed to be fully opened or closed. There is a drainage channel and port in a hydrant that allows water trapped in the barrel to drain out when the hydrant is shut down. If the hydrant is not open all the way, this drain hole is not closed all the way and water from the drain area can be siphoned back into the water flowing through the barrel."

Sampling in storage tanks can be performed using a depth-sampling device, also commonly used for lake sampling, that has been cleaned and disinfected. Such sampling devices are designed to be engaged and closed at predetermined depths within the storage facility, enabling sampling at varying depths from a single entry point. To ensure that a consistent sampling depth is maintained between sampling periods and among sampling teams, a calibrated cord should be employed when lowering the sampler to a prescribed depth (Kirmeyer et al., 1999). Alternatively, a sampling pump can be used to collect a grab sample at an access hatch (Speight et al., 2009).

On-Line Monitoring. On-line monitoring equipment offers utilities an opportunity to collect continuous data from strategic points in the distribution system. While chlorine residual is the most commonly monitored parameter in the distribution system, on-line monitors are also used for pH, turbidity, color, conductivity, oxidation reduction potential (ORP), temperature, total organic carbon (TOC), UV-254, and system pressure. The primary limitations of on-line monitoring at this time are technology and cost, but advances may make on-line monitoring for a wider range of parameters more readily usable in the future. General reviews of on-line monitoring technology are available in AWWA (2006a), USEPA (2005a), ASCE (2004), and AwwaRF (2002).

Prior to 2001, on-line monitoring in distribution systems generally was limited to chlorine monitors in some larger utilities. With the increased water security concerns following the terrorist attacks of 2001, the water industry sought an available technology that could detect a wider range of potential contaminants. The primary solution has been the installation of an array of available monitors that, in tandem, hopefully would respond to a broad range of contaminants. A panel or suite of monitors typically will consist of some or all of the following monitors: pH, conductivity, temperature, ORP, turbidity, dissolved oxygen (DO), pressure, chlorine, and total organic carbon (TOC). Recently, UV spectrophotometers have been installed in some systems as a surrogate for TOC. An automated sampler that is activated when one or more of the monitors trigger an alarm is also frequently included (Grayman et al., 2007).

It is generally recognized that chlorine and TOC are the two most important components in detecting and maybe identifying the broadest range of contaminants. An approximate cost for all the instruments just described is in the \$40,000 to \$50,000 range (2009 dollars). However, depending on the specific location and availability of shelter, electricity, sewer, and related items, the fully installed cost could increase to \$250,000 or even more (Grayman et al., 2007).

Other advanced on-line monitors that have been used (less commonly) to monitor water in distribution systems include gas chromatographs, fluorometers, photoionization units, and radiation monitors. In general, these instruments are relatively expensive and have been used very sparingly in distribution systems with installation primarily in laboratory settings. There is also experimental use of biological monitors in distribution systems. These instruments monitor the response of living organisms such as fish, mussels, algae, daphnia, and bacteria to the water and set off an alarm when an unusual response is seen. Although used quite widely as part of early-warning systems in rivers, their adaptation to distribution systems has been slow owing to cost, maintenance, and the need to dechlorinate the water. Various grab sample and manual tests have supplemented on-line monitoring primarily as part of a screening or confirmation process. These tests include toxicity tests, PCR, and immunoassays (Grayman et al., 2007).

There are many emerging technologies within the monitoring area. These include on-line toxicity tests, ultrafiltration for contaminant concentration and separation, automatic pathogen detection (APD) systems, microchip technology, cell and tissue biosensors, and multi-angle light-scattering measurements. In most cases, these technologies are being developed by commercial interests. Actual implementation for these technologies as affordable and dependable products is likely to be 2 to 10 years in the future (Grayman et al., 2007).

Theoretical Approaches to Sampling Plan Design

While the practical aspects of sampling for water quality in distribution systems, such as access to suitable sample sites, often dictate the sampling plan design, there are elements of theoretical sampling theory that can be applied to strengthen confidence in the data that are collected. Randomization is an important part of a statistically based sampling methodology. When samples are selected without using randomization, bias can be introduced into the results. For water quality in distribution systems, samples collected from locations receiving fresh water from the treatment plant may not reflect the water quality in remote areas of the system, possibly giving a false impression that water quality is acceptable everywhere. The degree of bias introduced by the use of nonrandom sampling depends on the variability in the system under investigation. If the parameters being sampled are relatively constant over space and time, the amount of bias from nonrandom sampling may be negligible. Logistically, it is difficult for water utilities to sample at all locations throughout a distribution system, so the goal of true random sampling may not be achievable. However, utilities should strive to design sampling programs that incorporate some elements of sampling design theory to maximize the effectiveness of their investment in sample collection and analysis.

The critical first step in developing a sampling protocol for a water distribution system is to define the goal of the sampling event. Often there will be multiple sampling goals. For quality-control purposes, the sampling goal may be to ensure that a certain percentage of the samples meets a predetermined water quality level (e.g., free chlorine concentration above 0.2 mg/L). For operational purposes, a sampling program may be designed to identify areas of the system where water quality problems are occurring (e.g., in cast iron pipes or in a specific pressure zone). The goal of the sampling program dictates the total number of samples to be collected and the allocation of samples across space and time.

Number of Samples. Sampling is used to estimate information about a population, which in this case is the population of all water quality samples in a distribution system, by collecting a small number of data points. Information from the small number of samples then is used to estimate properties about the population. The total number of samples n required to meet a sampling goal can be calculated for a given sampling program based on the desired precision of the estimate and historical information about the system to be sampled.

A commonly used measure of precision for an estimate obtained from samples is the margin of error d . The precision of an estimate is linked to the variability in the parameters being sampled. An upper bound on the number of samples that would be required to provide a given margin of error at a desired confidence level can be determined using simple random sampling variance estimator (Kish, 1995):

$$V = \frac{S^2}{n} = \left(\frac{d^2}{t^2} \right) \tag{21-3}$$

where V is the variance of the estimate, t is the Student's t statistic for the desired confidence level (equal to 1.960 for the 95 percent confidence level, two-tailed), S is the standard deviation, and n is the sample size. Historical data or data from other similar studies can be used to estimate S for the system and parameter to be sampled. Equation 21-3 does not depend on the size of the population, which in this case is the total of all potential 100-mL samples of water quality throughout the distribution system, because it is assumed that the population is much greater in size than the number of samples. For cases where the population is closer in size to the sample, a finite population correction factor would be added (Kish, 1995).

Selection of the appropriate margin of error for a sampling program also must consider the accuracy of the analytical method. If a test method has a large analytical error, a larger sample size will be required to estimate parameters accurately from the data set.

Example 21-1 Determine Sample Size

A water utility would like to measure the incidence of low chlorine residual throughout the distribution system using the average chlorine concentration. An analysis of the results for October for chlorine residual samples has yielded the following:

- Number of October samples = 200.
- Average chlorine concentration $\mu = 1.04$ mg/L.
- Standard deviation of chlorine concentration $S = 0.20$ mg/L.

Rearranging Eq. 21-4 for three different margin-of-error values and three different confidence levels to assess the impact of those parameters on the number of samples, we obtain Eq. 21-4 and the results in the following table:

$$n = \frac{S^2 t^2}{d^2} \tag{21.4}$$

Number of Samples n Based on $S = 0.20$

Confidence level (t statistic, two-sided)	Margin of error d (mg/L)		
	0.05	0.1	0.15
99% (2.57)	106	26	12
95% (1.96)	61	15	7
80% (1.28)	26	7	3

Therefore, the utility could take 26 samples to provide that the estimate of chlorine residual would yield a margin of error of 0.1 mg/L with a confidence of 99 percent. This sample size is quite small and reflects the low variability in the historical data, with a standard deviation of 0.2 mg/L. Consider the difference if the utility had analyzed 1 year of historical chlorine residual data and found a standard deviation of 0.42 mg/L for that data set. Recalculating the number of samples would yield the following:

Number of Samples n Based on $S = 0.42$

Confidence level (t statistic, two-sided)	Margin of error d (mg/L)		
	0.05	0.1	0.15
99% (2.57)	466	117	52
95% (1.96)	271	68	30
80% (1.28)	116	29	13

For the second case, the increase in variability in the historical data set is reflected in an increase in the number of samples required to achieve a given statistical precision. The utility now would need to take 117 samples instead of 26. ▲

To further refine the sampling design, the system to be sampled can be divided into categories, or strata, to allow for analysis of both the overall water quality and the water quality within each stratum. This type of design can be helpful in understanding differences in water quality behavior and in identifying underlying factors contributing to problems. For the best results, the stratification variables used to categorize samples should be correlated with the outcome measurement and should address the sampling goal.

Example 21-2 Allocation of Samples to Strata

The primary goal of a special sampling program is to determine the extent of low chlorine residuals within the entire distribution system, defined as free chlorine ≤ 0.1 mg/L. For this sampling study, a secondary goal is to evaluate if low chlorine residual is related to pipe material.

- Total number of samples = 60.
- Select stratification variable of pipe material. Pipe material within the distribution system is as follows:
 - 10 percent cast iron
 - 70 percent cement-lined ductile iron
 - 20 percent PVC

To meet the primary goal of a good overall system estimate, choose proportional allocation of the samples across the pipe materials. Do not consider time variations in this example. Therefore, the sampling program design has

- 6 samples in cast iron pipe
- 42 samples in cement-lined ductile iron pipe
- 12 samples in PVC pipe

However, to meet the secondary goal of evaluating if chlorine residual is related to pipe material, a proportional allocation as shown above does not provide many samples in the cast iron pipes, which are suspected of having a higher incidence of low chlorine residual than the other pipe materials. Therefore, to meet the secondary goal, a balanced allocation would provide a better distribution of samples while still achieving the overall goal of estimating the system-wide low-chlorine incidence. For a balanced allocation, the sampling program design would allocate one-third of the samples to each of the three pipe materials as follows:

- 20 samples in cast iron pipe
- 20 samples in cement-lined ductile iron pipe
- 20 samples in PVC pipe ▲

Sampling Frequency. The frequency of sampling for a given sampling program is directly related to the sampling goal(s). The theoretical number of samples required for a given sampling program is calculated without explicit regard for the frequency of sampling. However, implicit in the calculation is the concept that the sampling frequency should be compatible with the frequency of occurrence of the phenomena under investigation. For example, to investigate seasonal shifts in water quality parameters, samples should be taken at least quarterly. Water quality sampling in distribution systems poses some challenges with regard to sampling frequency in that a number of phenomena are occurring, many at different time scales. Seasonal changes in water temperature and organic content are contrasted with daily changes in treatment such as chlorine residual. Further, hydraulic transient events occur at a time scale on the order of seconds. For short-duration events on the order of a few hours, it has been shown for a simple distribution system that daily grab samples are unlikely to capture the contamination (Grayman et al., 2007a).

Practical considerations often dictate sampling frequency. Most water utilities do not operate laboratories 24 hours per day, so sampling schedules need to reflect the schedule and timing of different laboratory tests. Utilities using contract laboratories need to collect and ship samples before a shipping deadline. Most water utilities conduct their sampling during the day-shift hours, except in emergencies. However, the increasing availability of on-line or continuous monitors for water quality parameters is shifting the way that water utilities conduct their sampling. These on-line monitors can provide a continuous stream of water quality data, often linked directly to the utility information system for remote monitoring. Most water quality regulations specify sampling frequency for compliance measurements.

Optimization. In general terms, the design of sampling programs is highly suited to optimization. If the sampling goal can be expressed in terms of an objective function, the number of samples, location of sampling sites, and sampling frequency all could be optimized to meet the objective function. Several optimization software packages are available commercially, and many distribution system modeling software programs also include optimization routines.

The application of optimization to the problem of sampling program design for water quality in distribution systems is not a straightforward task. There is a wide range of different, competing objectives that are important to consider, such as minimizing the number of samples, minimizing the installation and maintenance costs of monitoring equipment, minimizing the response time to a contamination event, and minimizing the extent of contamination (Berry et al., 2005). In addition, it is difficult to quantify the health impact of contaminant occurrence because consumer water usage is poorly characterized in terms of both water consumption patterns and dose-response for health outcomes. Consequently, optimization routines require the use of surrogate measures such as average annual water consumption to model health impacts.

Sampling Related to Water System Security

The water security field has evolved over the past decade, primarily in response to a small number of actual or potential water quality-related events. Various industrial spills or unregulated discharges around the world have led to contamination of surface water and groundwater sources, resulting in the development of sophisticated source water monitoring technologies. Following the events of September 11, 2001, the interest in water security in the United States shifted to the potential for intentional contamination of water supplies, with primary concern on impacts within the distribution system. As a result, there has been

extensive research and development related to technology and procedures that could be used to prevent, detect, analyze, and mitigate intentional contamination events. Advances in several areas of water security have potential applications beyond security concerns for water quality monitoring. Real-time, on-line monitors have come to be considered as the most expeditious mechanism for detecting the presence of a contaminant in a water distribution system.

In the most extensive project to date in this area, the USEPA has developed and is applying the Threat Ensemble Vulnerability Assessment (TEVA) program (Murray et al., 2004; USEPA, 2009). TEVA software analyzes the vulnerabilities of drinking water distribution systems, measures public health and economic impacts, and designs and evaluates threat mitigation and response strategies. Using a hydraulic model of the distribution system as a basis, TEVA applies a probabilistic framework for assessing the vulnerability of the system to a variety of contamination attacks and the potential for a water utility to decrease this vulnerability through a set of mitigation strategies (Grayman et al., 2007). This procedure is being applied to several large and medium-sized water utilities across the United States (Murray et al., 2008).

One of the TEVA programs was developed to assist the user to design sensor networks as part of a contaminant warning system. The TEVA sensor placement optimization tool (TEVA-SPOT) program models the impacts from intentional contamination events to drinking water distribution systems and uses the results to optimally locate on-line monitors in the distribution system. The optimization algorithm uses objective functions specific to security applications to solve the sensor placement problem. For example, the sensors might be located to provide notification of a contamination event with a given time period or prior to exposure of a given population of consumers. A dual-use adaptation of TEVA-SPOT is under development (Murray et al., 2008). This extension to the current TEVA-SPOT program would provide a dual-use sensor placement tool that allows the user to identify ideal locations for placing water quality monitors for both security goals and operational and/or regulatory sampling goals. The challenge in using this tool successfully will be to develop measurable metrics for a utility's current operational and regulatory sampling, which often do not have easily quantifiable outcomes.

On-line monitors, supervisory control and data acquisition (SCADA), and other sources of real-time or near-real-time data provide the potential for rapid detection of an unusual water quality event in a distribution system. These events could be related to intentional contamination or to an operational problem. Event-detection software is designed to analyze data to determine whether the data indicate an actual contamination event or just a normal variation in the data. In order to be useful, the software should minimize both false-positive (incorrectly detecting that an event is occurring) and false-negative results (missing the detection of an event).

The field of signal analysis and event detection is quite advanced and provides a basis for recent research related to water quality event detection (USEPA, 2005b). Several event-detection products have become available recently. CANARY is a research-oriented water quality event-detection algorithm development tool being developed by Sandia National Laboratories with partial support from the USEPA TEVA program (Hart et al., 2007). CANARY analyzes time-series data, most often water quality data from on-line monitors, using a variety of mathematical algorithms for detecting events. Several proprietary event-detection products are being developed to analyze on-line water quality data and include vector analysis of a suite of parameter measurements to recognize normal data patterns and triggers for levels that deviate from normal (Kroll, 2007). However, event detection in water distribution systems is in the early stages of application, and considerable research remains to be done before on-line monitoring data can be used reliably to detect all types of distribution system water quality events (Grayman et al., 2007).

Integrated Distribution System Management

With the increasing use of electronic databases, geographic information systems (GIS), SCADA, hydraulic models, and on-line water quality monitoring, water utilities are beginning to realize the value of integrated distribution system management. The concept is based on the desire to link data regarding the distribution system from all available sources to provide near-real-time information on the status of the distribution system. Many of the security-related projects are pursuing this type of data integration, but the concept has broad applications in distribution system water quality and operations. The implementation of integrated distribution system management systems varies widely depending on the available databases within the utility and the desired uses for different utility departments. Figure 21-7 presents a data-flow schematic with one data process mapped. For the data process shown, the GIS and SCADA provide information for the hydraulic model of the distribution system, which is a tool used by engineering, operations, and field staff. Many of the different databases shown in the figure are currently implemented at water utilities in the United States. However, the integration of these databases generally requires a central data-processing application. Integrated distribution system management also supports asset management applications (Speight, 2005). The development of sophisticated data-integration systems is in early stages, but the current trends indicate that this concept will be adopted widely by water utilities in the future.

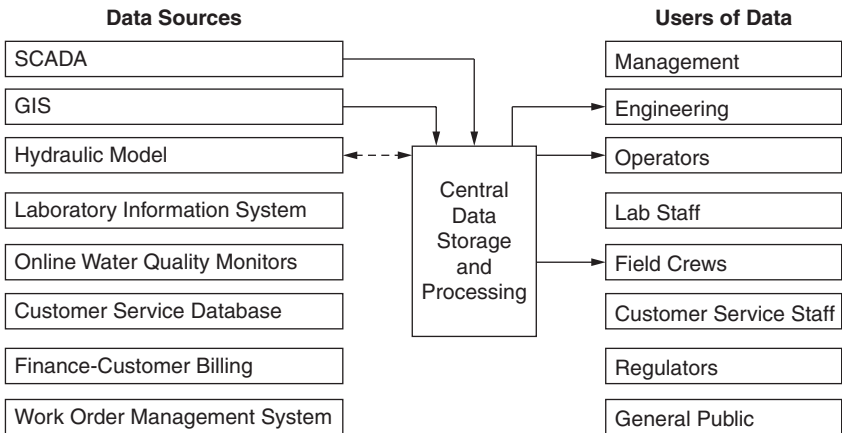

FIGURE 21-7 Example schematic of data-flow processes for integrated distribution system management. (Source: Adapted from Speight, 2005.)

ENGINEERING AND DESIGN OF DISTRIBUTION SYSTEMS

While operational procedures have a great impact on distribution system water quality, it is equally important to engineer and construct distribution systems using best practices to ensure system integrity and promote water movement to reduce adverse water quality impacts. A number of engineering practices, standards, and tools are available to water utilities to assist in controlling distribution system water quality.

Use of Distribution System Models

Hydraulic and water quality modeling tools provide a way to link hydraulic and water quality parameters. These models can provide valuable insight into the behavior of flows and water quality constituents and are an important component of a holistic approach to managing distribution system water quality.

Hydraulic models have been in use for several decades and can provide reliable simulations of flows and pressures when calibrated appropriately to real-world conditions (Ormsbee and Lingireddy, 1997). Figure 21-8 shows the input data required for hydraulic and water quality models using chlorine modeling as an example (Speight, 2008). A number of publications are available that outline the development, calibration, and application of distribution system models, including Speight and colleagues (2010), Walski and colleagues (2003), USEPA (2005c), Cesario (1995), Clark and Grayman (1998), AWWA (2004), and Boulos and colleagues (2006). Several commercial modeling software packages are available. Most of the commercial packages are compatible with EPANET, which is a free software developed by the USEPA that is available for download (USEPA, 2008a).

Grayman and colleagues (2007) list the following five areas where hydraulic modeling can be used for distribution system water quality management:

1. *Fate and transport of contaminants.* A hydraulic/water quality model can be used to simulate the movement and behavior of a contaminant in the distribution system and to determine its impacts over time. When a range of different contaminants are studied, models can be used to assess alternative schemes for reducing vulnerability of distribution systems to contamination.

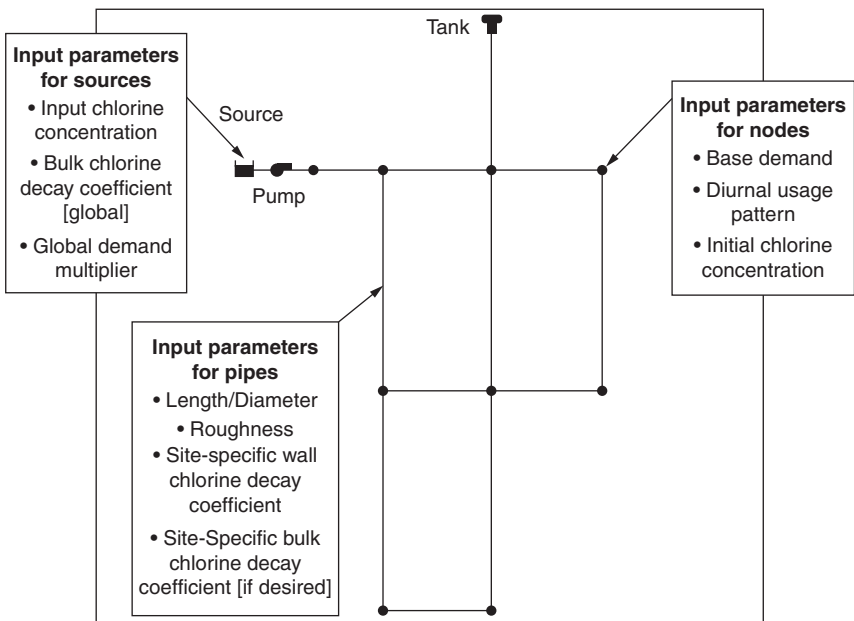

FIGURE 21-8 Summary of model input parameters. (Source: Speight, 2008.)

2. *Design of monitoring networks.* On-line continuous monitors have been a major focus as a means of detecting a contaminant in the distribution system. Optimization, simulation, and heuristic methods that combine hydraulic/water quality models with search techniques can be used to gauge the effectiveness of a particular set of monitors in the distribution system.
3. *Contamination source determination.* Hydraulic/water quality models can be used in a forensic mode to determine the likely source of a contaminant that has been observed in a distribution system. The models could be applied in real time to determine and characterize a source or could be used following an event to understand its origin. This form of analysis is referred to as *contaminant source determination, backtracing, or an inverse solution.*
4. *Real-time assessment, emergency response, and remediation.* When a contamination event occurs and is detected, a rapid response is needed to minimize the impact of the event. A properly formulated and current hydraulic/water quality model of the distribution system can be used to assess and predict the movement of contaminants through the distribution system, determine the source of the contamination (if not known), provide information on how the movement of the contaminant can be controlled, and assist in the development of a cleanup strategy.
5. *Historical reconstruction of waterborne outbreaks.* There have been many cases of contamination of water systems that have resulted in waterborne outbreaks associated with consumption of the water. Distribution system hydraulic/water quality models have served as key tools in the quantitative reconstruction of a number of major waterborne events.

Accurate modeling of hydraulic and water quality behavior in distribution systems is heavily dependent on the accuracy of the model input data. For many water utilities with old pipes, collecting and verifying pipe diameter and material and location of the installation are still a large focus of effort. A key challenge in hydraulic modeling is the determination of customer water usage at all points in the distribution system over time. Where customer meters exist, they are generally read on a monthly or quarterly basis and do not provide real-time data. Innovations in automated meter reading (AMR) may improve the ability to collect real-time customer usage data, but the data management challenges are significant (Speight, 2008).

Water quality modeling is an emerging field, but it is used increasingly to assist in operational decisions and planning studies. Water quality modeling applications include water age analysis, source tracing, and modeling of water quality constituents such as chlorine. Water quality models generally require a greater degree of detail within the model than for modeling applications that focus strictly on hydraulics, such as master planning modeling. An extended-period simulation (EPS) is required for water quality modeling to calculate constituent reactions over time. The development of “all pipes” models that include even the small-diameter water mains in a system is often driven by the desire to include the flow pathways to the point of consumption for more accurate water quality analysis. While skeletonized models, which include only larger-diameter mains, are not preferred for water quality applications, they can be used if the precision of the water quality predictions is not important. Water trace and water age analyses can be conducted without further input data beyond the base hydraulic information. However, modeling of water quality parameters requires reaction kinetic coefficients and additional field data for calibration (Speight et al., 2010).

Chlorine is the most commonly modeled parameter for water quality. A relatively simple first-order decay model for chlorine has been shown to provide good simulations of field data (Vasconcelos et al., 1997). Modeling of disinfection by-products has been

less successful using deterministic models (Speight et al., 2000). Probabilistic models of water quality hold some promise in that they allow the use of uncertain mechanistic formulations with appropriate accounting of uncertainty; however, these probabilistic models are computationally intensive and currently remain in the research arena (Speight et al., 2009).

Modeling of microbial contaminants within the distribution system is limited by the lack of knowledge about biofilm processes, attachment or detachment of microbes to particles, growth mechanisms in low-nutrient environments, concentrations of microbes that enter the system through different pathways (e.g., low-pressure transient versus cross-connection with a sewer), and occurrence of pathogens. Particle transport and deposition modeling is especially challenging for distribution systems because of the highly variable nature of flow, which, in turn, is caused by the highly variable nature of individual water usage (Speight, 2008).

Water Quality Impacts Associated with Distribution System Design Practices

Several standards exist for design and construction of distribution system components. In the United States, designs for water systems typically are reviewed and approved by state regulatory agencies. *Ten States Standards* (Great Lakes Upper Mississippi River Board 2007) summarizes a number of best practices for sizing mains, storage tanks, and other distribution system facilities in a general sense. But many water utilities are moving toward a site-specific assessment that includes a water quality evaluation to appropriately size water mains and storage facilities. The use of hydraulic models is valuable in assessing the impact on water age for different design alternatives. For example, while head loss may be minimized by selecting a large-diameter water main, a water age analysis may reveal that the large-diameter main increases water age and the potential for water quality degradation.

The design standards in the United States require the provision of fire flows in most cases. The quantities of water required for fire flow typically are much higher than normal production levels, and therefore, concerns for adequate fire flow dominate capacity calculations. Research is ongoing in Europe to investigate the potential to size water mains for domestic usage only and therefore reduce water quality concerns, including accumulation of sediment (Blokker et al., 2007). The implementation of such a design philosophy would require the cooperation of fire departments and state regulators in the United States.

As users change and distribution systems evolve, areas of the system may contain oversized mains designed to serve customers that are no longer present. In addition, large mains are often built in anticipation of future development that does not occur. The best practice for main sizing includes an assessment of current and future uses and considerations for water quality impacts. Construction of looped pipe systems that eliminate dead ends is also considered to be a water quality management tool. Many water utilities are instituting development standards that require developers to construct looped systems. However, it is not possible in all situations to construct a fully looped system, and dead-end mains are still prevalent in distribution systems across the United States. As with all water main sizing, water utilities need to consider the impact of construction of loops and connectors on water quality. In some cases, if the loop connection piping requires a long main with few users connected, the construction of the loop may produce an undesired effect by increasing water age.

The continuous maintenance of positive pressure at all locations within the distribution system is likely the most important daily operational requirement for a water system. However, maintenance of pressure is not only an operational practice. The distribution system

must be designed properly to minimize the occurrence of low pressures. Maintenance of pressure on a regular basis requires the correct sizing and operation of pumps, tanks, and water mains. Hydraulic models can be used to evaluate the ability of distribution system facilities to provide adequate pressure under different flow conditions. Field data collected from pressure gauges at key points in the system such as pump stations, pressure-reducing valves, and areas with high ground elevation can be used to further understand the ability of the system design to maintain appropriate pressure.

AWWA (2005c) has developed standard procedures that are used, with variations, by most of the water supply industry for disinfecting new and repaired water mains. These recommendations address six general areas of concern: (1) protection of new pipe sections at the construction site, (2) restriction on the use of joint packing materials, (3) preliminary flushing of pipe sections, (4) pipe disinfection, (5) final flushing, and (6) bacteriological testing for pipe disinfections.

Pipe sections, fittings, and valves stockpiled in yard areas or at the construction site should be protected from soil, seepages from water or sewer-line leaks, storm water runoff, and habitation by pets and wildlife. Each of these sources could deposit contamination in the interior of pipe sections awaiting installation. Septic tank drain fields, subsurface water in areas of poor drainage or high water table, and seasonal or flash flooding also may introduce significant contamination into unprotected pipe sections. Contamination from these sources may become lodged in pipe fittings and valves and be released into the bulk flow of water supply after the main is placed into service. Commonsense protective measures include end covers for these pipe materials, drainage of standing water from trenches before pipeline assembly, and flushing of new construction or line repairs to remove all visible signs of debris and soil.

Water use in a community varies continuously as a reflection of the activities of the general public and local industries. Water treatment operations cannot easily gear production to frequent and sudden changes in water demand from all consumers. For this reason, storage facilities are an essential element of a distribution system. Storage tanks supplement flows during periods of fluctuating demand on the system, equalize operational water pressures, augment supply from production facilities that must be pumped at a uniform rate, and provide a backup source of water in case of system outages. Design and construction standards specify that adequate storage capacity be provided for fire emergencies.

Care must be taken to prevent potential contamination of the high-quality water entering storage facilities. Water volumes in large reservoirs mix and interchange slowly with fresh water from the distribution system, and under certain circumstances, old water with degraded water quality can be distributed to customers. Temperature differences between stored and fresh water result in stratification of water in the tank. Old water may be discharged from the tank as a consequence of a major water loss in the system caused by a major main break or intensive system flushing. Storage tanks also can be a deposition zone for sediments and associated microbes. Abrupt changes in water flow resuspend the sediment deposits, moving the contamination into the distributed flow of water.

CONTROLLING MICROBIAL OCCURRENCES IN DISTRIBUTION SYSTEMS

It is often difficult to determine the location of microbial infiltration given the vastness of many distribution systems, and therefore, determining the cause of total coliform positive results can be extremely challenging. Increasingly, utilities are focusing on assessments of best management practices and distribution system integrity rather than on monitoring to ensure the public health integrity of distribution systems.

Treatment Approaches

The utility needs to verify that any cause of microbial occurrence in treated water is not the result of a deficiency in treatment. Deficiencies associated with nutrient loading, excessive disinfectant demand owing to inadequate corrosion control, inadequate removal/inactivation of microbes, or needed modifications to secondary disinfection can contribute to microbial loading or growth in the distribution system. The utility should be able to adequately demonstrate to regulatory agencies that the system is meeting all *best available treatment* (BAT) requirements. In addition, a sanitary survey by an approved state agency can provide an independent evaluation of treatment plant operations. For the treatment plant, the continuity of disinfection and maintenance of low turbidity levels are critical items to document. Surface water plants should ensure that they are meeting the turbidity and disinfection requirements outlined in the SWTR and subsequent revisions. Groundwater systems should ensure that they are not under the direct influence of surface water and have an active wellhead protection program. Monitoring of treatment plant effluent needs to be complete enough to document the absence of total coliforms and *E. coli*. To increase a treatment plant effluent bacterial detection database, the utility may process high-volume samples (Hargy et al., 2008; Friedman et al., 2009) and examine the samples for the presence of injured coliform bacteria (LeChevallier and McFeters, 1985a; McFeters, 1990) or HPC bacteria using sensitive media such as R2A agar.

Nutrient Loading. Microorganisms in the distribution system can thrive if provided with organic and inorganic nutrients that promote growth. Carbon typically is the growth-limiting nutrient in North American drinking water systems (Camper et al., 2000). However, as summarized in the USEPA White Paper, “Effect of Treatment on Nutrient Availability” (USEPA, 2002c), the presence or absence of nitrogen, phosphorus, and metals can enhance or limit growth in drinking water distribution systems. For example, a few studies have determined that phosphorus levels could limit microbial growth in the distribution system. Investigators (Sang et al., 2003; Miettinen et al., 1997) indicate that in some regions, such as Finland, China, Norway, or Japan, phosphorus can be a limiting nutrient in drinking water supply sources. Carbon becomes the limiting nutrient, however, when nitrogen is added.

Some systems have investigated source waters to determine if excessive nutrient levels may be linked to widespread recurring coliform problems. Indiana-American Water Company (Muncie, Ind.) determined that 53 percent of samples collected had assimilable organic carbon (AOC) levels greater than 100 µg/L, with 16 percent having levels greater than 200 µg/L. AOC levels greater than 100 µg/L have been shown to enhance coliform regrowth in certain conditions (Norton and LeChevallier, 1997). In response to historical coliform problems, one of several mitigation actions taken by the Muncie system in 1997 included changing the anthracite in the multimedia filters to granular activated carbon (GAC). Research (Volk and LeChevallier, 2002) has indicated that GAC reduces AOC levels 25 percent better than conventional anthracite/sand filters. Following the implementation of GAC adsorption/filtration in 1997, coliform rates over an 8-year period were the lowest they had been over the past 25 years. A complete case study of Muncie’s coliform control program can be found in Friedman and colleagues (2009b).

Corrosion Control and Finished Water Quality Stability. Corrosion control can be an important yet often overlooked aspect of microbial water quality control. The accumulation rate of corrosion products (measured from 22 unlined cast iron mains collected from 9 different utilities) can be as much as 3555 kg/km (6.3 tons/mi) of 200-mm (8-in) pipe (Friedman et al., 2010). This voluminous amount of scale, which is partly comprised of biomass, represents a huge potential source of inorganic and microbial water quality

degradation products. Key recommendations for maximizing corrosion control benefits and minimizing corrosion scale/biomass release largely center around providing a stable finished water quality with regard to pH, alkalinity, and oxidation-reduction potential (ORP). Enhanced stability of pH and alkalinity often can be achieved through careful application of corrosion control chemicals at the treatment plant. Ideally, the water should be well enough buffered to avoid pH changes of ± 0.2 pH units. Wide shifts in pH can affect corrosion scale stability owing to changes in ORP, sorption/desorption reactions, and precipitation/dissolution reactions. Other methods of enhancing corrosion control with regard to ORP include (Friedman et al., 2010) the following:

- Avoid uncontrolled blending of groundwater and surface water sources because these types of water supplies typically have widely differing ORPs. Switching back and forth affects corrosion scale stability and could exacerbate corrosion scale/biomass release.
- Avoid uncontrolled blending of chlorinated and chloraminated sources. The ORP of waters with free chlorine residuals typically will be higher than that of waters with chloramine residuals. Uncontrolled blending or switching back and forth can cause scale destabilization and exacerbate corrosion scale/biomass release.

Secondary Disinfection. Maintenance of a disinfectant residual throughout the distribution system is considered (in the United States) to be a critical part of assessing and enhancing the integrity of the distribution system. With regard to microbial water quality, the maintenance of a disinfectant residual can contribute to inactivation of microorganisms in bulk water as well as provide some control of biofilms. The USEPA (1999a) has identified free chlorine, chloramines, and chlorine dioxide as being appropriate for secondary disinfection. While none of these options is ideal for all systems, each has characteristics that may meet a specific system's needs for secondary disinfection. Selection of the most appropriate secondary disinfectant must be made on a system-by-system basis, with consideration given to the system's concerns regarding inactivation requirements, DBP formation potential, water quality, distribution system condition, and treatment experience and capabilities.

Systems should investigate the stability of disinfectant residual levels at locations that coincide with positive coliform samples. However, it should be noted that high disinfectant residuals will not always be associated with an absence of positive coliform samples, especially if the cause is biofilms. For example, Pinellas County Utilities (PCU) investigated total chlorine residual levels associated with positive coliform samples collected from November 2002 through December 2004. The average total chlorine concentration for coliform positive samples was 2.89 mg/L (Friedman et al., 2009). In contrast, Metro Vancouver found that 82 percent of samples had less than 0.1 mg/L of free chlorine and that 90 percent of samples contained less than 0.2 mg/L of free chlorine. Metro Vancouver and member utilities installed booster chlorination at five locations to provide a higher disinfectant residual in response to frequent coliform positive samples. A unidirectional flushing program also was initiated in several member municipality distribution systems. Figure 21-9 shows the number of communities served by Metro Vancouver that experienced more than 10 percent positive coliform samples in a given month prior to and after implementing booster chlorination in 1997. The figure shows a significant decline after implementing booster chlorination (Friedman et al., 2007).

Utilities may address microbial distribution system problems by increasing disinfectant residual throughout the distribution system or at problematic locations or by changing the disinfectant used to provide a distribution system residual. Table 21-7 provides a summary of secondary disinfection changes made by several utilities in response to coliform occurrences (Friedman et al., 2009).

FIGURE 21-9 Metro Vancouver: Percentage of communities with more than 10% positive monthly coliform samples (booster chlorination implemented in 1997). (Source: Friedman et al., 2007.)

Operations and Maintenance Approaches

Operations and maintenance procedures can be implemented and/or optimized to address microbial problems in the distribution system. For example, the Greenville Water System (Greenville, S.C.) implemented the following changes in operation and maintenance practices to address microbial issues (Friedman et al., 2007): (1) comprehensive flushing program, (2) tank cleaning and inspection program, (3) criteria for return to service after pipe replacement and repair, and (4) goal for total chloramine residual throughout the distribution system of 2.0 to 2.5 mg/L. Figure 21-10 presents the percentage of positive monthly coliform samples between January 1991 and October 2005 collected by Greenville Water System. This figure shows significant reductions in the percentage of positive coliform

TABLE 21-7 Summary Secondary Disinfectant Strategies for Responding to Total Coliform Occurrences

Case study utility	Secondary disinfectant strategy used
Pinellas County Utilities	Average total chlorine concentration for positive coliform samples was 2.89 mg/L.
Virginia American	During a period of time associated with positive coliform samples, fewer than 3% of distribution system chlorine residual samples were below 1.0 mg/L free chlorine.
Indiana American	Determined that free chlorine levels in the distribution system associated with positive coliform samples were 0.5 to 2.0 mg/L.
MWRA	Found that 65% of samples had total chlorine levels of 0.2 mg/L and fewer than 1% had total chlorine residuals of 1.0 mg/L.
Metro Vancouver	82% of samples had less than 0.1 mg/L free chlorine and 90% of samples contained less than 0.2 mg/L free chlorine.

samples after implementation of the operations and maintenance (O&M) practices just described. Additionally, the percentage of positive coliform samples declined further after Greenville Water System implemented a new filtration plant.

Maintaining Disinfectant Residuals. Approaches for increasing disinfectant residuals include (1) reducing water age in storage facilities and pipe network, (2) reducing disinfectant demand in the source water, (3) reducing disinfectant demand associated with sediment and scale buildup on pipe walls, and (4) increasing disinfectant dose.

The effectiveness of each approach will vary from system to system and may well vary from location to location within a specific system. Recommendations associated with reducing water age through storage facilities and reducing disinfectant demand in the source water and demand associated with sediment and scale buildup are discussed elsewhere in this chapter.

Reducing Water Age in Pipe Networks. Prudent capital planning necessitates installation of facilities that have excess capacity for water storage and distribution. It is not uncommon to size pipelines for water demands that will occur 20 years or more into the future (AWWA and EES, 2002a). *Ten State Standards* (Great Lakes Upper Mississippi River Board, 1997) specifies a minimum pipe size of 150 mm (6 in) at all locations for providing fire protection. Table 21-8 shows the volumetric effect of increased pipe diameter

TABLE 21-8 Pipe Diameter versus Pipe Volume per Mile or Kilometer

Pipe diameter	2 in (50 mm)	4 in (100 mm)	6 in (150 mm)	8 in (200 mm)	10 in (250 mm)	12 in (300 mm)	18 in (450 mm)
Gal/mi	86	3,466	7,755	13,786	21,540	31,019	69,792
L/km	202	8,154	29,362	52,197	81,556	117,445	262,249

Source: AWWA and EES, 2002.

on a per-kilometer and per-mile basis. Thus, for every kilometer (or mile) of 100-mm (4-in) pipe that is replaced with 200-mm (8-in) pipe, the effective volume of the distribution system increases by greater than 37,850 L (10,000 gal).

Excess capacity within piping networks can lead to significantly increased water age, causing loss of disinfectant residual, increased microbial growth, and other water quality problems. It is important to note that there is no *ideal* water age that is appropriate for all systems. Variables such as the degree of source water treatment, disinfectant type and dose, water temperature, and distribution system materials all will have an impact on the degree of water quality degradation that might occur as a result of water age.

Water age-related problems can be analyzed using a range of techniques from simple manual calculations through computer models (Brandt et al., 2006). The most common tools used for assessing water age in piping networks include use of existing water quality and operational information, use of tracer studies, and use of calibrated hydraulic models (AWWA and EES, 2002a). Existing water quality data such as temperature, disinfectant residual, and trihalomethanes (THMs) can provide valuable insight into locations that are experiencing water age problems. Alternatively, in systems with multiple sources with varying water quality characteristics (such as differences in water hardness or conductivity), these natural constituents can be used as the tracer. Finally, during transitional periods in system operation, such as changeovers from chlorination to chloramination, the resulting constituents can be traced. Other utilities have taken advantage of a fluoride system shutdown, use of alternative water sources, or a switch in coagulant to trace water through the distribution system (AWWA and EES, 2002a). Brandt and colleagues (2006) describe the selection of appropriate trace chemical, duration and nature of dose, sampling frequency, sampling method, travel time and network complexity, and tracer studies of storage tanks.

Mathematical models that represent the hydraulic behavior of the movement of water have been used to estimate water age in distribution systems (Clark and Grayman, 1998). As described in the preceding section, water quality models can be used in conjunction with hydraulic models to predict concentrations of chlorine, DBPs, and other constituents in a distribution system (Speight et al., 2009). The effect of interaction of the flowing water with the pipe wall can be estimated using relationships proposed by Rossman and colleagues (1994). For each nonconservative water quality parameter, rates and mechanisms of reaction (decay and growth) must be identified and measured for a particular system.

Once problematic areas of the distribution system are identified and confirmed through water quality monitoring, the utility can evaluate potential water age mitigation strategies. The most appropriate strategy will be associated with the likely contributing causes of excess water age. Example strategies applicable to piping networks are summarized in Table 21-9.

Controlling retention time will affect other operational or service-level requirements of the network (such as fire flow or pressure requirements). Potential impacts should be considered prior to the implementation of water age-reduction strategies.

Increasing Disinfectant Dose. Typically, one of the first responses to positive coliform results is to increase disinfectant residuals by increasing the dose. For systems that maintain minimal disinfectant levels (generally considered to be 0.2 mg/L for free chlorine or 0.5 mg/L for chloramines in all parts of the system), higher residuals may help to penetrate biofilms or sediments to achieve better levels of microbial inactivation.

Free chlorinated systems should attempt to maintain at least 0.5 mg/L residuals at dead-end sites. According to AWWA Manual M56, *Fundamentals and Control of Nitrification in Drinking Water Distribution Systems* (AWWA, 2006b), chloraminating systems should maintain a minimum chloramine concentration of 2.0 mg/L leaving the plant. Systems should maintain a minimum chloramine concentration of 0.5 mg/L at all monitoring points in the distribution system. Many utilities set internal goals of 1.5 mg/L chloramine or

TABLE 21-9 Methods for Controlling Water Age

Method	Rationale
Altering the valving of networks	By changing valve arrangements and hydraulic boundaries, travel times can be reduced and water rerouted to increase velocities in low-flowing pipes to maximize velocities.
Installing time-varying valves	Time and other control valves can be used to control flows.
Manual flushing	Periodic flushing to remove sediment and reduce water age in dead ends and low-velocity sections of pipe.
Automated flushing	Automatic programmed flushing to remove sediment and reduce water age in dead ends and low-velocity sections of pipe.
Abandoning mains	Remove surplus capacity from the system.
Downsizing mains	Reduce system capacity to increase velocities and reduce retention time.
Adjusting pump schedules	Optimize pumping regime to match supply and demand, minimize energy requirements and retention times (linked to optimizing system storage).

Source: Adapted from Brandt et al., 2006.

higher for all distribution system sites. LeChevallier and colleagues (1996) recommend that chloraminated systems set goals to maintain a minimum of 1.0 to 2.0 mg/L at dead-end locations.

Disinfectant dosages can be increased at the treatment plant or through booster disinfection at specific locations within the distribution system. The advantage of this approach is that most systems can make these changes relatively quickly. In some cases, the utility should get approval from the state regulatory agency before increasing residual levels, but in all cases, it is good to be in close contact with the regulatory authorities.

The disadvantages of increasing disinfectant residuals include (1) the potential for increased disinfectant by-products, (2) increased customer complaints about chlorinous taste and odor, (3) increased chemical costs, and (4) most important, it may not have any impact on coliform occurrence. It is well recognized that increased disinfection residuals alone may not suffice to eliminate coliform occurrences.

Flushing. Flushing is recommended as one of many tools for controlling biofilm growth, removing accumulated sediment, restoring disinfectant residual, improving hydraulic capacity, and improving taste and odor. Most loose deposits are readily removed from smooth pipes [such as PVC pipe or new ductile iron (DI) pipe] and slightly tuberculated pipe at velocities between 0.6 and 1.2 m/s (2 and 4 fps) (Friedman et al., 2003). With respect to tuberculated mains, higher flushing velocities are needed, but they tend to produce a diminishing increase in particle-removal performance for severely tuberculated mains. If the flushing objective is to scour and clean the pipe wall, high-velocity flushing [i.e. ≥ 1.5 m/s (5 fps)] generally is needed. However, flushing at excessively high velocities can damage pipe linings and result in decreased pressures upstream. Additionally, water may be wasted without obtaining a water quality benefit.

Unidirectional flushing (UDF) is the recommended method of removing the hydraulically mobile (and in some cases loosely adhered) solids. Unidirectional flushing involves the purposeful and sequential isolation of specific water mains, control of overflow direction and velocity, and introduction of only clean water (i.e., previously flushed or close to the source of supply or a clean water front) into the main to be flushed. UDF protocols and recommendations regarding flushing duration, velocity, and other programmatic elements are described in *Establishing Site-Specific Flushing Velocities* (Friedman et al., 2003).

Many utilities still conduct conventional flushing in which hydrants are randomly opened to temporarily increase flow within a specific area of the distribution system or to respond to customer complaints related to taste, odor, or discolored water. Utilities typically choose conventional flushing over UDF because it is less time-consuming and requires significantly less planning. The disadvantages of conventional flushing, however, include stirring up of mobilized solids and sediments in adjacent areas of the distribution system and failure to remove the mobilized solids from the distribution system. Discolored water often reaches the customer tap after conventional flushing events, and this practice actually can increase coliform episodes rather than reducing them. It also may result in customer exposure to elevated levels of regulated inorganic contaminants such as lead, barium, arsenic, and other trace elements (USEPA, 2006b; Friedman et al., 2010).

Storage Facility Operations Practices. Excessive water age in many storage facilities can be an important factor related to water quality deterioration and disinfectant residual loss. The excess water age is caused by (1) underutilization (i.e., water is not cycled through the facility) and (2) short circuiting within the reservoir. Poor mixing (including stratification owing to temperature differences) can exacerbate the water quality problems by creating zones within the storage facility where water age significantly exceeds the average water age throughout the facility (AWWA and EES, 2002b). Distribution systems with storage facilities where water cascades from one facility to another (such as pumping up through a series of pressure zones) can result in exceedingly long water age in the most distant tanks and reservoirs.

Operationally, water age in storage facilities is managed by routine turnover of the stored water and fluctuation of the water levels in storage facilities. Kirmeyer and colleagues (1999) recommended a 3- to 5-day complete water turnover as a starting point but cautioned that each storage facility should be evaluated individually and given its own turnover goal. Water storage management for water quality must take into account influent water quality, environmental conditions, retention of fire flow, and demand management, as well as factors specific to the design and operation of the tank, such as velocity of influent water, operational level changes, and tank design. Consequently, water level fluctuations in a distribution system are managed as an integrated operation within pressure zones, demand-service areas, and the system as a whole rather than on an individual-tank basis. Available guidelines for water turnover rates are summarized in Table 21-10.

The Philadelphia Water Department estimated mean residence time and turnover rate in several standpipes by measuring fluoride residual and water levels. Mean residence time of water in the standpipes was determined to be 50 percent longer than expected because old water reentered the standpipes from the distribution system. One major conclusion from this work was that for water to get out into the distribution system and away from the standpipes, standpipe drawdown needs to correspond to peak demands or precede peak demands (Burlingame et al., 1995).

Mixing processes within a storage facility should be controlled to minimize water age (Grayman et al., 2000). When mixing does not occur throughout the storage facility, stagnant zones can form where water age will exceed the overall average water age in the facility. Therefore, mixed flow is preferable to plug flow in distribution system storage. Mixing can be encouraged through the development of a turbulent jet. In order to ensure turbulent jet flow, the following relationship between inflow Q in gallons per minute and inlet diameter d in feet must hold (Grayman et al., 2000):

$$Q/d > 11.5 \quad \text{at } 20^{\circ}\text{C} \quad (21-5)$$

$$Q/d > 17.3 \quad \text{at } 5^{\circ}\text{C} \quad (21-6)$$

TABLE 21-10 Guidelines on Water Turnover Rate for Distribution Storage

Source	Guideline	Comments
Georgia Environmental Protection Division	Daily turnover goal equals 50% of storage facility volume; minimum desired turnover equals 30% of storage facility volume	As part of this project, state regulators were interviewed by telephone
Virginia Department of Health, Water Supply Engineering Division, Richmond, VA	Complete turnover recommended every 72 hours	As part of this project, state regulators were interviewed by telephone
Ohio EPA	Required daily turnover of 20%; recommended daily turnover of 25%	Code of state regulations; turnover should occur in one continuous period rather than periodic water level drops throughout the day
Baur and Eisenbart, 1988	Maximum 5- to 7-day turnover	German source, guideline for reservoirs with cement-based internal surface
Braid, 1994	50% reduction of water depth during a 24-hour cycle	Scottish source
Houlmann, 1992	Maximum 1- to 3-day turnover	Swiss source

Temperature differences between the inflow and the ambient water temperature within the storage facility can cause the water to form stratified layers that do not mix together. Stratification is more common in tall tanks such as standpipes and tanks with large-diameter inlets. This can be avoided by increasing the inflow rate.

Mahmood and colleagues (2005) provide an evaluation of water mixing characteristics in distribution system storage tanks. For example, these authors found that standpipes in the Virginia Beach, VA, distribution system had an average fill time of approximately 3 hours and an inflow rate of approximately 126 L/s (2000 gpm) with an inlet pipe diameter of 600 mm (24 in). This resulted in inadequate momentum to mix the bulk water within the 3-hour fill time. Computational fluid dynamics modeling showed that reducing the inlet diameter to 300 mm (12 in) would result in complete mixing within 1 hour of filling. For standpipes and elevated tanks, Mahmood and colleagues (2005) recommend reducing the inlet pipe diameter so that an inlet momentum of approximately 1.7 to $2.6 \times 10^{-1} \text{ m}^4/\text{s}^2$ (20 – $30 \text{ ft}^4/\text{s}^2$) can be achieved. The authors concluded that momentum, pipe location and orientation and temperature differences will control the effectiveness of mixing within storage facilities. Mixing systems also are described in Kirmeyer and colleagues (1999).

Prevention of Distribution System Contamination

Direct microbial and chemical contamination of the distribution system is possible where there are physical breaches in distribution system integrity. *Physical integrity* has been defined as the ability of the distribution system to act as a physical barrier that prevents external contamination from affecting the quality of the internal drinking water supply (National Academy of Sciences, 2006). Examples of physical integrity breaches include unprotected cross-connections; leaks in water main, seals, or gaskets; submerged air-vacuum valves; and open access hatches, roof holes, or unscreened vents associated with storage facilities. A description of physical barriers and potential associated contaminant sources is provided in Table 21-11.

TABLE 21-11 Infrastructure Components, What They Protect Against, and Common Materials

Component	External contamination the barrier protects against	Materials used
Pipe	Soil, groundwater, sewer exfiltration, surface runoff, human activity, animals, insects, and other life forms	Asbestos cement, reinforced concrete, steel, lined and unlined cast iron, lined and unlined ductile iron, PVC, polyethylene and HDPE, galvanized iron, copper, polybutylene
Pipe wrap and coatings	Supporting role in that it preserves pipe integrity	Polyethylene, bitumastic, cement-mortar
Pipe lining	Supporting role in that it preserves pipe integrity	Epoxy, urethanes, asphalt, coal tar, cement-mortar, plastic, insects
Service lines	Soil, groundwater, sewer exfiltration, surface runoff, human activity, animals, insects, and other life forms	Galvanized steel or iron, lead, copper, chlorinated PVC, cross-linked polyethylene, polyethylene, polybutylene, PVC, brass, cast iron
Premise plumbing	Air contamination, human activity, sewage, and industrial nonpotable water	Copper, lead, galvanized steel or iron, iron, steel, chlorinated PVC, PVC, cross-linked polyethylene, polyethylene, polybutylene
Fittings and appurtenances (meters, valves, hydrants, ferrules)	Soil, groundwater, sewer exfiltration, surface runoff, human activity, animals, insects, and other life forms	Brass, rubber, plastic
Storage facility walls, roof, cover, vent hatch	Air contamination, rain, algae, surface runoff, human activity, animals, birds, and insects	Concrete, steel, asphaltic, epoxy, plastics
Backflow-prevention devices	Nonpotable water	Brass, plastic
Liquids	Not applicable	Oils, greases, lubricants
Gaskets and joints	Soil, groundwater, sewer exfiltration, surface runoff, human activity, animals, insects, and other life forms	Rubber, leadite, asphaltic, plastic

Numerous AWWA standards, manuals of practice, white papers, research reports, and committee reports address the causes and mitigation strategies associated with most of the physical integrity components, including main repairs, storage facility maintenance practices, and cross-connection control. Table 21-12 summarizes methods for preventing loss of physical integrity, as presented in National Academy of Sciences (2006). Table 21-13 lists some of the relevant AWWA standards that pertain to distribution system water quality (for a complete listing of standards, go to the AWWA Web site at www.awwa.org).

Preventing Intrusion through Water Main Leaks or Other Appurtenances. Friedman and colleagues (2004) and Flemming and colleagues (2006) provide detailed guidance on measuring and controlling pressure transients and intrusion. Guidelines for use of high-speed data loggers, conventional pen-and-chart recorders, and distribution system surge models are described. A multidisciplinary approach is needed for adequate transient and intrusion control, as shown in Fig. 21-11.

TABLE 21-12 Summary of Approaches for Preventing Loss of Physical Integrity

Component	Mechanism of integrity loss	Prevention by
Pipe	Permeation	Standards on pipe applications, local assessments of soil and groundwater for contamination
	Structural failure (leak or break)	Better design and installation, early leak detection with rehabilitation and repair, optimized scheduling of pipe renewals, optimized placement of valves for effective shutoffs and isolations
	Improper installation	Standards and certification for installation, followed by inspection
	Unsanitary activity	Strict requirements and inspections during repair, rehab, installation
Fitting and appurtenance	Structural failure	Improved materials quality as well as quantity in the operating components of valves and hydrants, periodic valve exercising followed by maintenance or replacement as needed
	Improper installation	Strict requirements on installation and design
	Unsanitary activity	Strict requirements during repair, rehab, installation, and inspection
Storage facility wall, roof, cover, vent, hatch	Structural failure (crack, hole)	Better design and installation, early leak detection with rehabilitation and repair
	Absence of proper installation	Inspection and better design with inspection
	Unsanitary activity	Strict requirements on installation and design
Backflow	Unsanitary activity	Strict requirements during repair, rehab, installation, and inspection
	Absence of proper installation	Inspection and certification
	Operational failure	Strict requirements on installation and design Annual testing and maintenance

Small systems may have characteristics that contribute to susceptibility to low or negative pressures, including a lack of surge-control devices (Flemming et al., 2006). The smaller systems [<37.9 million L/d (10 mgd)] examined also were found to have fewer floating storage facilities (e.g., storage facilities that provide pressure by gravity, or “float” on the hydraulic grade line), more supply inputs per mile of main, and operation at lower steady state pressures, all of which are potential contributing factors to increased low- or negative-pressure development. Flemming and colleagues (2006) identified the following additional system characteristics that were found to increase susceptibility to low- and negative-pressure surges with individual systems:

- Located near a pump station with downstream velocity greater than 0.9 m/s (3 fps)
- Located greater than 1 mile away from elevated storage
- Elevations greater than 12 to 15 m (40–50 ft) above surroundings
- Located near a dead end
- Located near a hydrant on a major main

Operational Transient Control Strategies. Operational transient control strategies generally focus on minimizing activities that cause rapid changes in water velocity, thereby minimizing the generation of pressure transients. These activities include (Friedman et al., 2004)

- *Rapid imposition of demands.* Rapid imposition of fire flows, high-demand customers, or due to tanker truck filling should be avoided through increased valve opening time.
- *Pump shutdown time.* Increasing pump shutdown time should be implemented by ramping down speeds for pumps with variable-speed drives and by slowly closing a pump control valve for constant-speed pumps.
- *Pump sequencing.* For multiple-pump pumping stations, the largest pump should be shut down first, and the smallest pump should be shut down last. By staggering the shutdown sequences, the magnitude of the change in flow at any one time is reduced.

- *Valve operations.* The magnitude of transients initiated by valve operations can be reduced by slowing the rate of opening and closing, as described earlier.

Figure 21-12 documents the pressure transients that were generated during a pump startup and shutdown at a water treatment plant (LeChevallier et al., 2002; Friedman et al., 2004). Measurements were made using high-speed pressure data loggers placed at three

(a)

(b)

FIGURE 21-12 Pressure transients caused by pump shutdown and startup at a treatment plant (a) and magnification of one of the transients (b) (1 psi = 6.894 kPa). (Source: LeChevallier et al., 2002, and Friedman et al., 2004.)

different locations within the system, as described below. During this test, the main service pumps were shut down at the treatment plant clearwell and restarted with all flow going through one venturi meter. Two high-speed electronic monitors were installed at high elevation points on a 760-mm (30-in) main [one was ~4 km (2.5 mi) from the plant, and the other was about 7.2 km (4.5 mi) from the plant], and a third monitor was located about 24 m (80 ft) from the treatment plant's high-service pumps. Pressure readings both near the treatment plant and within the distribution system showed large pressure fluctuations (Fig. 21-12a). While the static pressures near the plant ranged between 125 and 150 psi (860–1030 kPa), the pressure transients caused by the pump shutdowns resulted in pressures as low as 18 psi (124 kPa) in the plant effluent. However, several miles away in the distribution system, these fluctuations resulted in pressures as low as minus 10 psi (~70 kPa) lasting for 16 seconds (Fig. 21-12b). The valve closure speed for the main service pumps was 20 seconds. It was felt that this valve closure speed may have been too fast, thus contributing to the pressure transient. A second test was conducted with the valve closure speed slowed to 30 seconds, but negative pressures resulted from this second test as well.

Engineering Transient Control Strategies. Proper engineering control strategies will help to minimize the impacts of transients should they be generated. Such engineering strategies include (1) installation of surge-control tanks, (2) installation of other surge-control devices, (3) evaluating the impacts of increasing steady state pressures in vulnerable sections of the distribution system, (4) providing overhead storage, (5) looping dead ends, and (6) encasement of new mains.

Additionally, air relief valves and similar appurtenances should be designed to have above-grade venting (designed to be tamperproof to avoid deliberate contamination of the system). All below-grade vacuum or air relief valves should be retrofitted to above-grade venting or modified in a way to prevent flooding of the vault (e.g., drainage or pump) (LeChevallier et al., 2002). Both the generation and propagation of pressure transients can be reduced as a result of these design elements (Friedman et al., 2004; Flemming et al., 2006).

Maintenance Control Strategies. Maintenance strategies can help to minimize the likelihood of intrusion should a surge occur and propagate through the distribution systems. Such maintenance strategies include (1) leak detection, (2) main repairs, (3) inspections of valve and meter boxes, (4) cross-connection control, and (5) hydrostatic testing of new mains.

Efforts to reduce distribution system pipeline leakage are beneficial not only from a water conservation standpoint but also minimize the potential for microbial intrusion into potable water supplies. Leaks are not simply a loss of revenue for a water utility, but the leak is a potential pathway for contamination. The public health benefits of leak control should be recognized and encouraged. Repair of leaking sewer lines similarly should be a top priority not only to minimize the occurrence of pathogens near drinking water pipelines but also to reduce these sources of contamination being transported to groundwater supplies and receiving streams, particularly under wet weather conditions (LeChevallier et al., 2002).

Inspection of valve and meter boxes, especially air-vacuum valve boxes that are below grade, is critical for controlling the potential for intrusion. The standing water in flooded air-vacuum valve boxes, which can be backsiphoned into the distribution system during transient pressure events, is highly unsuitable for consumption, as demonstrated in Fig. 21-13.

Preventing Contamination Through Cross-Connections. Prevention of cross-connections is paramount to maintaining the safety of water delivered to the customer. According to USEPA (2002a), contamination owing to backflow incidents may not be detected or reported for several reasons:

- Bacterial contamination tends to be transient and highly localized (ABPA, 1999).
- Water system operators monitor routinely for coliform bacteria, but most often that is the only microbial monitoring conducted (USEPA, 2002a). While these bacteria are important

FIGURE 21-13 Photographs of flooded air-release and air-vacuum vaults (the vault on the right contains a dead mouse). (Source: LeChevallier et al., 2002.)

indicators of distribution system problems, some microbial contaminants may go undetected. The limited nature of biological monitoring, especially in smaller systems (as infrequent as once per year), makes it unlikely that contamination will be detected in a timely manner.

- Most backflow incidents are detected and reported to the local authority only if customers detect an irregularity in their water supply. Not all contamination that produces illness and disease can be detected by taste, color, or odor (Hoxie et al., 1997).
- Even if an irregularity is detected, it may not be reported by the consumer.
- When water system operators suspect backflow incidents, they have a disincentive to document and report them because of concerns about legal liability and loss of consumer confidence, as noted by an USEPA Office of the Inspector General Report (USEPA, 1995). (Fortunately, these same concerns provide the utility with an incentive to protect the distribution system.)
- The difference between epidemic and endemic transmission is obscured by limitations in recognizing when an outbreak occurs (Frost et al., 1996). A study of waterborne cryptosporidiosis estimates that out of every 10,000 infections by *Cryptosporidium*, only 3 would be reported and concludes that surveillance for detected cases of a reportable illness may underestimate rates of infection and morbidity substantially (Perz et al., 1998).
- Some contaminants that enter the distribution system through cross-connections and backflow may not be reportable.
- The incidents of reduced pressure and some cross-connections are often transient in nature. Pressure changes may not be detected by conventional pressure monitoring equipment. Reduced pressures also may affect only a portion of the distribution system, a specific pressure zone, or only piping beyond the service connection.

Common backflow control devices include air gaps, reduced pressure zone backflow preventers, double check valves, vacuum breakers, and complete isolation. Numerous organizations provide detailed description of approved backflow prevention assemblies as well as guidance for implementing a cross-connection control program. As summarized by the National Academy of Sciences (2006), examples include the University of Southern California (USC), the American Society of Sanitary Engineering (ASSE), Underwriters Laboratories (UL), the International Association of Plumbing and Mechanical Officials, Factory Mutual, and the Canadian Standards Association. The three most commonly used guidance manuals are the *USC Manual of Cross Connection Control* (USC, 1993), AWWA's *Recommended Practice for Backflow Prevention and Cross-Connection Control Manual M14* (AWWA, 2004b), and USEPA's *Cross Connection Control Manual* (USEPA, 2003b). Table 21-14 describes many of the critical elements of cross-connection control program and summarizes the number of states that require each program element (USEPA, 2002a).

TABLE 21-14 Summary of Cross-Connection Control Program Elements and State Requirements

Requirement	Number of states with requirement
Does the state have a requirement for the control of cross-connections and/or backflow prevention?	50
Is it specified in the requirement that the system must implement or develop a cross-connection control and/or a backflow-prevention program?	32
Does the state require authority to implement a local ordinance or rule for cross-connection control and/or backflow prevention?	33
Must the authority cover testing of backflow-prevention assemblies?	27
Must the authority cover the use of only licensed or certified backflow assembly testers?	16
Must the authority cover the entry of the premises for the sake of inspecting the premises?	14
Must the authority cover the entry of the premises for the sake of inspecting and/or installing backflow-prevention assemblies?	15
Does the state require training, licensing, or certification of backflow-prevention assembly testers?	26
Does the state require training, licensing, or certification of backflow-prevention assembly and/or device installers?	6
Does the state require training, licensing, or certification of backflow-prevention assembly and/or device repairers?	10
Does the state require training, licensing, or certification of cross-connection control inspectors?	19
Does the state require inspection of backflow-prevention devices and/or testing of backflow-prevention assemblies?	37
Does the state require the system to include recordkeeping as part of cross-connection control?	34
Does the requirement include recordkeeping of hazard assessment surveys?	11
Does the state require the system to notify the public following the occurrence of a backflow event?	3
Does the state require the local rule or ordinance to allow the system to take enforcement action against customers that do not comply with the cross-connection control and backflow-prevention requirements?	23
Does the state conduct periodic reviews of cross-connection control programs?	3
Does the state regulation or plumbing code require public education regarding cross-connection control and/or backflow prevention?	7

Source: USEPA, 2002a.

Considerable variability exists in state statutes, regulations, and policies related to cross-connection control and backflow prevention. In some cases where states do not require programs, some water systems within the state have implemented comprehensive and active programs in the absence of a state requirement to do so (USEPA, 2002a).

Preventing Contamination Associated with the Installation and Repair of Water Mains. Exposure of piping materials to contaminants can begin at the point of manufacture. Subsequent handling and storage of piping also present opportunities for exposure. The distribution system white paper entitled, “New or Repaired Water Mains” (AWWA and EES, 2002c), describes the potential for contamination associated with main break and repair and also discusses contamination prevention and mitigation strategies. Excerpts from AWWA and EES (2002c) are provided below.

Design Practices. Water mains should be designed to provide adequate separation from potential sources of contamination such as pipes carrying sewage, storm water, or reclaimed wastewater. The selection of adequate separation is based on factors such as pipe material and joint type, soil conditions, and space for repair. The *Ten State Standards* (Great Lakes Upper Mississippi River Board, 2007) recommend the following minimum separation distances: (1) 3 m (10 ft) horizontal separation between water mains and sanitary sewer force mains or sewers installed in parallel and (2) 0.460 m (18 in) vertical separation for water main crossing above or below a sewer or force main.

In practice, separation distances vary based on site-specific conditions. Best management practices for pipeline design are outlined in Pierson and colleagues (2001). These include (but are not limited to) (1) adequate numbers and types of hydrants, blow-offs, and valves, (2) the ability of valves to provide for complete isolation, (3) minimization of the number and length of tie-ins, (4) minimization of the distance between flushing point and valve that terminates the new main, and (5) simple installation configurations to enable unidirectional flow. Design practices should facilitate the effective and sanitary repair or installation and should facilitate contamination removal through flushing.

Condition of Piping Materials. The sanitary handling and storage of materials constitute perhaps the most critical step in protecting against microbial contamination during water main construction (Burlingame and Neukrug, 1993). The AWWA C600-99 Standard provides guidelines on pipe storage and handling procedures but not on sanitary protection of materials and tools used in main work. AWWA C600-99 was replaced by AWWA C600-05 (AWWA, 2005a). In addition to storing materials at the site prior to construction, many utilities stockpile pipe materials for future use at their utility yard. Protection from contamination is equally important for stockpiled pipes. The use of pipe caps and wraps can secure new mains and prevent contamination prior to installation. The literature cites examples where pipe caps are recommended during the curing of cement mortar linings both at the factory (North American Society for Trenchless Technology, 1999) and in situ (CSIRO, 2002). In these instances, pipe end caps prevent the circulation of air that otherwise could accelerate drying and lead to cracking of the cement lining.

Construction and Repair Practices. AWWA Standards C600 (AWWA, 2005a), C602 (AWWA, 2006c), C604 (AWWA, 2007), C605 (AWWA, 2005b), and C606 (AWWA, 2006d) address pipe installation procedures, as well as guidelines on inspection, trench construction, pipe installation, joint assembly, flushing, and pressure and leakage testing. Best management practices during the construction or repair of water mains are provided by Pierson and colleagues (2001). Topics of interest include (1) maintenance of pipe caps, plugs, or other protective coverings until pipes are joined, (2) provision positive-flow shut-off, (3) protection of existing mains and service connections with watertight caps or covers, (4) completion of all pipe and fitting joints in a trench before work is stopped, (5) use of recommended packing and sealing materials, (6) gasket cleaning, (7) disinfection of fittings, joints, valves, and exposed existing connections with swab or spray technique, and

(8) disinfection of hand tools, tapping machines, and other equipment that come in contact with pipes and fittings.

Main breaks are a pervasive problem for many utilities. The causes for breaks are varied; however, according to Deb and colleagues (2000), one of the primary causes of main breaks in otherwise structurally sound water mains is improper installation. Broken mains may become depressurized owing to water loss or service shutdown. According to AWWA Manual M20, *Water Chlorination Principles and Practices* (AWWA, 1973), contractors and workers should be thoroughly familiar with all pertinent state and local requirements governing installations of mains. The manual recommends the use of watertight plugs at all times when construction is not actually in progress.

Trenchless technologies have gained increasing popularity over the past several years because they reduce disruption and can be cost efficient (Pierson et al., 2001). The authors discuss contamination control methods for trenchless rehabilitation and replacement techniques, including pit excavation, pit dewatering, storing and handling of new liners, coupling methods, extraction of bentonite slurry, lubricant use, flushing, and chlorination. The AwwaRF manual, *Demonstration of Innovative Water Main Renewal Techniques* (Deb et al., 1999), demonstrates and evaluates various trenchless technologies and identifies conditions under which each technology can be best applied.

Trench Work. As described previously, trench water has a high potential for contaminating water mains during installation and repair. Dewatering the trench to a level below the pipe invert may be necessary to avoid contamination. Pierson and colleagues (2001) suggest using submersible pumps and fittings used for clean water work only to avoid cross-contamination from sewage water applications.

Preparing for Service. The elements for contamination control associated with preparing a new, rehabilitated, or repaired mains for service include hydrostatic testing, flushing and cleaning, disinfection, and water quality testing. In North America, disinfection typically is performed in accordance with AWWA Standard C651, which was updated in 2005 (AWWA, 2005c). Based on a survey of 250 utilities, Haas and colleagues (1998) found that 75 percent of respondents reference AWWA Standard C651 in their construction documents. Haas and colleagues (1998) document the results of actual field evaluations to test the adequacy of AWWA Standard C651 for disinfecting water mains. The researchers concluded that the AWWA standard provides adequate disinfection: The AWWA-recommended disinfection dose of 25 mg/L for a 24-hour contact time provides more than a 4 log (99.99 percent) inactivation of HPC organisms. It also was found that approximately 10 mg/L of free chlorine reduces HPC bacteria to less than 100 CFU/mL.

AWWA Standard C600 (AWWA, 2005a) states that the interior of all pipes, fittings, and other appurtenances shall be kept free from dirt or foreign matter at all times. While the current ANSI/NSF 61 standard does not provide specific requirements for the sanitary conditions of piping materials that are intended for use in drinking water systems, other manuals of practice, such as AWWA Manual M20, *Water Chlorination/Chloramination Principles and Practices* (AWWA, 2006), recommend precautionary measures such as the use of watertight plugs at all times when construction is not actually in progress.

Several AWWA standards provide recommendations for pressure and leakage testing (Table 21-13). Problems that can occur if the new or repaired pipe section is not pressure tested adequately include (1) deflection of flexible couplings greater than that acceptable for the type of coupling may lead to leaks and subsequent contaminant intrusions, (2) pipe joints are designed to seal under high internal pressure conditions but may leak if the external pressure is higher than the internal pressure (e.g., a low-pressure pipe where there is a high groundwater level), and (3) adapters may leak if not installed properly.

Haas and colleagues (1998) report another potential source of contamination from stagnant water created by closed valves directly adjacent to the area of main construction or repair. Distribution system water that lies stagnant for extended periods in dead-end sections

around the area of construction or repair can have no disinfectant residual and low dissolved oxygen, conditions that may promote the growth of bacteria. (AWWA and EES, 2002c).

Preventing Contamination Associated with Storage Facilities. Storage facilities are most susceptible to external contamination owing to the absence or failure of an essential component, such as a cover, vent, hatch, and so on. Even when covered, storage facilities can suffer from algal growth on the tops of floating covers that can gain entry into the tank through rips and tears or missing hatches. Algae can also be airborne or carried by birds and gain entry into storage tanks through open hatches and vents. Algae increase the chlorine demand of the stored water, reduce its oxygen content on their degradation, affect taste and odor, and in some cases release toxin by-products (National Academy of Science, 2006).

Tank inspections provide information used to identify and evaluate current and potential water quality problems. Both interior and exterior inspections are employed to ensure the tank's physical integrity, security, and high water quality. Inspection type and frequency are driven by many factors specific to each storage facility, including its type (i.e., standpipe, ground tank, etc.), vandalism potential, age, condition, cleaning program or maintenance history, water quality history, funding, staffing, and other utility criteria (AWWA and EES, 2002b). Depending on the nature of the water supply chemistry, detailed inspections should be made every 3 to 5 years and consist of tanks needing to be drained, sediment removed, and appropriate rustproofing applied to the metal surfaces (such as where the water level rises and falls more frequently). These inspections are in addition to daily or weekly inspections for vandalism, security, and water quality purposes (such as identifying missing vents, open hatches, leaks, etc.) (Kirmeyer et al., 1999).

Storage facility maintenance activities include cleaning, painting, and repair to structures to maintain serviceability. Based on a utility survey conducted by Kirmeyer and colleagues (1999), it appears that most utilities that have regular tank cleaning programs employ a cleaning interval of 2 to 5 years. This survey also showed that most tanks are painted (exterior coating) on an interval of 10 to 15 years. Three finished water steel elevated spheroids at the City of Brookfield Water Utility in Brookfield, Wis., were the subject of a field study conducted to document the underwater cleaning process and its water quality impacts. The time since last cleaning was 15 years for one tank and 7 years for the other two tanks. The tank with the longest cleaning interval contained the most accumulated sediment of 710 mm (28 in) maximum depth compared with 100 to 300 mm (4–12 in) in the other two tanks and the highest HPC bacteria levels before cleaning of 1300/mL compared with 640 and 80/mL in the other two tanks. As a result of underwater cleaning, HPC bacteria and turbidity levels were reduced significantly (Kirmeyer et al., 1999).

FINAL COMMENTS

Maintenance of the microbial quality within the distribution requires a multidisciplinary approach that integrates the biological, physicochemical, engineering, material sciences, and operations to ensure a safe, high-quality product at the consumer's tap. The availability of advanced tools, including molecular assays, computer models, geographic information system (GIS) interfaces, and on-line monitors and information management systems, is changing and deepening our understanding of the microbial ecology of the distribution system network. Although not under the jurisdiction or control of water utilities but nonetheless important to consumers' perceptions of water quality, increasing attention is being focused on the ecology of premise plumbing. It would not be surprising to find that the ecology of plumbing systems is as different from that of the rest of the distribution system as treated water is different from raw water. Over the next decade, this will be a challenging and active area of research.

Advances in water treatment technology and increased regulation over the past three decades have resulted in marked improvements in drinking water quality and reductions in drinking water–related waterborne disease. Yet there are still challenges with risks emanating within the distribution system. The transient nature of contamination events, the complicated hydraulics of the pipe network, and the limited monitoring capabilities of even the most progressive water utilities mean that detecting and controlling distribution system microbial risks will require greater investments in research for on-line and remote monitoring. The concept that collecting a few grab samples can reveal any meaningful microbial information must be abandoned and replaced with a new scientifically based program that links online process control data for disinfectant residuals, pressure management, and infrastructure integrity into a real-time hydrologic model so that the distribution system operator can monitor and control the distribution system like the treatment operator does with a SCADA system.

All this means that the system operator for the twenty-first century will need to continue to be highly skilled, well-trained, competent, and knowledgeable water professional. Their constant vigilance is the essential glue that makes all the pieces fit together to produce safe drinking water day after day and year after year.

INTRODUCTION

Increasingly, the water treatment process itself and the residuals produced by it are interwoven and considered together rather than looked on as two separate systems. The quality and characteristics of these residuals are completely interrelated to the main treatment process and two different treatment processes achieving the same finished water goals can produce much different residuals. From economic and environmental standpoints, the residuals produced by different treatment processes can have significantly different treatment costs and disposal or reuse options for safe handling. Historically, despite these strong interrelationships between the treatment processes and their residuals, water treatment plant residuals management has historically been treated as a stand-alone management problem. With increasing costs and environmental concerns and desires for beneficial reuse, it has become increasingly common when evaluating or designing the main water process to consider the residuals quality and characteristics and view residuals management as part of the overall process to be optimized when determining the most economical manner in which to meet a specific set of finished water quality goals. This water process and residuals interrelationship is becoming more critical as removal of specific pollutants such as arsenic and radionuclides has emerged.

The original term used to describe water treatment plant wastes was *sludge*. In fact, sludge is just the solid component of many different types of waste streams. The term *residuals* is now used to describe the range of process side-streams—liquid, solid, or gaseous—that can be produced by water treatment processes. These water treatment plant wastes are referred to as residuals and are outlined in Table 22-1. The names of individual waste streams are generally a function of how the residual is produced.

There are five general types of water treatment processes that produce residuals. The first is produced at those plants that coagulate and oxidize a surface water to remove

TABLE 22-1 Major Water Treatment Plant Residuals

Solid/liquid residuals

1. Alum sludges
2. Iron sludges
3. Polymeric sludges
4. Softening sludges
5. Spent filter backwash water
6. Spent GAC or discharge from carbon systems
7. Slow sand filter wastes
8. Wastes from iron and manganese removal plants
9. Spent precoat filter media
10. Spent membrane backwash

Liquid phase residuals

11. Ion-exchange regenerant brine
12. Spent regenerant from activated alumina
13. Membrane concentrate or brine

Gas phase wastes

14. Air stripping off-gasses

Specific residuals

15. Arsenic residuals
 16. Radionuclide residuals
 17. Perchlorate residuals
-

particles (both organic and inorganic) and dissolved contaminants such as color, organic carbon, iron, manganese, and occasionally trace metals. These coagulation plants produce two major residuals, *clarifier* (sedimentation or dissolved air flotation (DAF)) *sludge* and *spent filter backwash water* (SFBW).

The coagulation process itself generates most of the solid residuals. Generally a metal salt (aluminum or iron) is added as the primary coagulant. In addition to the coagulant other solids producing chemicals such as powdered activated carbon (PAC), polymer, clay, lime, or activated silica may be used. These added chemicals all produce solids. They are usually removed, along with the solids in the raw water, in a clarifier. These residuals are referred to as *clarifier sludge* or *clarifier blowdown*. They are more specifically referred to by the type of coagulant used. For example, alum sludge is residuals produced from the use of an aluminum-based coagulant and iron sludge is residuals produced by the use of an iron-based coagulant. When dissolved air flotation is used as the clarification step, the residuals are referred to as *float*. The second major residual produced at coagulation plants is from the batch process of backwashing the filters as described in detail in Chap. 10. Note that the residuals are not called backwash water but rather spent filter backwash water. Backwash water is used to clean the filters. The solids collected on the filters are those remaining after sedimentation or caused by the addition of a filter aid or formed by oxidation of perhaps iron or manganese. In a direct filtration process, these are the only solids produced. The volume of SFBW produced is a function of the amount of water used for backwashing. In areas with good raw water quality, the clarification step is occasionally omitted and the solids are removed by filtration only. This process, commonly known as *direct filtration*, is usually used for water with low turbidity and one that requires low levels of coagulant.

The residuals can be further treated resulting in additional residuals streams. Much of the terminology is somewhat obvious. A thickener treating clarifier sludge or clarifier sludge plus SFBW produces *thickened sludge* (which could be thickened alum or iron sludge) and thickener supernatant. A thickener that only treats SFBW will produce SFBW settled solids. A dewatering device will produce a *sludge cake* (also called *dewatered solids*) as well as a liquid stream. The liquid stream is referred to by the type of dewatering used, such as filtrate, decant, and centrate.

The second type of treatment plants are those that practice lime-soda ash softening for the removal of calcium and magnesium as described in Chap. 13. These plants may also remove trace metals, radioactivity, and particles if surface water is being treated. The residuals produced are the same types as in coagulation and include clarifier sludge (*lime sludge*), spent filter backwash water, thickened sludge, and so on.

Ion-exchange processes are the third type of treatment processes that produce residuals. As their name implies, these processes are used to remove cation or anion contaminants such as calcium and magnesium, arsenic, nitrate, and barium as described in Chap. 12. These processes produce a *brine* residual as well as *spent rinse water*. There are also adsorption processes that produce similar types of residuals. Some adsorption processes use throw-away media such that the residual produced is the *spent adsorption material*. Adsorption media may also need to be backwashed so *spent backwash water* is produced.

The fourth general category of treatment is when membranes are used to remove particulates or dissolved solids as described in Chap. 11. Membranes can be used to remove a variety of contaminants. The size of contaminant removed depends on the type of membrane selected and its associated pore size. As membrane systems are increasingly used for water utility applications, the management of their residuals has become a growing challenge. Membrane technology uses a driving force (e.g., electrical, pressure/vacuum, etc.) to separate contaminants from the water. Pressure-driven membranes include *microfiltration* (MF), *ultrafiltration* (UF), *nanofiltration* (NF), and *reverse osmosis* (RO). Electrically

driven membranes include *electrodialysis* (ED) and its variant *electrodialysis reversal* (EDR). Whereas MF and UF membranes are designed for particle removal and use low pressure, NF, RO, and ED/EDR are designed for desalination (and softening).

MF and UF processes are low-pressure membranes that primarily remove particles. The particles buildup on the membranes and are backwashed off to clean the membrane. This membrane backwash residual contains the particles that were removed from the source water. Occasionally a coagulant or PAC is added to the raw water prior to the membrane and that will also be in the membrane backwash. These residuals are referred to as spent *membrane backwash*

Desalting membranes such as RO and NF primarily remove dissolved ions. These membranes produce a fairly continuous residual that contains the concentrated ions that the membrane rejects. The residuals are referred to as *concentrate* and occasionally *brine*.

Additional residuals generated by membrane processes are spent chemical solutions that are used to perform deep cleaning of the membranes to remove foulants via *clean-in-place* (CIP) processes; these are labeled *CIP waste*.

Finally, *gaseous residuals* are produced by air stripping processes that release gases to the atmosphere. These releases are primarily volatile organic compounds and radon.

There can also be a wide variety of what are referred to as *minor waste streams* produced at water treatment including analysis waters, sample line and sink drainage, leakage from pipes and pump seals, pump packing water, floor and laboratory drains, roof drains, granular activated carbon (GAC) transport water, leakage from chemical tanks, and process overflows.

There are several additional residuals that are referred to by the fact that they result from the removal of a specific contaminant. The contaminant presence in the residuals describes them, such as arsenic residuals and radionuclide residuals. These residuals have significant regulatory issues associated with their proper management.

COAGULATION AND LIME-SOFTENING RESIDUALS

Quantities

The quantity of solids or sludge dry weight generated from water treatment plants depends on the raw water quality and dosage of treatment chemicals used.

One of the most difficult tasks facing the water utility or engineer in planning and designing a residuals treatment process is determining the amount of residual to be handled. The residual quantity is usually determined as an annual average for a given design year and is a function of flow demand projections. Sometimes overlooked, but important, is information on seasonal or monthly variations. It is not unusual for order of magnitude differences in residuals production to exist for different months of the year.

The amount of alum (or iron) sludge generated can be calculated fairly closely by considering the reactions of alum or iron in the coagulation process. Using an empirical relation to account for the sludge contribution from turbidity improves the estimate and the contribution from other sources can be added as required.

When alum is added to water as aluminum sulfate under dosing and pH conditions such that the solubility of Al is exceeded, an amorphous (am) Al-hydroxide solid is produced. Assuming all of the added Al ends up in the solid, the reaction is typically represented by the simplified equation (see Chap. 8 for details of alum coagulation).

If inadequate alkalinity is present, lime or sodium hydroxide is normally added to maintain the proper pH for precipitation of the aluminum hydroxide. There are three waters of hydration associated with the aluminum hydroxide. These three waters of hydration satisfy the covalent bonding number of 6 for aluminum. Not including the waters of hydration in the reaction underestimates the amount of solids that are produced. This chemically bound water increases the sludge quantity, increases the sludge volume, and also makes it more difficult to dewater since the chemically bound water cannot be removed by normal mechanical methods. The resulting aluminum hydroxide species has a molecular weight of 132, and therefore, 1 mg/L of alum added to water will produce approximately 0.44 mg/L of inorganic aluminum solids. Suspended solids present in the raw water produce an equivalent weight of sludge solids since they are non-reactive. It can be assumed that other additives such as polymer (expressed on a dry weight basis) and powdered activated carbon produce sludge on a one-to-one basis. The amount of sludge produced in an alum coagulation plant for the removal of suspended solids is then

$$S = Q (0.44Al + DOC_r + SS + A) \quad (22-2)$$

where S = sludge produced (kg/day)
 Q = plant flow (MLD)
 Al = alum dose as 17.1 percent Al_2O_3 (mg/L)
 SS = raw water suspended solids (mg/L)
 DOC_r = dissolved organic carbon removed
 A = additional chemicals added such as polymer, clay, or PAC (mg/L)

If iron is used as the coagulant, then the equation becomes

$$S = Q (2.9Fe + DOC_r + SS + A) \quad (22-3)$$

where the iron dose is expressed as mg/L of Fe^{3+} added or produced via Fe^{2+} oxidation (note that significant Fe^{2+} in the raw water will also produce sludge at a factor of 2.9 if it is oxidized). It should not be interpreted from the above two equations that iron produces several times the amount of sludge that alum produces. The units for the coagulant are significantly different for the two equations. In reality 1 mole of coagulating equivalent of iron produces about 20 to 25 percent more dry weight sludge than 1 mole of aluminum. Iron can be purchased as ferric chloride or ferric sulfate. Ferric chloride ($FeCl_3$) dosing is usually reported as equivalent dry weight of chemical without waters of hydration (although this should be confirmed with the manufacturer) and thus has a molecular weight of 162.3. This relationship results in 1.0 mg of solids produced for each milligram of ferric chloride added. Ferric sulfate is reported by different manufacturers with different waters of hydration, and the individual products need to be referenced.

These equations can be used to track yearly or even daily variation changes in sludge mass produced. The difficulty in applying the relationships is that most plants do not routinely analyze raw water suspended solids concentrations. The logical correlation is to equate a turbidity unit to a suspended solids unit. Unfortunately the relationship is generally not 1 to 1.

$$SS \text{ (mg/L)} = b \cdot Tu \quad (22-4)$$

where Tu is raw water turbidity.

The value of b for waters low in color, predominately turbidity removal plants can vary from 0.7 to 2.2. It may vary seasonally for the same raw water supply. A utility can therefore either continually measure suspended solids or develop a correlation between turbidity and suspended solids. Figure 22-1 shows one such correlation for a low-color raw water source. Ideally, this correlation should be done weekly until information is learned as to seasonal

FIGURE 22-1 Suspended solids versus turbidity. (Courtesy of EPCOR, Inc., Edmonton, Alberta.)

variations in the suspended solids/turbidity relationship. Afterward a monthly correlation may be sufficient.

Another complication exists for raw water sources that contain a significant amount of natural color. Color can be a large contributor to sludge production. For some waters, color is filterable on a 0.45- μm filter and therefore is measured in a suspended solids analysis. Values of b for colored raw waters can be as high as 20, but unless turbidity and color vary together, a correlation between SS and Tu will not exist.

Figure 22-2 compares calculated and measured solids production done by the city of Philadelphia. The city used iron as the coagulant during this time period. A correlation was developed that showed the ratio of suspended solids to turbidity was 1.4. The calculated quantities were within 5 percent of the measured quantities. Through careful calibration and measurements, a complete solids mass balance can be prepared, as was done by the city of Philadelphia and is shown in Fig. 22-3.

FIGURE 22-2 Baxter WTP theoretical versus measured residuals quantities. Note: multiply by 0.454 to convert to kg/day. (Source: EE&T, 1996.)

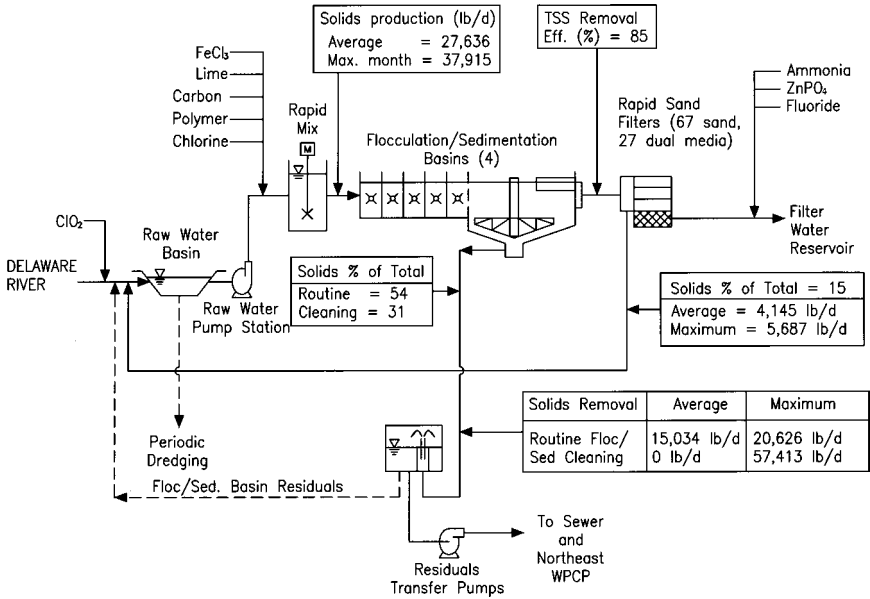

FIGURE 22-3 Baxter WTP baseline residuals distribution. Note: multiply by 0.454 to convert to kg/day. (Source: EE&T, 1996.)

Example 22-1 Calculating Sludge Solids

The residuals treatment processes at a water treatment plant are to be sized to accommodate the equivalent of the 90th percentile of the historical daily solids production. The available historical data are summarized in the following table. Although the data shown are monthly values, normally daily data for several years would be utilized. Additionally, after conducting a correlation study between suspended solids and turbidity, it was determined the *b* value for this raw water to be 1.4 mg/L-ntu.

Solution

Month	Plant production (ML)	Turbidity (ntu)	Monthly average	
			FeCl ₃ dose (mg/L)	PAC dose (mg · L)
January	1550	4	25	—
February	1540	5	24	—
March	1860	4	25	—
April	1800	15	30	—
May	2015	20	35	3
June	2250	12	25	3
July	2635	10	22	3
August	2790	14	28	3
September	2250	20	35	3
October	1860	15	32	—
November	1500	12	30	—
December	1395	6	25	—

The solids production for each month can be found using Eq. 22-3. The data presented are expressed in mg/L as FeCl_3 , so it is necessary to convert to Fe for the August data.

$$\frac{\text{MW Fe}}{\text{MWFeCl}_2} = \frac{56 \text{ g/mole Fe}}{161 \text{ g/mole FeCl}_3} (28 \text{ mg/L as FeCl}_3) = 9.74 \text{ mg/L as Fe}$$

Continuing to use the August data as an example, the solids production calculated using Eq. 22-3 is

$$\begin{aligned} S &= 0.001 \frac{\text{L} \cdot \text{tonne}}{\text{ML} \cdot \text{mg}} (2790 \text{ ML}) \\ &\times \left[1.4 \frac{\text{mg}}{\text{L} \cdot \text{ntu}} (14 \text{ ntu}) + 2.9 \frac{\text{mg}}{\text{mgFe}} (9.74 \text{ mg/L as Fe}) + 3 \text{ mg/L FAC} \right] \\ &= 114.9 \text{ tonne} \end{aligned}$$

With this approach, we can determine the average solids production for each month, as shown in the following table.

Month	Plant production (ML)	Monthly average			Solids production (tonne)
		Turbidity (ntu)	FeCl_3 dose (mg/L)	PAC dose (mg/L)	
January	1550	4	25	—	47.8
February	1540	5	24	—	48.1
March	1860	4	25	—	57.3
April	1800	15	30	—	92.3
May	2015	20	35	3	133.6
June	2250	12	25	3	101.3
July	2635	10	22	3	103.3
August	2790	14	28	3	141.9

December	1395	6	25	—	46.9

A statistical analysis will indicate that the 90th percentile of the monthly average solids production is 141 tonnes. Converting to kilograms and dividing by 30 days per month provides a daily solids production of 4700 kg/day. This can be compared to the average monthly solids production of 88.9 tonnes, equivalent to a daily average of approximately 2969 kg/day. This difference between the 90th percentile solids production and the average solids production illustrates the problem of sizing facilities based only on average data. Furthermore note that in the example, the turbidity and coagulant dose are paired to the flow for that month. If unpaired data are used (e.g., calculating solids production by calculating lb/MG and multiplying that by the design plant flow), bias can be introduced because peak solids production may or may not occur during periods of peak plant flow. ▲

Polyaluminum chloride (PACl) is the third major coagulant used. Care needs to be used when converting PACl dose to solids production since each purchased chemical has different strengths and utilities report these doses differently. Some utilities report PACl dose as a neat solution, some as Al_2O_3 , and some as PACl product. A typical manufactured PACl liquid contains about 30 to 35 percent PACl and around 10 percent Al_2O_3 . As an example, one manufactured product contains 33.3 percent PACl and 10.3 percent Al_2O_3 . In this case, 1 mg of PACl will produce 0.8 mg of solids, assuming that the coagulation process is operated at a dose and pH that promotes precipitation of aluminum hydroxide.

Through similar theoretical considerations a general equation has been developed for plants that use a softening process with or without the use of alum, iron, or polymer (Cornwell, 2006). The equation is

$$S = Q [2.0\text{CaCH} + 2.6\text{MgCH} + \text{CaNCH} + 1.6\text{MgNCH} + 0.44\text{Al} + 2.9\text{Fe} + \text{SS} + \text{A}] \quad (22-5)$$

where

- S = sludge production (kg/day)
- CaCH = calcium carbonate hardness removed as CaCO_3 (mg/L)
- MgCH = magnesium carbonate hardness removed as CaCO_3 (mg/L)
- CaNCH = calcium noncarbonate hardness removed as CaCO_3 (mg/L)
- MgNCH = magnesium noncarbonate hardness removed as CaCO_3 (mg/L)
- Fe = iron dose as Fe (mg/L)
- Al = alum dose as 17.1 percent Al_2O_3 (mg/L)
- Q = plant flow (MLD)
- SS = raw water suspended solids (mg/L)
- A = other additives (mg/L)

If the source of the water to be softened contains turbidity (suspended solids) or DOC, then those are added to the equation the same as for coagulant solids. If the lime dose is known by operating records or separate calculation, then the lime sludge production can be estimated by the lime added (as CaCO_3) plus the calcium removed (as CaCO_3) plus 0.6 times the Mg removed (as CaCO_3).

These equations or prediction procedures allow the estimation of the dry weight of sludge produced. They do not predict the volume of sludge that is produced.

Volumes and suspended solids concentrations of sludges leaving the sedimentation basins or clarifiers are a function of raw water quality, treatment process, and the sludge removal method. Sludges which are allowed to build up in basins and are being cleaned only periodically by manual procedures, tend to compact and thicken in the bottom of the basins. There is often a stratification of solids with the heavier particles settling to the bottom and the hydroxide or lighter particles at the top. However, the actual concentration produced will depend largely on the amount of water used to flush the solids out of the basin during cleaning. With increasing finished water quality standards, there is a trend to remove the solids as quickly as possible, generally with continuous collection equipment. In this case the solids concentrations are lower since compaction height and time has been less. Solids concentrations for sludges produced with alum or iron coagulants and for low to moderate turbidity raw waters are about 0.1 to 1.0 percent. The higher the ratio of coagulant to raw water solids, the lower the solids concentration is, and the higher the sludge volume. Coagulant sludges from highly turbid raw waters may be in the 2 to 4 percent range and occasionally higher. Sludge volumes tend to be 0.1 to 3 percent of the raw water flow, with one survey (Cornwell and Susan, 1979) finding an average of 0.6 percent, but this is highly dependent on the removal method. The type of clarification process used also impacts the solids concentration and volumes. For example some clarification processes like ballasted sand sedimentation can produce weak solids concentrations in the 0.1 percent

range, whereas a process like DAF can produce solids concentrations of up to 3 percent or greater (see Chap. 9). Softening sludges will concentrate higher, usually as a function of the $\text{CaCO}_3:\text{Mg}(\text{OH})_2$ ratio and the type of clarifier. Conventional sedimentation basins in softening plants may only produce solids concentrations of 2 to 4 percent, whereas sludge blanket clarifiers can produce solids concentrations of up to 15 percent. Sludge volumes correspondingly vary considerably, from less than 0.5 up to 5 percent of the water plant flow.

Spent filter backwash water is characterized by its large water volume and low solids concentration. Filters can be backwashed at rates of 35 to 70 m/h (15 to 30 gpm/ft²) depending upon the media size and water temperature, and the backwash time may be 15 to 20 min. Backwash water volumes are typically in the range of 3 to 10 percent of plant production. Accurate plant records often exist on the amount of backwash water used. The percentage of plant production used for backwashing can be computed from the ratios of the unit run volumes. For example, a filter producing water at 9.65 m/h (4 gpm/ft²) with a 24-hour run time has a unit production of 235 m³/run/m² (5760 gal/run/ft²). If it is backwashed at 48.9 m/h (20 gpm/ft²) for 20 min, the unit volume of backwash water is 16.3 m³/run/m² (400 gal/run/ft²), for a ratio of about 7 percent backwash water compared to production water. Typically operators will try to maintain backwash water use to around 4 percent of plant influent flow. Spent filter backwash water contains 10 to 15 percent of the total solids production depending on the efficiency of the clarification process and have suspended solids concentrations of 30 to 300 mg/L depending on the applied turbidity to the filters and the ratio of backwash water to production. Table 22-2 shows example SFBW suspended solids concentrations reported by Cornwell et al. (2001).

Characteristics

The terms *solid/liquid residuals* or *sludges* are used to describe free-flowing liquids that are predominantly water all the way up to mixtures that are predominantly solids and behave like a soil texture. Therefore, whenever referring to the physical properties of sludge, it is important to know the suspended solids concentration of the solid/liquid mixture in order to assess the physical state. Cornwell et al. (1992) used the Atterberg limit test to classify sludges. The Atterberg test describes quantitatively the effect of varying the water content on the consistency of fine-ground soils. The test consists of measuring five limits; however, the liquid and the plastic limits are the most applicable to sludges. The plastic limit identifies the solids concentration at which a sludge transitions from a semisolid to a plastic (the plastic state ranges from soft butter to stiff putty) stage. The liquid limit is the solids concentration below which the sludge exhibits viscous behavior; the consistency could be

described as ranging from soft butter to a pea-soup-type slurry. Coagulant sludges that were tested had liquid limits in the 15 to 20 percent solids concentrations range. Solids concentrations below but near this range result in a material that still has free water associated with it but may not be flowable. Generally, a coagulant sludge is still free flowing up to an 8 to 10 percent solids concentration. The plastic limit for coagulant sludges was found to be anywhere from 40 to 60 percent solids concentration.

Knocke and Wakeland (1983) divided the physical properties of sludge into their macro and micro properties. Macro properties are such parameters as specific resistance, settling rates, and solids concentrations. The indices described could be considered macro properties. Micro properties include particle size distribution and density. Vandermeijden et al. (1997) studied the micro and macro properties of about 80 water plant sludges. Coagulant sludges had a median particle diameter of 0.005 mm with a range of approximately 0.001 to 0.03 mm as shown in Fig. 22-4. Lime sludge had a similar range but the median diameter was 0.012 mm. They also measured the specific gravity of the solid material in the sludge mixtures shown in Fig. 22-5. The coagulant residuals had an average specific gravity of 2.32

FIGURE 22-4 Average particle diameter for coagulant and lime residuals. (Source: Vandermeijden et al., 1997.)

FIGURE 22-5 Specific gravity distribution for coagulant and lime residuals. (Source: Vandermeijden et al., 1997.)

and the lime residuals averaged 2.50. Note that this specific gravity is of the solid material. Wet densities tend to be close to water, around 1.05.

Vandermeijden et al. (1997) also evaluated drainage properties of the 80 residuals using the *capillary suction time* (CST), *specific resistance* (SR), and *time to filter* (TTF) tests.

The CST test is a fast and relatively simple test that is performed to determine the rate of free water release from a residual sample. The test is especially useful for comparing the drainage characteristics of different residuals and for optimizing polymer conditioning of residuals. The test consists of measuring the time in seconds for free water to travel 1 cm when a 5 to 7 mL sample of residuals is placed in a special cylinder which is located on a Whatman No. 17 chromatography paper. As the free water drains from the residuals through the chromatography paper, it passes by an electronic sensor that activates a timer. The timer stops when the free water reaches a second electronic sensor, 1 cm away. The time, in seconds, recorded by the instrument is the CST time.

The resistance to fluid flow exerted by a cake of unit weight of dry solids per unit area is defined as the SR. In order to evaluate SR, a sample of residuals is subjected to a vacuum using a Buchner funnel apparatus. Typically, 100-mL portions of residuals are added to the Buchner funnel which is lined with a paper filter and a vacuum is applied to the filter apparatus. The volume of filtrate generated at various times is recorded. This procedure is continued until enough water has been drawn out to produce cracking in the cake on the filter paper and subsequent loss of vacuum.

A simplification of the SR test is the TTF test. This test is set up with the same Buchner funnel apparatus as the SR test, but is much simpler to run. The only data collected is the amount of time it takes for one half of the sample volume to filter. The result is expressed in seconds. Details of the procedures for all these tests are in Vandermeijden et al. (1997).

Vesilind (1988) proposed that the water released from the sludge material is a function of solids concentration and viscosity. It has long been recognized that solids concentration has an effect on CST. The sludge concentration is directly proportional to the filterability constant. The filterability constant can be determined as follows:

$$\chi = \Phi \left[\frac{\mu SS}{CST} \right] \quad (22-6)$$

where χ = filterability constant ($\text{kg}^2/\text{s}^2\text{m}^4$)
 Φ = dimensionless instrument constant
 μ = viscosity (centipoise)
 SS = solids concentration (mg/L)

The purpose in utilizing such a model is to make the filterability constant a fundamental measure of sludge dewatering rate. Due to the cumbersome nature of the SR test it is often preferable to use an easily determined value such as CST that allows calculation of a measure of dewatering rate that is independent of solids concentration.

If the filterability index and specific resistance are both measures of dewatering rate, then they should plot linearly. Figure 22-6 shows a plot of the inverse of the filterability constant and SR. As predicted by Vesilind, a strong correlation exists between the filterability index and the specific resistance.

The CST and the TTF tests are both direct measurements of the rate of water release from the sludge, and therefore one would expect a relationship to exist between the two tests. A plot of such a relationship is shown in Fig. 22-7. The strong correlation suggests that either test can be used successfully to evaluate sludge drainage characteristics.

Table 22-3 shows the summary statistics for each of the measured drainage tests (Vandermeijden et al., 1997). Interestingly, the general trends from all the tests were similar. For example, lime sludges had the lowest CST, TTF, and SR. The tests would predict the ease of dewatering order to be lime, ferric, alum, and PACI.

Two additional physical factors are important when dealing with a dry sludge that is to be disposed of in a landfill or monofill or utilized as backfill or a soil substitute. Those factors are the compaction density and the shear strength. Compaction tests are used to determine the achievable dry density for a particular sludge. This value is useful when estimating volumes required for a landfill or the truck volumes required to haul a certain weight of sludge. Generally, water plant sludges have been found to exhibit increasing density with increasing solids concentrations (Cornwell et al., 1992). At high solids concentrations, 80 percent dry weight densities for coagulant sludges are approximately 1000 kg/m^3 (60 lb/ft^3); at 30 percent solids concentrations, the dry unit weights are about 284 kg/m^3 (20 lb/ft^3). Wet unit weight, the weight to be hauled, is around 1065 kg/m^3 (75 lb/ft^3) at 20 percent solids concentration increasing to 1278 to $1,420 \text{ kg/m}^3$ (90 to 100 lb/ft^3) at 60 percent solids concentration for alum and iron sludges.

The shear strength of sludges relates to the overall ability of the sludge to support itself and external loadings, such as vehicle traffic or earth-moving equipment. Measuring shear strengths of water plant sludges is complicated by the fact that the shear strength varies with sludge age and with disturbance. Figure 22-8 shows an example of shear strength as a function of solids concentrations for three different water plant sludges (Cornwell et al., 1992).

FIGURE 22-8 Shear strength versus solids concentration, cone penetration, and triaxial compression tests (Note: 1 psi equals 6.895 kPa). (Source: Cornwell et al., 1992.)

Chemical characterization of solid/liquid water plant residuals is primarily concerned with determining total metal concentrations, leachable metals, and nutrient levels. Several publications (Cornwell et al., 2006; AWWA, 1996; Cornwell et al., 1992; Cornwell and Koppers, 1990) have presented values for total metal concentrations of coagulant sludges; one such example is shown in Table 22-4. The source of the metals can be the raw water as well as the coagulant itself. Metals that are often found in coagulant sludges include aluminum, arsenic, occasionally cadmium, chromium, copper, iron, lead, manganese, nickel, and zinc.

Extraction tests are designated by USEPA to be one of the methods to determine if a waste is hazardous as per Subtitle C of Resource Conservation and Recovery Act. The *toxicity characteristic leach procedure* (TCLP) is used to determine if a waste is toxic, and therefore classified as hazardous. The presence in the extract from the TCLP test of any one

TABLE 22-4 Example Total Metal Analysis for Coagulant Sludges

Metal	Alum sludge 1 (mg/kg dry weight)	Alum sludge 2 (mg/kg dry weight)	Alum sludge 3 (mg/kg dry weight)
Aluminum	107,000	123,000	28,600
Arsenic	25.0	32.0	9.2
Barium	30	<30	230
Cadmium	1	1	2
Chromium	120	130	50
Copper	168	16	52
Iron	48,500	15,200	79,500
Lead	11	9	40
Manganese	1,180	233	4,800
Mercury	0.1	<0.1	0.2
Nickel	24	23	131
Selenium	<2	<2	<2
Silver	<2	<2	<2
Zinc	91.7	393	781

Source: Cornwell et al., 1992.

of a number of contaminants above a specified regulatory level constitutes failure of the test and results in the waste being classified as hazardous. There are no reported coagulant or lime sludges that have failed the TCLP test. In fact, it is rare to even find detectable levels of the regulated contaminants in the extract from a TCLP test on a coagulant or lime sludge.

Leaching tests in a lysimeter were subjected to rainfall for an equivalent time period of about 12 years, and the leachate was analyzed for metal concentrations. The actual test was conducted over a 6-month period. Figure 22-9 shows an example of the leaching of arsenic from the three sludges and compares the arsenic in the leachate to in-stream water quality standards and to the drinking water MCL. Only arsenic, copper, iron, manganese, and zinc leached from all three sludges. A slight degree of leaching was exhibited by the ferric sludge only, and cadmium leached from the ferric sludge only. Selenium leached from two sludges, but only during the first week. Aluminum did not leach from any of the sludges,

FIGURE 22-9 Arsenic leaching in relation to drinking water and in-stream water quality for an alum sludge. (Source: Cornwell et al., 1992.)

and none of the primary drinking water MCLs for metals monitored were exceeded in any of the leachate samples analyzed.

Water plant coagulant sludges are generally considered to be low in nutrient content, particularly nitrogen and phosphorus. However, some residuals can have as much as 3 percent total nitrogen content which can have some fertilizer value. In fact, in some cases nitrogen can be the limiting constituent in determining the maximum amount of residuals that can be applied to a specific land (EE&T, 1992).

THICKENING

After removal from a clarifier or sedimentation basin most water plant sludges can be further thickened in a gravity concentration tank. Thickening can be economically attractive in that it reduces the sludge volume and results in a more concentrated sludge for further treatment in the dewatering process. Some dewatering systems will perform more efficiently with higher solids concentrations. Thickening tanks can also serve as equalization facilities to provide a uniform feed to the dewatering step.

Although there are a few types of thickeners available on the market, the water industry almost exclusively uses gravitational thickening.

Sludge thickening is performed primarily for reduction in the volume of sludge. The relationship between the volume of sludge and the solids concentration is expressed as

$$V = \frac{M}{\rho s P} \quad (22-7)$$

where V = volume of sludge (m^3)
 M = mass of dry solids (kg)
 ρ = density of water, 10^3 kg/m^3 (at 5°C)
 s = specific gravity of the sludge
 P = percent solids expressed as a decimal (weight/weight)

An approximation for determining volume reduction on the basis of percent solids is expressed as

$$\frac{V_2}{V_1} = \frac{P_1}{P_2} \quad (22-8)$$

This is a quick and useful equation since the specific gravity of the sludge is not always known, but generally does not change within the limits of most thickening operations. Therefore, for thickening a 1 percent solids concentration sludge to 10 percent solids concentration, a volume reduction of approximately 90 percent, is achieved.

Example 22-2 Sludge Volumes

Alum sludge is removed from a sedimentation basin at a 0.3 percent solids concentration. The plant produces 150 kg of dry solids per day. What is the volume of sludge that is produced? What would be the volume of thickened sludge produced if a thickener were used to increase the solids concentration to 2 percent?

Solution

To determine the volume from Eq. 22-7, the specific gravity of the sludge must be known. For coagulant sludges below approximately 10 percent solids, the specific gravity

of the sludge is essentially 1.0. This range encompasses the performance of most gravity thickeners. Therefore, the specific gravity of 1.0 can be used in Eq. 22-7, and Eq. 22-8 applies.

$$V = \frac{M}{rsP} = \frac{150 \text{ kg/day}}{10^3 \text{ kg/m}^3 (1.0)(0.003)} = 50 \text{ m}^3/\text{day}$$

Assuming there are essentially no solids in the overflow, the volume after thickening would be

$$V_2 = \frac{P_1}{P_2} (V_1) = \frac{0.3}{2.0} (50 \text{ m}^3/\text{day}) = 7.5 \text{ m}^3/\text{day} \quad \blacktriangle$$

Gravity sludge thickeners are generally circular settling basins with either a scraper mechanism in the bottom (see Fig. 22-10) or equipped with sludge hoppers (Fig. 22-11). They may be operated as continuous flow or as batch fill-and-draw thickeners. For continuous flow thickeners, the sludge normally enters the thickener near the center of the basin and is distributed radially. The decanted water exits the thickener over a peripheral weir or trough, and the thickened sludge is drawn off the basin. For tanks equipped with a scraper mechanism, the scraper is located at the thickener bottom and rotates slowly. This movement directs the sludge to the draw-off pipe near the bottom, center of the basin. The slow rotation of the scraper mechanism also prevents bridging of the sludge solids. The basin's bottom is sloped to the center to facilitate collection of the thickened sludge.

Batch fill and draw thickening tanks are often equipped with bottom hoppers as shown in Fig. 22-11. In these tanks, sludge flows into the tank, usually from a batch removal of sludge from the sedimentation basin, until the thickening tank is full. The sludge is allowed to quiescently settle, and a telescoping decant pipe is used to remove supernatant. The decant pipe may be continually lowered as the solids settle until the desired solids concentration is reached or the sludge will not thicken further. The thickened sludge is then pumped out of the bottom hoppers to further treatment or disposal. Occasionally a mixing system is added in the sludge layer to allow for efficient pumping of the thickened sludge.

FIGURE 22-10 Continuous flow gravity thickener schematic.

FIGURE 22-11 Batch-thickening tank schematic.

Design of batch or continuous flow thickeners is usually accomplished on the basis of previous experience of similar full-scale installations or on laboratory or pilot settling tests. Thickener design can be based on one of two parameters. If the supernatant is required to meet a specific quality goal (e.g., a discharge permit requirement), then the settling velocity and allowed overflow rate needs to be determined similarly as is done for a main treatment plant clarifier in order to design for the allowed clarified turbidity. A second design parameter can be to meet a specific thickened sludge solids concentration. In the former situation, the thickener is designed on the basis of hydraulic loading (e.g., m/h (gpm/ft^2)), whereas in the second case the thickener is designed on the basis of solids loading (e.g., $kg/day \cdot m^2$ ($lb/ft^2 \cdot hr$)). When both parameters are important, they must each be determined and the most limiting design condition used.

If the goal is to meet a specific overflow turbidity, then a standard jar test procedure (see Chap. 8) can be used with or without polymer settling aids. However, as the solids concentration of the influent sludge increases, the thickener design may be constrained by the amount of solids the thickener can accommodate. When the influent solids loading exceeds the rate at which the sludge blanket compresses, then the depth of the sludge blanket will increase. This can lead to excessive solids carryover in the thickener supernatant and low solids concentrations for the thickener underflow. Pilot testing is typically required to determine the limiting solids loading rate for a particular sludge.

Depending on the sludge, either solids loading or hydraulic loading will limit the thickener design. Figure 22-12 shows the relationship between the solids concentration of the influent sludge and the hydraulic and solids loading rates. After the limiting loading conditions have been determined by testing, this figure can be used to determine whether

FIGURE 22-12 Equivalent solids and hydraulic loading rates by influent sludge solids concentration. Note: multiply gpm/ft² by 2.44 to convert to m/h; multiply lb dry/hr-ft² by 4.88 to convert to kg dry/h-m².

the hydraulic loading rate or the solids loading rate is the limiting design factor, given the influent sludge design condition. For a given target solids loading rate and hydraulic loading rate, if the intersection between the influent sludge solids concentration and target hydraulic loading rate is to the left of the target solids loading rate curve, the thickener design is limited by the hydraulic loading rate. If the intersection is to the right of the curve, the target solids loading rate is the limiting factor.

As mentioned above, determining the solids loading rate that will provide a specific underflow solids concentration is more involved and more difficult to do on a small scale than testing to determine acceptable hydraulic loading rates. The common settling test used in the laboratory is conducted in a transparent cylinder filled with sludge and mixed to evenly distribute the solids. At time zero the mixing is stopped and the solids are allowed to settle. Water plant sludges from clarifiers and sedimentation basins will generally settle as a blanket with a well-defined interface. By recording the height of the interface with time, a plot such as Fig. 22-13 can be created. The free settling velocity is then determined as the slope of the straight-line portion of the plot.

Pilot scale thickening studies require careful on-site considerations in order to maintain representative sludge flows and solids concentrations to the pilot thickener. However, done properly they are a much better design tool than the laboratory methods as they provide direct data on loading rates (liquid or solids) and overflow turbidities and underflow solids concentrations.

Example 22-3 Sizing of a Thickener

A thickener is to be sized to thicken underflow solids from four sedimentation basins from an initial average solids concentration of 0.2 to 2 percent. Each sedimentation basin is blown down twice per hour, and each blow down lasts for 5 min. The thickener

FIGURE 22-13 Thickening test in a cylinder with resulting interface height-versus-time curve.

supernatant is discharged to a nearby creek and must meet a discharge limit of 10 mg/L suspended solids. The plant produces 2720 kg (6000 lb) of solids per day.

Solution

To properly size this thickener, two types of pilot study are required. The first study would determine the effective solids settling velocity to achieve a supernatant suspended solids of 10 mg/L. This testing could be done using techniques described in AWWA M37 (1992). The second type of pilot testing required could include on-site thickener column piloting. For this example, testing determined that the supernatant discharge limit can be met provided the hydraulic loading rate is maintained at or below 0.61 m/h (0.25 gpm/ft²). Testing also indicated that the maximum solids flux for this system is 0.98 kg/h-m² (0.2 lb/h-ft²).

Whether the design is liquid or solids limited can be determined by comparing the influent solids concentration and design loading rates to Fig. 22-12. From this figure it can be seen that the intersection of the influent solids concentration (0.2 percent) and design hydraulic loading rate (0.61 m/h (0.25 gpm/ft²)) lies above the curve equivalent to the design solids loading rate 0.98 kg/h-m² (0.2 lb/h-ft²); thus, this thickener will be solids limited. Therefore, the maximum solids flux rate will be the factor used for design.

To determine the surface area required for thickening, it is first necessary to determine the influent solids loading rate. Assuming the sedimentation basin sludge collector system completely removes all of the solids present in the basin, the loading rate is

$$\frac{2720 \text{ kg/day}}{4 \text{ sed. basins}} \left(\frac{1 \text{ h-sed. basin}}{2 \text{ blowdowns}} \right) \left(\frac{1 \text{ blowdown}}{5 \text{ min}} \right) \left(\frac{60 \text{ min}}{1 \text{ hr}} \right) \left(\frac{1 \text{ daay}}{24 \text{ h}} \right) = 170 \text{ kg/h}$$

Note that this solids loading rate is greater than the average solids loading rate given by dividing the daily solids production by 24 h/day. This method accounts for the fact that solids are not continuously removed from the sedimentation basins, but are instead removed in periodic bursts. Therefore, the *instantaneous* loading rate must be used rather than the *average* loading rate. At a larger facility with more sedimentation

basins, the instantaneous loading rate may approach the average loading rate because it can be assumed that at least one sedimentation basin is being blown down at any given time.

Once the appropriate solids loading rate has been determined, it is a simple matter of applying the maximum solids flux rate to calculate the required surface area for the thickener.

$$\frac{170 \text{ kg/h}}{0.98 \text{ kg/h-m}^2} = 174 \text{ m}^2 \quad \blacktriangle$$

NON-MECHANICAL DEWATERING

Non-mechanical dewatering, as the name implies, is the dewatering of water treatment plant residuals through means that do not require the use of mechanical appurtenances such as centrifuges or filter presses. Often used in locations where land is available and monetary constraints prohibit the use of mechanical dewatering, non-mechanical dewatering can be both economical and efficient for the dewatering of water treatment plant residuals.

A variety of means are employed to accomplish non-mechanical dewatering. The most basic of these is separation of solids and free water through sedimentation followed by natural air drying of the residuals. A second method allows free water to be percolated through sand and into an underdrain system, whereas additional solids concentration increases are achieved through evaporation. In northern climates, a third system is utilized whereby water treatment plant residuals are subjected to freezing and thawing which results in a dramatic reduction in residuals volume and a corresponding increase in solids concentration.

Sand Drying Beds

Sand drying beds were initially developed for dewatering municipal wastewater biosolids but have since also been used to dewater residuals from water treatment plants. Drainage (percolation), decanting, and evaporation are the primary mechanisms for dewatering residuals in sand drying beds and are utilized in a two-step process until the desired cake concentration is achieved. Following residuals application, free water is allowed to drain from the residuals into a sand bottom from which it is transported via an underdrain system consisting of a series of lateral collection pipes. This process continues until the sand is clogged with fine particles or until all the free water has been drained, which may require several days. Secondary free water removal by decanting can take place once a supernatant layer has formed. Decanting can also be utilized to remove rainwater that would otherwise hinder the overall drying process. Water remaining after initial drainage and decanting is removed by evaporation over a period of time necessary to achieve the desired final solids concentration. Manufacturers have developed variations of this standard design, such as replacing the sand with a porous, rigid material or adding vacuum to the underdrain area to speed the water release process.

Layout and construction of sand drying beds is site specific; topography, available land, and operational constraints must all be considered. Topography plays a key role in how beds are laid out on a site, and operational constraints, such as residuals pumping distance, must also be considered when siting a bed location. Materials used in construction are typically

cast in-place concrete or concrete block when the beds are constructed at grade or earthen sides with a liner when the beds are constructed below grade.

Underdrain systems for sand drying beds are used to collect water that has percolated down through the sand and gravel and transmit it to a point of discharge. When the plant has the capability to decant, the flow from the decant mechanism is often tied to the underdrains so that a combined effluent is produced. Underdrains are typically constructed of vitrified clay or plastic piping and a host of underdrain configurations exist, but the most common is collecting drainage with laterals and conveying the flow to a header pipe. Figure 22-14 shows a section view of a typical sand drying bed.

Several sand drying beds are typically used at a given site, which offers some advantages from an operations point of view. Chief among these is the ability to rotate bed use, so that as one sand drying bed is loaded and the residuals begin to dry, another bed can be cleaned and readied for a new application of residuals. Once they have been initially loaded with residuals, the sand beds should not be loaded with additional residuals until the original solids have fully dewatered and been removed; otherwise, the partially dewatered residuals from the initial loading will blind the sand layer and prevent the drainage of free water from the newly applied residuals. For this reason, some form of residuals storage is required to allow a sufficient volume of residuals to accumulate so that a bed can be loaded to capacity during the initial loading. For plants that practice manual cleaning of sedimentation basins, this storage can be achieved within the sedimentation basins themselves. Plants that have continuous sludge removal equipment will likely need a separate sludge storage tank to hold the sludge prior to loading the sand drying beds.

Although manual cleaning of sand drying beds may be feasible for the smallest water treatment plants, mechanical equipment is generally required to efficiently clean sand drying beds of any significant size. Concrete support runners are essential for mechanical cleaning, serving to protect the underdrain system and prevent excessive sand removal and/or sand compaction (Vandermeijden et al., 1997). Front-end loaders and Vac-haul trucks have been used successfully by utilities operating sand drying beds.

The time required to evaporate the water remaining after percolation and decanting is the controlling factor in determining the bed size required. Therefore maximizing the removal of water prior to evaporation will also maximize the bed yield. The solids that remain after drainage and decanting are referred to as the drained solids. The value of the drained solids concentration is dependent on the initial solids concentration, the use of conditioning agents such as polymer, the applied depth, and the efficiency of the water removal system. A series of pilot tests can be conducted to determine the combination of loading depth, initial solids concentration, and polymer use that maximizes the drained solids concentration. Vandermeijden et al., (1997) developed the following equation to determine the bed yield once the drained solids concentration is known:

$$Y = (0.833) \frac{SS_f SS_d E}{SS_f - SS_d} \quad (22-9)$$

where Y = sand bed yield (kg/m²/yr)
 SS_f = desired final solids concentration (percent)
 SS_d = drained solids concentration (percent)
 E = net pan evaporation (cm/mo)

Alternatively, by determining the depth of evaporation required to achieve the required evaporative drying, it is possible to use numerical methods to model non-mechanical dewatering performance using historical plant data, which in turn can be used to determine the

FIGURE 22-14 Typical sand drying bed section.

required bed area. This approach is based on the following equation from Cornwell and Vandermeijden (1999):

$$\Delta D_e = D_d - \left(\frac{D_d SS_d}{SS_f} \right) \quad (22-10)$$

where ΔD_e = required depth change due to evaporation (cm)
 D_d = drained depth (cm)

$$D_d = D_i \frac{SS_i}{SS_d}$$

where D_i = initial depth of residuals at loading (cm)
 SS_i = initial solids concentration (percent)

Using the required depth change due to evaporation, historical evaporation data can be utilized to determine the time required for a sand bed to reach the desired solids concentration, depending on the time of year during which the bed was initially loaded. Coupling this model to solids production projections based on historical plant data and can allow sand drying bed performance to be numerically simulated. For best performance, sand drying bed sizing should be determined on the basis of monthly, or even daily, solids production and evaporation numbers rather than annual averages in order to account for production and climatic variables (Vandermeijden et al., 1997).

Vandermeijden also found that when using net pan evaporation to predict the evaporation rate that the evaporation was underestimated. In three different field trials, a 25 percent dry cake solids concentration was reached in about 2/3 of the time predicted by using pan evaporation data. Thus, under the test conditions studied, using pan evaporation would result in a conservative sizing of the sand drying beds. At higher solids concentrations (>30 percent); however, pan evaporation overestimated the actual field evaporation. The point of crossover was speculated to be when the free water was evaporated and the chemically bound water remains. The bound water would be more difficult to evaporate, and the loss of bound water would be unlikely to correspond to volume reduction of the cake solids matrix, as is assumed by the model.

Solar Drying Beds

Solar drying beds are similar to sand drying beds in terms of shape and operation; however, they are constructed with sealed bottoms and have sometimes been referred to as *paved drying beds*. These beds have little or no provisions for water to be removed through drainage; all residuals thickening and drying is accomplished through decant of free water and evaporation. A principal advantage of this type of drying bed is low maintenance costs and ease of cleaning. No sand replacement costs are associated with this type of drying bed, and since the bottoms of these beds are sealed, neither initial underdrain costs nor underdrain repair costs are incurred. Also, because the entire solar bed bottom is often paved or concrete, cleaning with front-end loaders can be done quickly and efficiently. Because solar beds rely primarily on evaporation, they typically have lower solids loading rates than sand drying beds. Most solar beds are located in the southern and southwestern parts of the country where evaporation rates are high.

Dewatering Lagoons

Dewatering lagoons are similar to sand drying beds except that they operate at much higher loadings. The dewatering lagoons are equipped with a decant structure and underdrains, similar to a sand bed. For a dewatering lagoon, the lagoon is filled over a long time and then allowed to dry for a long period while another lagoon is filled. Dewatering lagoons can have an advantage over sand drying beds in reducing peaks, since the loading is often spread over several months. Because dewatering lagoons use a much higher loading rate, the drainage volume would generally be lower than a sand drying bed. The main difficulty in sizing a dewatering lagoon is in predicting the drained solids concentration after the loading is complete. Plugging of the sand media on the bottom of the dewatering lagoon with multiple loadings is difficult to predict and would require a carefully planned pilot test with dewatering columns, or even pilot-scale dewatering lagoons would be necessary to accurately size and design the system. The bottom of the lagoon would have a higher solids concentration than the top of the lagoon and a net average solids concentration must be estimated. During the evaporation phase, the bottom layers often do not dry out. Some utilities have found that tilling the sludge during the evaporative cycle helps to expose all of the residuals to drying.

A lagoon can be sized by selecting a desired fill cycle and estimating the drained solids concentration. The lagoon area can be calculated for varying drained solids concentrations as

$$\text{Dewatering lagoon area} = \frac{(\text{kg sludge})}{(\text{Depth in cm}) (SS_d)(10)} \quad (22-11)$$

Freeze-Thaw Beds

It has long been recognized that when coagulation residuals are subjected to freezing, the resulting volume reduction and increased solids concentration is appreciable. Typically, the volume reduction is well over 70 percent and solids concentrations may reach as high as 80 percent when freeze-thaw is followed by evaporation. Freeze-thaw followed by evaporation dramatically converts the residuals from a fine particle suspension to granular particles. The granular particles often resemble coffee grounds in both size and appearance, and they do not break apart even after vigorous agitation. This change is irreversible, and the resultant solids drain almost without resistance if subsequently rewetted (Vesilind and Martel, 1990). Thus, if the frozen residuals are placed on a porous medium, the melt water drains away easily on thawing (Martel and Diener, 1991). As noted by Parker et al. (1998), improvement in dewaterability of the residuals is influenced by the rate of freezing. At slow freezing rates, the interface between the ice and the melt water advances as a planar interface that causes the residual flocs to migrate ahead of the ice interface and subsequently aggregate into larger flocs before becoming entrained by the ice. At faster freezing rates, the ice-melt interface is composed of dendrites that entrap and fragment the flocs. This results in smaller flocs following thawing, and this reduces the dewaterability of the residuals.

Traditionally, freeze-thaw beds have relied on natural freezing and were thus operated most effectively in northern climates, although mechanical freeze-thaw conditioning may be cost effective in regions where electricity rates are low and residuals disposal costs are moderate to high (Parker and Collins, 2000). Under climatic conditions the rate of freezing will generally be slow, which enhances the dewaterability of the resultant residuals. Generally, the range of effective operation for non-mechanical *freeze-thaw* beds begins at approximately 40° North latitude and extends northward.

Some water treatment plants in cold climates already take advantage of this process by modifying the operation of their lagoons or drying beds. One technique is to decant a

lagoon down to the residuals interface and allow it to freeze over the winter months. Martel and Diener (1991) report that this technique is not always successful because the residuals do not freeze to the bottom. Another technique is to pump a shallow layer (20 to 45 cm) of residuals from a storage lagoon into drying beds or ponds that are then allowed to freeze in the winter. This technique works well because the residuals usually freeze completely, but it requires a considerable amount of land and storage volume.

Combination sand drying beds and *freeze-thaw* beds can also be utilized. In this case the design must consider the evaporative condition for the drying bed cycle and the freezing and thawing conditions for the freeze-thaw cycle.

The area required for a freeze-thaw bed is generally determined by the depth of residuals that can be frozen. For some climates with long freezing periods, the depth that can be thawed can be the controlling depth. Martel (1989) developed equations to allow the calculation of these two depths. The freezing depth can be found by

$$D(z) = \frac{t(f)(T_f - T)}{\rho_f F \left(\frac{1}{h} - \frac{d(z)}{2K} \right)} \quad (22-12)$$

where $D(z)$ = total depth of sludge that can be frozen (m)

T_f = freezing point temperature = 0°C

T = average ambient temperature (0°C)

$t(f)$ = freezing time (hours)

ρ_f = density of frozen sludge = 917 kg/m³

F = latent heat of fusion = 93 W·h/kg

h = convection coefficient = 7.5 W/m²°C

$d(z)$ = thickness of the sludge layer (m)

K = conductivity coefficient = 2.21 W/m°C

Since many of these parameters are known or assumed constants, the equation was reduced by Vandermeiden (1997) to

$$D(z) = \frac{-t(f)T}{11,371 + 19,294 d(z)} \quad (22-13)$$

This equation would be used when the design calls for multiple layers of sludge to be frozen, each layer of thickness $d(z)$. In this case the utility personnel would apply the layer to the bed, and as soon as one layer had frozen then another would be applied. In Eq. 22-13, $t(f)$ and T can be found (for U.S. locations) from NOAA through records that are generally on file at the National Climatic Data Center in Asheville, N.C.

For the case of a one-time bed loading, $D(z)$ would be set equal to $d(z)$. Solving this equation requires use of the quadratic rule which results in the following expression (Vandermeiden et al., 1997):

$$D(z) = \frac{-11,371 + \sqrt{1.3 \times 10^8 - 7.7 \times 10^4 t(f)T}}{3.9 \times 10^4} \quad (22-14)$$

Example 22-4 Sand Drying Beds

The feasibility of non-mechanical dewatering via sand drying beds is being investigated for a treatment plant that produces thickened sludge at a solids concentration of 2 percent. Pilot testing has indicated that the optimum loading rate for the beds is 18.48 kg of dry

solids per square meter. At this loading rate, the beds achieve a drained solids concentration of 12 percent once the free water has percolated through the bed bottom. The drying beds will be designed to further dewater the solids to a solids concentration of 20 percent, at which point the solids will be removed from the beds and transported off-site.

On the basis of the historical solids production and evaporation data shown in the following table, it is possible to numerically simulate bed utilization, which in turn can provide the number of beds that are required.

Week	Weekly solids production (metric tons)	Monthly average net evaporation (cm/week)
0	0.0	1.482
1	7.3	1.482
2	10.9	1.482
3	9.1	1.482
4	13.6	1.778
5	11.8	1.778
6	20.9	1.778
7	16.3	1.778
8	9.1	0.889
9	6.4	0.889
10	5.4	0.889

Solution

First, it is necessary to determine the initial depth of loading, based the initial solids concentration and solids loading rate.

$$D_i = l/SS_i = \left(\frac{18.48 \frac{\text{kg}}{\text{m}^2}}{20,000 \frac{\text{mg}}{\text{L}} \left(\frac{1 \text{ kg}}{10^6 \text{ mg}} \right) \left(\frac{1000 \text{ L}}{\text{m}^3} \right)} \right) = 0.924 \text{ m}$$

From this, we can determine the drained depth of the solids using the initial and drained solids concentrations.

$$D_d = D_i \frac{SS_i}{SS_d} = 0.924 \text{ m} \left(\frac{2 \text{ percent solids}}{12 \text{ percent solids}} \right) = 0.154 \text{ m}$$

As the drained solids continue to lose water to evaporation, the depth of the solids will decrease proportionally to the evaporation rate. The amount of depth change required to reach the final solids concentration of 20 percent is given by Eq. 22-10.

$$\Delta D_e = D_d - D_d \frac{SS_d}{SS_f} = 0.154 \text{ m} - 0.154 \text{ m} \left(\frac{12 \text{ percent solids}}{20 \text{ percent solids}} \right) = 0.062 \text{ m}$$

Thus, after a bed is loaded and the solids have drained, 0.062 m of water must be lost through evaporation to dewater the sludge to the target solids concentration. A numerical simulation of this process using the data presented previously is shown in the following table. For the purposes of this simulation, it is assumed that each sand drying bed will be 15.25 m wide by 38.1 m long. At the optimum solids loading rate of 18.48 kg/m², it will take 536,474 L of sludge at a solids concentration of 2 percent to load the drying beds.

Week	Weekly solids production (metric tons)	Monthly average net evaporation (cm/week)	Weekly sludge production (liters)	EQ volume (liters)	Bed 1 (m)	Bed 2 (m)	Bed 3 (m)	Bed 4 (m)	Bed 5 (m)	Bed 6 (m)	Bed 7 (m)	Bed 8 (m)

9	6.4	0.889	320,000	300,256	0.044	0.062	—	—	0.008	0.026	0.026	0.044
10	5.4	0.889	270,000	33,782	0.035	0.053	0.062	—	—	0.017	0.017	0.035

In order to ensure that sufficient sludge is available to load an entire bed at once, it is necessary to provide an equalization volume to store the sludge prior to bed loading. The volume of sludge produced weekly can be calculated assuming a unit weight of 1 kg/L.

As shown in the preceding table, once sufficient sludge has accumulated in the sludge storage tank, 536,474 L of sludge are removed from storage and loaded into an empty bed. At the time the bed is loaded and the drained depth has been achieved (this occurs through drainage/decant of the free water in the sludge, which typically takes less than a day), the remaining sludge depth must decrease by 0.062 m to achieve the target dewatered solids concentration. This is simulated in the numerical model by showing an active bed depth of 0.062 m in one of the eight-bed columns representing the bed that was loaded. This active bed volume is iteratively reduced by the weekly evaporation (as taken from the monthly average net evaporation for the treatment plant locale) until the entire depth of 0.062 m is lost to evaporation. This simulation assumes that the beds will be available for loading 1 week after the final solids concentration has been achieved, as can be seen in Week 7 where Bed 1 is utilized for a second loading. ▲

Based on the 10 weeks of data presented in this example, eight drying beds will be sufficient to accommodate the sludge production from this treatment plant. Therefore, at least 4,645 m² of sand drying bed area will be required. In practice, it is recommended that at least 1 year's worth of data be simulated to determine seasonal effects on dewatering performance. A spot check must be done on the starting month to make sure that the assumption of a bed being available is corrected. For more detail on these calculation procedures, see Vandermeijden et al. (1997).

MECHANICAL DEWATERING

Several mechanical devices are available to dewater water treatment plant residuals. However, only five general types are in common use—centrifuges, plate and frame filter presses, diaphragm filter presses, belt filter presses, and vacuum filters. Vacuum filters have only found use on lime sludges whereas the other four are used on coagulant as well as lime sludges. Centrifuges, belt presses, and vacuum filters are all considered low-pressure systems, whereas the other two types of filter presses can both operate at higher pressures and thus produce a higher-solids-concentration cake. For coagulant sludges, centrifuges and belt presses produce a sludge cake in the 15 to 25 percent solids concentration range, although some centrifuge applications may be capable of producing sludge cake up to 30 percent solids at higher polymer loading rates/lower solids loading rates. Diaphragm and plate and frame presses can produce a cake of 30 to 45 percent solids concentration. All of the devices tend to produce cakes in the 55 to 65 percent range on lime sludges produced by softening groundwater, although vacuum filters can produce cakes in the 40 percent range. The choice of equipment can be first narrowed down by the required final cake concentrations, which for coagulant sludges especially, separate the low-pressure devices from the high-pressure devices. However, even when a high cake solids concentration is required, some utilities have found it desirable to use a lower pressure device followed by air drying in order to produce the desired final cake solids concentration since the low-pressure devices tend to be more economical and easier to operate. Ultimately pilot studies comparing performance of the different devices on a site-specific situation are necessary to select the best equipment. Scale up from pilot results to full scale then becomes an important design issue.

Vacuum Filters

Many types of vacuum filters exist. Each is subject to the same limitation; that is, the maximum theoretical pressure differential that can be applied is atmospheric, 103 kPa (14.7 psi). In practice, a differential pressure of about 70 kPa (10 psi) is achieved.

The equipment itself consists of a horizontal cylindrical drum that rotates partially submerged in a vat of sludge that, in order to assist dewatering is usually conditioned by either a coagulant or a body feed such as fly ash (Fig. 22-15). The drum surface is covered by a

FIGURE 22-15 Typical vacuum filter schematic. (Source: Innocenti, 1988.)

filtering medium that is fine enough to retain a thin cake of sludge solids as it is formed. The filtering medium usually consists of a fabric mesh. The drum surface is divided into sections around its circumference. Each section is sealed from its adjacent section and the ends of the drum. A vacuum is applied to the appropriate zone and subsequently to each section of the drum. From 10 to 40 percent of the drum surface is submerged in a vat containing the sludge slurry. The submerged area is the cake-forming zone. When the vacuum is applied to this zone, it causes filtrate to pass through, leaving a cake formed on the cloth. The next zone, the cake-drying zone, represents from 40 to 60 percent of the drum surface. In this zone, moisture is removed from the cake under vacuum. The zone terminates at the point where the vacuum is shut off. Finally, the sludge cake enters the cake discharge zone where it is removed from the medium. This is accomplished by the filter cloth belt leaving the drum surface and passing over a small diameter discharge roll that facilitates cake discharge. No vacuum is applied to this zone. Additional information on vacuum filters can be found in *Water Treatment Residuals Engineering* (Cornwell, 2006).

Belt Filter Presses

Belt filter presses use a combination of gravity draining and mechanical pressure to dewater sludges. A typical belt filter press consists of a chemical conditioning stage, a gravity drainage stage, and a compression dewatering stage (see Fig. 22-16).

The dewatering process starts after the feed sludge has been properly conditioned, usually with polymer. The slurry enters the gravity drainage stage, where it is evenly distributed onto a moving porous belt. Readily drainable water passes through the belt as the slurry travels over the full length of the dewatering stage. Typically, 1 or 2 min are necessary to allow for the filtrate separation in the drainage stage.

Following gravity drainage, the partially dewatered sludge enters the compression dewatering stage. Here, the sludge is sandwiched between two porous cloth media belts which travel in an S-shape path over numerous rollers. Both belts operate under a specific tension which induces dewatering pressure onto the sludge. The S-shape path the sludge follows creates shear forces which assist in the dewatering process. The compressive and shear forces working on the sludge increase over the length of this dewatering stage. The final sludge cake is removed from the belts by blades.

Proper sludge conditioning is considered critical for obtaining acceptable dewatering results. A typical sludge-conditioning unit consists of chemical conditioner storage, metering pumps, mixing equipment (chemical and chemical/sludge), controls, and process piping.

FIGURE 22-16 The three basic stages of belt press. (Source: Innocenti, 1988.)

In general, polymer is used for chemical conditioning. To achieve proper sludge conditioning, the polymer is first diluted to between 0.25 and 0.50 percent by weight before it is applied to the feed sludge. Next, the sludge and the polymer are thoroughly mixed. The required mixing time depends on sludge characteristics and the type of polymer used.

The design and selection of a belt filter press is often based on the throughput of the machine; that is, the rate the sludge can be dewatered by the press. The throughput capacity can be limited either by the water in the sludge (hydraulically) or can be solids limited. A belt filter press having a particular type of belt at a particular width has a maximum loading capacity for a particular sludge. Generally, the solids loading is considered the most critical factor and the throughput is expressed in terms of solids loading. The loading units are usually similar to a yield except expressed as belt width, mass/width/time.

Centrifuges

Centrifugation of sludge is basically a shallow depth settling process enhanced by applying centrifugal force. Centrifugation enhances settlement of the solids. In conventional settling tanks, the solids are acted on by the force of acceleration due to gravity (g). In centrifugation, the applied force is $r\omega^2$, where r is the distance of the particle from the axis of rotation and ω is the rotational speed. In modern centrifuges $r\omega^2$ may be 1500 to 4000 times the value of g .

The comparison of $r\omega^2$ to g has led to efforts by many to develop equations for centrifugation by substituting $r\omega^2$ for g . However, this substitution relates to discrete particles only and does not account for hindered settling and the effect of scrolling (moving the solids out of the bowl). These deficiencies in the theory of centrifugation limit the use of sedimentation theory as a basis for the design of centrifuges, and evaluation and design needs to be based on pilot studies.

The major type of centrifuge used for the dewatering of water plant sludge is the scroll-discharge, solid bowl decanter centrifuge. The solid bowl centrifuge (also called *scroll* or *decanter centrifuge*) is a horizontal unit that utilizes a scroll conveyor inside the centrifuge bowl (see Fig. 22-17). The unit is fed continuously with the solids settling against the bowl wall. The scroll rotates at a slightly different speed than the bowl and conveys the dewatered sludge to the small end of the centrifuge where it is discharged. The water is directed from the central axis of the centrifuge toward the centrifuge's large end where it is discharged. The water exits through adjustable weirs (level rings), which also control the pool depth.

FIGURE 22-17 Schematic of horizontal scroll centrifuge. (Source: EE&T, 1996.)

The best procedure for evaluation of centrifuges is pilot tests on prototype equipment. Tests should be conducted on a centrifuge exactly like that to be used in full scale except smaller. Tests should be conducted for operational parameters of concern such as feed flow rate, feed suspended solids concentration, polymer conditioning, bowl speed, pool depth, and scroll speed. Scale-up considering only liquid loading is often referred to as the *Sigma concept*. The Sigma concept is based on Stokes' law describing the settling of discrete particles under the influence of gravity. Gravity is replaced by the centrifugal acceleration and the expression is integrated over the depth of the water pool. One then ends up with a term for the allowable flow (Q) through the centrifuge.

$$Q = \left(\frac{V\omega^2}{g \ln\left(\frac{r_2}{r_1}\right)} \right) \left(\frac{g(\rho_p - \rho)d^2}{18\mu} \right) \quad (22-15)$$

where V = volume of sludge/water in the pool
 ω = radial velocity of centrifuge (rad/s)
 r_2 = radius from centerline of centrifuge to bowl
 r_1 = radius from centerline of centrifuge to pool level
 ρ_p = particle density
 ρ = fluid density
 d = particle diameter
 μ = viscosity

Note that the first set of terms on the right hand side of the equation consists of machine variables and the next set of terms relates to sludge variables. Therefore, in scale-up, if it is assumed that the sludge is the same for full scale as in the pilot studies,

$$Q_2 = \frac{Q_1 \Sigma_2}{\Sigma_1} \quad (22-16)$$

where Q_2 is the allowable flow in the full-scale centrifuge based on the optimal flow (Q_1) obtained in the pilot plant, and

$$\Sigma = \frac{V\omega^2}{g \ln\left(\frac{r_2}{r_1}\right)} \quad (22-17)$$

which are variables obtainable for the particular size pilot and full-scale centrifuge. An analysis of the solids-loading limitation is known as the *Beta concept* and is expressed as

$$Q_{s2} = \frac{Q_{s1} \beta_2}{\beta_1} \quad (22-18)$$

where Q_s is the solids throughput in units such as kg/h and

$$\beta = \Delta W S_b N D z \pi \quad (22-19)$$

where ΔW = bowl/conveyor differential speed
 S_b = pitch of blades
 N = number of leads
 D = total bowl diameter
 z = pool depth

Again, all beta terms are made up of machine variables and set by the manufacturer for the unit of interest.

In addition to the Sigma and Beta concepts, many centrifuge manufacturers have established scale up factors to predict the performance of their equipment based on pilot test results. In scale-up, multiple scale-up factors should be calculated to determine the limiting condition for design.

Example 22-5 Centrifuge Performance and Scale-Up

A centrifuge pilot study is typically conducted to evaluate performance as well as to allow for scale-up to select the appropriate size for the final installation. Figure 22-18 shows example results from such testing with a pilot centrifuge. Recovery refers to the solids capture and a desired value is over 95 percent. If, for this example, a 24 percent cake was desired, then the pilot centrifuge performed adequately at about 9.084 m³/h (40 gpm) using a polymer dose of 2000 to 2500 mg/day-kg (4 to 5 lb/day-ton). The pertinent information for the pilot centrifuge, as well as for an example full-scale unit is shown following. Using the Sigma concept, what is the capacity of the full-scale unit?

	Pilot unit	Full-scale unit
Clarification length (cm)	78.74	232.664
Bowl radius (cm)	21.336	36.83
Radius to pool (cm)	12.954	24.13
rpm	3250	3150

FIGURE 22-18 Centrifuge pilot performance data. Note: multiply gpm by 0.23 to convert to m³/h; multiply lb/ton by 2 to convert to kg/tonne.

Solution

To calculate the sigma values, Eq. 22-17 needs to be used. The volume V of sludge or water in the pool can be found as

$$V = \pi L (r_2^2 - r_1^2)$$

where L is the clarification length. Therefore, for the pilot unit,

$$V = \pi(78.74 \text{ in}) [(21.336 \text{ cm})^2 - (12.954 \text{ cm})^2] = 71,0000 \text{ m}^3$$

and ω is found as

$$\omega = (3250 \text{ rpm}) \left(\frac{\text{min}}{60 \text{ s}} \right) \left(2\pi \frac{\text{rad}}{\text{revolution}} \right) = 340 \text{ rad/s}$$

Using Eq. 22-17,

$$\Sigma_1 = \frac{(71,000 \text{ cm}^3)(340 \text{ rad/s})^2}{(9.81 \text{ m/s}^2) (100 \text{ cm/mm})n \left(\frac{21.336 \text{ cm}}{12.954 \text{ cm}} \right)} = 1.68 \times 10^7 \text{ cm}^2 = 16.8 \text{ m}^2$$

Similarly, $\Sigma_2 = 157.7 \text{ m}^2$, such that the Sigma ratio, or scale-up factor, is $157.7/16.8 = 9.39$, and, from Eq. 22-16, the design flow for the full-scale centrifuge would be $9.084 \text{ m}^3/\text{h}$ (9.39) = $85.3 \text{ m}^3/\text{h}$. ▲

Filter Presses

The filter press is another process option available for dewatering sludge, and it generally produces the highest final cake concentration of any of the mechanical dewatering devices. Early filter presses were used frequently in Europe for dewatering thin slurries, such as china clays and wastewater sludges. Their practical use for water treatment residuals began around 1965. Experiments commenced in England in 1956, but were disappointing until the advent of the use of polymers as conditioners. The first known uses in the United States were at the Atlanta Waterworks and at the Little Falls Treatment Plant of the Passaic Valley Water Commission.

At the beginning of a filter cycle, sludge is forced into contact with the cloth, which retains the solid matter while passing the liquid filtrate. Very quickly the cloth becomes coated with a cake of sludge solids, and all future filtering occurs through this cake, which increases in depth as succeeding layers build up. The type of cloth does not affect the rate of filtration after the first few minutes, and it can be ignored from a theoretical point of view.

Filter presses are heavy, cumbersome pieces of equipment demanding costly foundations and relatively large buildings. Apart from minor refinements, for several decades filter press design changed little until the advent of the diaphragm filter. The original design of the plate and frame filter (Fig. 22-19) consisted of a series of frames into which sludge is passed under high pressure, up to 1570 kPa (225 psi), in order to dewater the sludge against the outer cloth-covered plate. The depth of the cake was consequently fixed, being governed by the distance between filter plates. Different sizes of plates were manufactured to give cakes of; for example, 19, 25, or 38 mm ($\frac{3}{4}$, 1, or $1\frac{1}{2}$ in) depth. Such filters have been used to dewater sludge in an acceptable manner for many years.

A considerable change in design resulted with the introduction of diaphragm filters (Fig. 22-20). The advantage of this system is that the thickness of the cake is infinitely variable within the limits of the machine dimensions. Sludge is filtered through a cloth for a fixed period of time, perhaps 20 min, at which stage the sludge supply is cut off and water

FIGURE 22-19 Plate and frame press schematic. (Source: Innocenti, 1988.)

FIGURE 22-20 Diaphragm filter press. (Courtesy of US Filter – JWI products, Holland, Mich.)

or compressed air is applied behind an expandable diaphragm that further squeezes water out of the sludge. The cake is dislodged by shaking or by rotating the cloth, depending on the manufacturer's design, and falls into a hopper for disposal. Hanging cakes, where the cake refuses to leave the cloth, an unhappy feature of the older plate and frame press, are consequently eliminated.

SPENT FILTER BACKWASH TREATMENT

All water treatment facilities (e.g., conventional, softening, iron removal, and direct filtration) that have granular media filters as well as low-pressure membranes generate spent filter backwash water during media cleaning operations. Untreated SFBW consists of the washwater and solids carried directly off the top of a filter or cleaned off the membrane during backwash operations. SFBW typically is the largest residual stream in terms of volume, though it is typically low in solids relative to other residual streams.

The volume of SFBW generated at a water treatment plant is dependent on a number of factors including backwash duration, washwater rate, backwashing frequency (filter run

length), and number of filters. Filters are typically backwashed every 1 to 4 days, depending on treatment effectiveness, water quality, season, and operator and state regulatory preferences. Many facilities stagger backwashes, so that even when filter run lengths are long, one or more filters are backwashed on a daily basis. Backwash duration and rate also vary with treatment process, water quality, and season.

Naturally, contaminants that are removed by filtration are concentrated in the SFBW. Cornwell et al. (2001) found that TOC levels in SFBW were on average higher by threefold compared to corresponding raw water levels. Observed increases in total trihalomethanes (TTHM) and haloacetic acids (HAA6) were 92- and 24-fold, respectively, in SFBW when raw water is prechlorinated. Average total aluminum and total iron levels in SFBW were 7- and 20-fold higher in SFBW, whereas manganese levels were increased by nearly 13-fold. Table 22-5 compares contaminants in the raw water to SFBW. Corresponding average increases in aluminum and iron concentrations for plants using alum and ferric coagulants were somewhat higher (22-fold and 12-fold, respectively), while the average increase in aluminum levels for plants using polyaluminum chloride coagulants was much higher (55-fold).

TABLE 22-5 Comparison of Contaminant Levels in Raw Water and Spent Filter Backwash Water

Parameter	Raw water		Spent filter backwash water		Multiple increase
	Range	Average	Range	Average	
TOC (mg/L)	0.7–5.4	2.4	0.8–191	8.0	3.3
TTHM (µg/L)	ND–21.8	0.6	ND–198	55.0	91.7
HAA6 (µg/L)	ND–21.5	1.9	ND–211	46.1	24.3
Br (mg/L)	ND–0.68	0.038	ND–0.46	0.033	–0.1
Al (mg/L)	ND–30	0.72	ND–145.8	14.7	20.4
Fe (mg/L)	ND–56.6	1.2	ND–132	8.7	7.3
Mn (mg/L)	0.01–5.5	0.11	0.01–17.9	1.4	12.7
Zn (mg/L)	ND–0.5	0.03	ND–1.0	0.1	3.3

Source: Cornwell et al., 2001.

Edzwald et al. (2001) showed that *dissolved organic carbon (DOC)*, dissolved metals, and UV-254 were not elevated in untreated SFBW relative to raw water levels. However, that work did support the Cornwell et al.'s (2001) findings that total metals levels and TOC were elevated compared to the corresponding raw water.

Removal of solids from SFBW can remove many of the contaminants since they tend to be associated with the solids. Solids removal reduces TOC, metals, and DBP precursors.

Research completed by Cornwell et al. (2001) on treatment options for SFBW yielded similar results, and also evaluated the effectiveness of more advanced treatment including *dissolved air flotation (DAF)*, clarification plus granular media filtration, and MF on removal of particles. In fact, results demonstrate that when paired with polymer conditioning, both sedimentation and DAF resulted in particle removals of greater than 90 percent. This research also indicated that treatment of SFBW to achieve at least 1 log of *Cryptosporidium* removal would reduce the cyst concentration in the SFBW to at or below raw water background levels, alleviating concerns over recycle or discharge to the environment. Other benefits of a 1-log treatment process could include reduction of contaminants such as TOC, Fe, Mn, and solids. Research also indicated that gravity treatment processes should include the use of a polymer to aid solids settling. The type of polymer applied is important for achieving successful treatment of the recycle stream.

Spent filter backwash is produced over a relatively short time periods (around 15 min per filter) but at a high instantaneous flow rate. Equalization (EQ) is a method whereby

the SFBW is captured in a storage device and released over a longer period of time and, therefore, at a lower flow rate. For example, capturing the volume of one backwash and releasing it over the next hour will reduce the flow to about 25 percent of the instantaneous rate. Reduction of the flow rate through equalization can be useful in sizing downstream treatment devices, reducing impacts to the main treatment plant if recycle is used, reducing impacts at wastewater plants or sewer line size requirements, or reducing flow rates into the receiving stream. The allowed rate of release from the equalization basin is established by the downstream control, for example, the sewer line capacity, regulatory or treatment limitations on recycle, stream flow discharge limits, and so on.

The EQ basin storage volume is determined on the basis of a flow balance of SFBW entering the basin and the rate of release of equalized SFBW leaving the basin. The storage curve is typically shown over a 24-hour period of fill-and-draw from the EQ basin. Because the rate of SFBW flow into the EQ basin usually exceeds the rate of discharge from the basin, the volume in the basin increases over time as long as filter backwashing is occurring. The volume in the EQ basin will then decrease until the next cycle of washes begins. The peak of the storage curve is the total EQ basin volume required to meet the backwash assumptions used.

SFBW typically flows by gravity to equalization basins, treatment processes, disposal, or recycle. EQ basins assist by buffering the flow of SFBW from filter washing into the treatment process, so that a controlled flow rate can be maintained. SFBW delivered to a lagoon system or batch clarification process may not require equalization as an intermediate step. SFBW treatment systems could include any of the following:

- Lagoons
- Conventional clarifiers with or without tubes or plates
- Decant basins
- DAF
- High-rate clarification processes
- Membranes

Chemical addition is commonly used to increase the allowed hydraulic loading rate for clarification processes. Polymers are most commonly used to aid separation, but in some cases metal salt coagulants are utilized.

From a quality perspective, the driving force behind the degree of treatment required depends on the fate of the treated SFBW. If the supernatant is to be discharged to a receiving surface water, then the state discharge permit requirements determine the treatment necessary. Generally, the permits contain a suspended solids limit of around 20 to 30 mg/L. The ratio of turbidity to suspended solids is site specific and needs to be evaluated in order to set a treated turbidity goal. Absent data, a turbidity of less than 10 ntu should satisfy a 20-mg/L suspended solids limit and a 10-ntu goal is reasonable and can be attained by a properly designed SFBW treatment system. The discharge permits will also often have a pH limit and a chlorine numerical water quality–based effluent limit (WQBEL) that is most likely to be below the method detection limit (MDL) for chlorine. A typical pH limit of 6 to 9 is generally not a problem for utilities to meet without needing adjustments. It is possible for softening plants to exceed a pH 9 limit, and a lowering of the pH may be required. Removing free chlorine is accomplished by the use of a dechlorinating agent such as sodium bisulfite or ascorbic acid. Therefore, for a SFBW treatment system that is to meet discharge limits, the driving force for the design is normally aimed at meeting a set suspended solids limit.

If the treated SFBW is to be recycled, then generally it is the utilities own goals for the quality that determines the treatment requirements. There are two excellent Awwa Research

Foundation reports available to help determine the goals for SFBW treatment prior to recycle: *Recycle Stream Effects on Water Treatment* (Cornwell and Lee, 1993) and *Treatment Options for Giardia, Cryptosporidium, and Other Contaminants in Recycled Backwash Water* (Cornwell et al., 2001). A lot of the contaminants of concern (TOC, DBP precursors, Mn, and metals) are associated with the solids in the SFBW, so again the ultimate goal for the SFBW treatment may well be based on solids removal. In this case, however, the treated turbidity goal may well be lower than for the discharge situation. For low-turbidity raw water, the recycle turbidity goal is often set at below the low water turbidity level which can correspond to <5 ntu or even <1 ntu. For higher-turbidity raw waters, contaminant removal for TOC, Mn, and so on, may set the turbidity goal.

SFBW treatment has traditionally been accomplished with either standard clarifiers or plate or tube settlers. Loading rates for standard clarifiers treating SFBW tend to be quite low in order to achieve low treated turbidities or particle counts. In one laboratory study, Cornwell and Lee (1993) found that an overflow rate of 0.12 m/h (0.05 gpm/ft²) was required to achieve 90 percent particle removal in the 3- to 10- μ m size range without the use of polymer. With polymer, acceptable performance could be achieved with an overflow rate of 0.49 m/h (0.2 gpm/ft²). These ranges were confirmed in a later study using field scale data although rates up to about 1.2 m/h (0.5 gpm/ft²) with polymer were successful for turbidity removal and total particle count removal. In a 2009 study on two full-scale plants, a plate loading of 0.61 m/h (0.25 gpm/ft²) with polymer was successfully used (Cornwell et al., 2010). In that same study, another facility had a plate settler designed to treat a surface hydraulic loading up to 2.9 m/h (1.2 gpm/ft²) although turbidity performance seemed to drop off above about 1.2 m/h (0.5 gpm/ft²).

High-rate clarification processes have been investigated for SFBW treatment in order to reduce footprint requirements. High-rate SFBW treatment alternatives include the following: (1) conventional-rate DAF (10 to 15 m/h), (2) high-rate DAF (up to 40 m/h), (3) high-rate solids contact clarification processes (including process trade names DensaDeg[®], CONTRAFAST[®], Trident[®] HSC, Actiflo[™]), and (4) membranes. The actual design of these devices is similar to other applications which are discussed in the various chapters of this book. However, the actual design parameters for each device are unique for SFBW. Table 22-6 shows loading rates for various devices.

RECYCLE

It is common for many utilities to recycle various streams back to the beginning of the treatment process. Recycle is most often done to reduce the volume of residuals for disposal, to conserve water, or because it is not convenient or possible to discharge the liquids to a surface water or sewer. The liquid volume associated with sedimentation underflow and spent filter backwash water can range from 3 to 10 percent of the plant production. In water-scarce areas the water is too valuable a resource to discharge, and returning it to the treatment process is an imperative water conservation measure. Discharge into surface waters is regulated by states under the National Permit Discharge Elimination System (NPDES) program. In some areas such a permit cannot be obtained and recycle is the only option.

Liquid streams can be recycled back to a terminal reservoir, to the beginning of the treatment train, or, in some cases, to an intermediate point in the treatment process. Possible streams that could be recycled include the following:

- Spent filter backwash water—with or without treatment
- Clarifier or sedimentation basin sludge
- Sludge thickener overflow (supernatant)

TABLE 22-6 Summary of SFBW Treatment

City	State	Year	Median untreated turbidity (ntu)	Clarification rate (gpm/ft ²)	Residuals concentration (percent solids)	Polymer needed?	Pilot- or full-scale
Standard-rate DAF							
Durham	NC	1999	100	up to 5	3.5	Yes	Pilot

^{*}Can operate without polymer, but more stable with polymer.

^HImpact of treatment without flocculation not reported gpm/ft² × 2.44 = m/h.

Source: Cornwell et al., 2010.

- Sludge lagoon decant or overflow
- Dewatering operation liquid wastes
 - Filtrate from belt or filter presses
 - Centrate from centrifuges
 - Leachate from sand drying beds

Recycling of these streams has the potential to upset the treatment process or to affect the quality of the finished water. The impacts could be caused by the solids in some of the recycle streams, constituents in the recycle streams, characteristics of the recycle streams

(e.g., pH, alkalinity, etc.), or hydraulic impacts. The principal constituents that could be in recycle streams and be of water quality concern include

- Microbiological contaminants
- *Giardia* and *Cryptosporidium* parasites
- Total organic carbon
- Disinfection by-products
- Turbidity and suspended solids
- Metals, such as manganese, aluminum, iron
- Taste and odor causing compounds

Giardia and *Cryptosporidium* in SFBW can have high cyst concentrations (Cornwell and Lee, 1993). For example, one plant studied had *Giardia* and *Cryptosporidium* concentrations of more than 150 cysts/L in the spent filter backwash water compared with 0.2 to 3 cysts/L in the raw water. Laboratory and full-scale confirmation in that research showed that sedimentation was effective in reducing particles (and cyst levels) in the spent filter backwash prior to recycle. However, low overflow rates (less than 0.12 m/h (0.05 gpm/ft²)) were required to achieve 70 to 80 percent particle removal in the cyst-size range. A nonionic polymer was effective in increasing particle removals to more than 90 percent at overflow rates of 0.5 to 0.75 m/h (0.2 to 0.3 gpm/ft²). A mass balance model was developed to estimate the increase of the cyst loading to the plant due to recycle; the model was based on varying recycle ratios and varying degrees of cyst removal from the recycle stream prior to recycle. For example, it was found from the model that if a plant was recycling settled SFBW into the raw water line at a 20 percent ratio and was using a backwash clarifier designed for an overflow rate of 0.6 m/h (0.25 gpm/ft²) without polymer addition, then the cyst loading to the treatment process would be 20 times that present in the source water. However, if the recycle ratio was reduced to 5 percent and the backwash water clarifier efficiency was increased with the use of polymer or with lower overflow rates, the increased cyst loading due to recycle would only be 1.1 times that of the source water. This analysis, however, discounts the additional disinfection that occurs as the cysts are recycled through the various treatment processes, and no information is available as to whether the cysts are viable. Additional discussion of filter backwash recycle and the impact of prefiltration clarification performance is presented in the backwashing section of Chap. 10.

Nearly all coagulant sludges contain high concentrations of manganese. Quantities of dissolved manganese in the water surrounding sludge can be in the range of 1 to 7 mg/L and on storage reach 20 to 30 mg/L. As sludge accumulates in manually cleaned sedimentation basins, the manganese levels in the clarified water can gradually increase. Therefore, some manganese is released to sludge thickener overflows and recycled to the plant or is released in manually cleaned sedimentation basins to the clarified water. Normally the manganese concentrations are low unless large spikes of waste streams are recycled. However, if sludge accumulation were allowed to occupy a significant portion of the thickener or manually cleaned basin or if a hydraulic upset occurred, a situation could develop where large concentrations of manganese could be recycled or released from the manually cleaned sedimentation basin.

In the research by Cornwell and Lee (1993) and Edzwald et al. (2001), it was generally found that if the solids were removed from the waste streams prior to recycle, *total trihalomethane formation potential* (TTHMFP) in the recycle streams was no higher than in the raw waters. The same was found for *total organic carbon* (TOC). However, without solids removal TTHMFP and TOC levels can be quite high in the waste streams. The recycle streams can contain preformed *trihalomethane* (THM), and therefore, THM concentrations leaving the plant with recycle were sometimes found to be higher than that without recycle. This increase could impact a utility's distribution system THM average.

Treatment of waste streams prior to recycle depends on the types of contaminants to be removed and the degree of removal required. Generally, sedimentation is sufficient to remove the solids leaving the supernatant to be recycled. Polymer or coagulant assistance can increase the removal efficiency of particles. The supernatant stream could also be disinfected prior to recycle using ozone, chlorine dioxide, or perhaps potassium permanganate. If particulate removal above that achievable by sedimentation is required, filters could be added or membrane technology employed. If recycle of streams is necessitated by conservation or discharge issues, it appears that an appropriate technology can be selected to allow for recycle without impacting finished water. However, more research and site-specific investigations are needed to determine appropriate treatment for each situation.

MEMBRANE RESIDUALS

As membrane systems are increasingly used for water utility applications, the management of their residuals has become a growing challenge. As outlined in Chap. 11, membrane processes are classified, among other things, by their pore size. Larger pore-size membranes, such as MF and UF systems, remove primarily particles and suspended solids from feedwater. Tighter membranes, such as NF, RO, ED, and EDR systems, are able to separate dissolved substances from feedwater. The types of residuals produced by both systems vary accordingly. In addition to the residuals produced during water treatment, membrane systems typically require various chemical cleaning methods to reduce fouling, which produce associated chemical wastes. In the next sections, membrane residuals fall into two categories on the basis of the system pore sizes and/or system pressure.

Low-Pressure Membranes

As with granular media filtration processes, low-pressure membrane systems require periodic backwashing. Backwashing counteracts the accumulation of foulants on the membrane surface and within pores, which over time can result in a loss of productivity. These foulants can be inorganic (clay or silt colloids, precipitated metals, etc.), organic (natural organic matter, coagulant aid polymers, etc.), and biological (biofilms, etc.). In addition to backwashing, chemical cleaning (or CIP) methods are used to control fouling and restore productivity.

Backwashing typically occurs every hour or so and is accomplished using air, air and permeate, or permeate alone from the permeate side to the feed side, in the opposite direction of filtration. Chemically enhanced backwash (CEBW) involves the addition of chemicals to increase the backwashing effectiveness by oxidizing or dissolving some of the solids in the fouling layer and by inactivating biological growth.

However, backwashing alone cannot completely prevent the loss of productivity, as over time foulants that cannot be removed via backwashing accumulate on the membrane surface and in the membrane pores. The removal of these foulants requires the system to be removed from service (typically for a half or full day) for chemical cleaning (or CIP). Tank-batched solutions of appropriate oxidant, caustic, acid, and detergent are recirculated individually or in combination to dissolve membrane foulants. Sometimes these solutions are heated to help loosen the foulants. Citric acid, caustic soda, and chlorine are the most common agents used for cleaning low-pressure membranes. CIP is usually performed on a monthly or greater interval.

The nature of the residuals produced by a low-pressure membrane system differ depending on if the membranes are used in combination with other treatment processes (integrated membrane systems) or as a stand-alone membrane system. The backwash waste contains not only the contaminants naturally occurring in the source water but also those added during

upstream treatment (e.g., coagulation). Therefore, residuals management alternatives (i.e., disposal, reuse, etc.) may differ accordingly (AWWA, 2003).

Generally, MF/UF systems produce residuals on an intermittent basis. However, in large membrane plants (>40 MLD (10 mgd) the backwash sequence operation is rotational such that intermittent backwash flow rates from individual trains essentially become continuous on a plant basis.

Backwashing Quantities and Characteristics. Specific characteristics of MF and UF backwash and concentrate residuals depend on the quality of the water being treated and the recovery of the membrane. Recovery is the ratio of water produced (i.e., feed flow minus water used for backwash, etc.) to feed flow and can range from 85 to 98 percent; thus, the solids in the feedwater may be concentrated by 7 to 50 times over the feedwater concentration, respectively. Backwash flow rates typically represent greater than 95 percent of the total volume of residuals produced (the remaining portion comes from chemical cleaning procedures). Table 22-7 presents typical spent backwash characteristics. If coagulants or other pretreatment chemicals are applied, the characteristics of the MF/UF residuals become more similar to the residuals from a conventional water treatment plant, while those from spent CEBW will more resemble those from CIP (AWWA, 2003).

TABLE 22-7 Typical Characteristics of Low-Pressure Membrane Spent Backwash

Parameter	Characteristics
Frequency of application	Every 30 to 60 minutes
Volume of waste produced	2 to 15% of plant feed flow rate for recoveries of 85 to 98%
Composition of spent backwash	<ul style="list-style-type: none"> • Algae, precipitated solids, possible chemical residues if using CEBW. • For recoveries of 85 to 98%, feedwater TSS will be concentrated 7 to 50 times. • pH may be <6 or >9. • Cl₂ residuals may be up to 1000 mg/L. • If coagulant is used, TOC could be 5 times the feed concentration; otherwise TOC can be up to twice that of the feed concentration.

Source: Adapted from AWWA, 2003.

Chemical Cleaning Quantities and Characteristics. CIP wastes reflect the chemicals used in the cleaning process. In addition to the portion of remaining active chemical ingredient, the resulting chemical cleaning waste includes dissolved organic materials, suspended solids, and salts from chemical reactions between the chemicals and foulants (AWWA, 2003). Table 22-8 describes typical CIP waste characteristics.

Chlorine residuals in CEBW and CIP wastes may range from 1 to 1000 mg/L as Cl₂, and pH may be acidic (pH < 6) or basic (pH > 9) depending on the chemicals used. When surfactants are employed, they may cause foaming when the spent cleaning solution is discharged. The need for neutralization chemicals can be minimized by mixing the acid and caustic waste solutions, but this practice may also precipitate additional solids such as calcium carbonate or some iron compounds, which will increase the suspended solids concentration of the waste solution. If citric acid is used in the CIP, the biochemical oxygen demand (BOD) of the spent cleaning solution is likely to be high as well.

Cleaning solution volumes will be 2 to 3 times the volume normally present in the membrane modules and piping (one volume for the actual cleaning solution, and one or two

TABLE 22-8 Typical Characteristics of MF/UF Spent Chemical Cleaning Solutions

Parameter	Characteristics
Frequency of application	Every month
Volume of waste produced	Monthly CIP wastes normally <0.05% of plant feed flow rate
Chemicals commonly used	<ul style="list-style-type: none"> • NaOCl (500–1000 mg/L as Cl₂) • Citric or hydrochloric acid (pH 1 to 2) • Caustic soda (pH 12 to 13)
Composition of spent CIP	<ul style="list-style-type: none"> • pH from 2 to 14 • TSS up to 500 mg/L (neutralization may precipitate additional solids) • Low concentrations of surfactants • Cl₂ residuals up to 1000 mg/L • TOC 10 to 30 times the feedwater concentration • BOD₅ up to 5000 to 10,000 mg/L if citric acid is used

Source: Adapted from AWWA, 2003.

additional volumes to rinse the solution), or for immersed systems equal to the tank volume (AWWA, 2003). Rinse waters typically have low levels of contamination and may either be returned and blended with the feedwater, combined with backwash wastes for recycling or disposal, or used to make up the next batch of cleaning solution. While the frequency of chemical cleaning varies as a function of the quality of the feedwater, overall chemical cleaning is performed far less frequently than backwashing and thereby contributes less than 5 percent in the generated residuals volume.

Membrane modules may be shipped to the plant preserved in specialty solutions, such as glycerin, which are typically discharged to the sewer. In the absence of a sewer connection, these wastes need to be collected and hauled to an appropriate disposal site (AWWA, 2003).

Residuals Management. Membrane residual treatment and disposal alternatives depend on site-specific factors such as local climate, land availability, size of the MF/UF installation, capabilities of the operating staff, and feasibility and local requirements for different disposal options. Smaller installations tend to use simple methods capable of handling both types of residuals (backwash and cleaning wastes), such as discharge to the sanitary sewer, settling lagoons or percolation/evaporation ponds, and equalization basins to store, mix, and neutralize chemical solutions (AWWA, 2003). It is believed that large installations will increasingly look toward recycling of backwash and reuse of chemical cleaning solutions to significantly reduce volumes and associated disposal costs (MacPhee et al., 2002). The comparative economics for each disposal alternative is influenced by the cost and availability of land, the local value of water, the availability of a sewer system to accept the residuals, and the demand (amount and seasonal variation) for irrigation water (AWWA, 2003).

Surface Discharge. Discharges to receiving surface waters are regulated under the National Pollutant Discharge Elimination System (NPDES), according to water quality standards that protect the designated usage of the receiving waters. Surface water discharge is the most common form of backwash waste disposal regardless of plant size (Kenna and Zander, 2000). Simple settling basins or lagoons typically provide sufficient treatment to allow subsequent surface water discharge for most installations.

Underground Injection. The underground injection control (UIC) program administers groundwater discharge permits (e.g., deep well injection) and provides safeguards to maintain current and future underground sources of drinking water. An NPDES permit may also

be involved if a secondary disposal method is required or if the receiving groundwater is hydraulically linked to surface water.

Sewer Discharge. Indirect discharge to a *publicly owned treatment works* (POTW) may be controlled under the *Industrial Pretreatment Program* (IPP) if the POTW practices surface water discharge and has its own NPDES permit (AWWA, 2003). Under the IPP, a POTW is required to enact local sewer ordinances and to enforce standards laid out in the IPP to protect the POTW's NPDES permit from any violation caused by indirect discharge. Other federal and local regulation may apply depending on the method of waste disposal used by the receiving wastewater treatment plant. Most plants do not provide any treatment of the spent backwash prior to discharge to a sewer, but discharges may need to be equalized to meet available sewer capacity (AWWA, 2003).

Land Disposal. Percolation ponds, leaching fields, and other land disposal methods that carry a risk of liquid discharge reaching any groundwaters are affected by the same regulations governing underground discharge (i.e., NPDES and UIC programs). When high concentrations of solids are present, land application of membrane residuals is regulated by the Solids Waste Disposal Act. If disposal is via a landfill, additional Resource Conservation and Recovery Act (RCRA) requirements apply.

Prior to land application, solid residuals must also undergo a TCLP test. Residuals that fail the TCLP test are deemed hazardous wastes and are subject to additional regulations, but in nearly all cases, low-pressure membrane process residuals do not fall into this category. Spray irrigation is a common, low-cost alternative for land application that provides benefits for both the water utility disposing of the residuals and the organization needing irrigation water. To be successful, spray irrigation requires year round demand, low concern for aesthetics, and proper soil conditions at the application site to avoid potential groundwater contamination. Spray irrigation may not be feasible for large MF or UF plants because of the large residuals volumes.

Evaporation Ponds. Although there is no federal regulation for evaporation ponds, as with land disposal, NPDES or UIC permits may be required if there is a chance of intermittent discharge to surface or groundwater. For this disposal method, optimal conditions include low flows and an arid climate. Adequate space should be provided for accumulating several years of solids within the evaporation ponds to reduce the frequency of required cleaning (AWWA, 2003).

Backwash Recycle. The Filter Backwash Recycling Rule (FBRR), which regulates the recycling of backwash and other recycled flows in conventional treatment plants, does not address membrane residual recycling unless membrane residuals are commingled with other conventional process residuals prior to recycling (AWWA, 2003). At large installations, recycling of spent backwash water is generally accompanied by some type of settling process (Kenna and Zander, 2000). At installations where backwash residuals contain a higher concentration of contaminants such as *Cryptosporidium*, additional treatment may be required to safely recycle backwash (MacPhee et al., 2002). The volume of residuals sent for disposal may be reduced by more than 90 percent by recycling the clarified backwash water and neutralized CEBW wastes to the front of the treatment process. This reduction in volume may make hauling the concentrated backwash solids off-site more economically feasible. The following recommendations were made for treatment of spent MF/UF backwash prior to recycle (Le Gouellec et al., 2004):

- MF backwash streams can vary widely in turbidity (<10 to >125 ntu).
- Addition of a metal salt coagulant is necessary if the raw water is not coagulated ahead of the membrane in the main treatment train.

- Ferric chloride generally outperformed aluminum based coagulants. pH adjustment was not needed.
- Sedimentation and DAF are both effective means of clarification for spent backwash.
- A sedimentation hydraulic overflow rate of 0.61 to 1.2 m/h (0.25 to 0.50 gpm/ft²) is appropriate for settling if the right dose of a primary coagulant is used. Addition of a polymer with the metal salt coagulant may enhance performance.
- Bench-scale testing is an excellent tool for screening coagulant, polymer, pH adjustment, and overflow rate requirements for treatment of MF/UF backwash streams intended for recycle.
- In general, a sedimentation treatment system for MF/UF backwash would include equalization to provide a relatively constant backwash quality and quantity for sedimentation and allow chemical dosing to be set on the basis of average conditions.
- Under suitable treatment conditions, an average of at least 1-log *Cryptosporidium* removal can be achieved through sedimentation of spent backwash.
- Removals of *Bacillus subtilis* and particle counts are similar to those of *Cryptosporidium*, suggesting that these parameters could be used as surrogates for gauging treatment performance for pathogen removal.
- To limit potential recycle impacts, backwash turbidity levels, and particle counts after treatment should be close to those of the raw (influent) water.

CIP Disposal. CIP residuals disposal methods for low-pressure membrane plants depend largely on the frequency of cleaning and the type and strength of chemicals used (AWWA, 2003). For example, large plants that perform frequent chemical cleanings may not be able to use surface water discharge for the spent CIP, unless the CIP wastes can be blended with spent backwash for chemical neutralization. CIP wastes are typically redirected to the sewer after pH adjustment and/or dechlorination if needed, or blended with the backwash residuals prior to joint disposal (AWWA, 2003).

Desalting Membranes

As discussed in Chap. 11, use of desalting membrane technologies is increasing as utilities recognize that such processes can extend water resources by treating seawater, brackish water, and reclaimed water into drinking water. With the continuing installation of desalting plants, residuals management has become a growing problem especially since the principal residual from these systems (i.e., concentrate) typically contains high levels of total dissolved solids (TDS) including heavy metals and radionuclides, which makes its disposal more challenging than for residuals from low-pressure (MF and UF) membrane systems.

The separation of dissolved substances from water can be made under a pressure differential (RO and NF) or under an electrical potential (ED/EDR). Typical overall recoveries for NF plants are 75 to 85 percent for brackish water plants depending on the types and concentrations of potential scaling species (sparingly soluble salts and silica) in the feedwater. Recoveries for seawater plants range from 40 to 60 percent because of material resistance limit imposed by the high osmotic pressure.

Fouling. As with low-pressure membrane systems, over time desalting membrane systems experience a loss in productivity from foulants accumulating on the membrane surface or within the feed channel between the layers of membrane material. As described in the

2004 report “Current Perspectives on Residuals Management for Desalting Membranes” (AWWA, 2004), there are several categories of foulants, including

- *Inorganic*. Clays and silts, in colloidal or suspended form; metal precipitates (e.g., aluminum, iron, and manganese oxides); precipitates from sparingly soluble salts, (e.g., barium sulfate, calcium carbonate, calcium sulfate, etc.); and silica
- *Organic*. Natural organic matter (humic and fulvic acids, etc.)
- *Biological*. Microorganisms that accumulate or actively colonize the membrane surface, as well as the exopolymeric substances (films or slimes) that such organisms produce for the purpose of attachment or protection (i.e., biofilm)

Although these categories encompass the range of desalting membrane foulants, fouling usually consists of a combination of factors, with the relative contribution of each foulant category a function of feedwater characteristics, membrane type, and system operating conditions (AWWA, 2004).

Residuals Quantities and Characteristics. The residuals of NF, RO, and ED systems result from the separation process itself, which generates concentrate, and the CIP process, which produces spent cleaning solution waste (AWWA, 2004). Concentrate contains both dissolved and particulate contaminants at levels that are a direct function of their feedwater concentration and recovery of the system. Thus, the final characteristics of the concentrate from the desalination membrane systems depend on what constituents are removed or added by the upstream treatment process. Spent cleaning solutions are typically generated semiannually, and generally contain high concentrations of the cleaning chemicals and removed contaminants. Concentrate is continuously produced by the membrane separation process; thus, the volume of concentrate that is produced is much greater than that of intermittently generated cleaning waste.

Since the characteristics of the concentrate from NF, brackish water RO (BWRO), and ED/EDR systems can be considered similar, residuals management is about the same. The exception is that ED/EDR systems produce a specialized waste stream of limited flow called *electrode waste* that contains significant levels of hydrogen and chlorine gases. These gases are typically stripped from the electrode waste stream using a degasifier. Although free chlorine may be present in the poststripper waste stream, it is diluted when the stripped electrode waste is mixed with the concentrate flow (AWWA, 2004).

The typical addition of acid and/or antiscalants as part of the pretreatment in desalting membrane systems helps to control scaling from sparingly soluble salts. Chemical cleaning is achieved by using appropriate acidic, caustic, and selected detergent solutions, either individually or in combination, to loosen and dissolve membrane foulants. These solutions are tank batched and circulated directly through the membrane train. Heating the chemical solution can be used to help loosen accumulated materials. Chemical cleaning is typically performed every 6 to 12 months depending on feedwater quality and operating characteristics. Some systems with low fouling feedwaters can operate indefinitely without the need for chemical cleaning, particularly if designed at conservative flux rates (AWWA, 2004).

In contrast to the concentrate, chemical-cleaning residuals from ED/EDR systems are different from those from NF and RO systems.

- NF and RO systems are typically cleaned with acid (mineral or citric) and alkaline (typically containing detergents/surfactants and sometimes chelants) solutions.
- ED/EDR systems are typically cleaned with concentrated sodium chloride solutions and sometimes with chlorine to remove biological foulants (NF and RO systems generally do not use chlorine since it can damage the membranes in these systems).

Concentrate. The concentration of contaminants in the concentrate is dependent on the rejection characteristics of the membrane and is directly proportional to recovery. In contrast to the spent backwash from low-pressure membrane systems, the concentrate from desalting membrane systems contains low particulate concentrations, typically less than 10 mg/L total suspended solids. This is because feedwater turbidity for these systems is required to be less than 1.0 ntu to avoid plugging the flow channels. Likewise, while scale-inhibiting agents added to the membrane feedwater to control precipitation is also concentrated in the desalting membrane process, the levels of these constituents in concentrate are typically less than 30 mg/L.

The majority of residuals present in desalting membrane concentrate are dissolved solids. For ED/EDR, ions will be concentrated in the waste stream to the same levels than described for NF and RO, but the concentrate will also contain free chlorine from the generation of chlorine gas at the electrode. For salinity, the brine concentration can be estimated on the basis of the feedwater quality and a concentration factor that is related to the water recovery as shown in the following. These equations assume a membrane process with 100 percent salt rejection and, therefore, provide a conservative (high) estimate of residuals concentrations:

$$C_b = \frac{C_f}{1-Y} \quad (22-20)$$

where C_b is the brine concentration, C_f the feed concentration, and Y the water recovery. For example, recoveries of 50 and 90 percent would correspond to concentration factors of 2 and 10, respectively.

The quantity of concentrate is a function of the amount of feedwater that is purified (or converted to permeate), as defined by the product water recovery. NF salt rejection is typically less than for RO; therefore for a given feed and recovery, NF concentrate will be less saline than RO concentrate. Additionally, NF rejects monovalent ions (e.g., sodium and chloride) to a lesser degree than multivalent ions (e.g., calcium and sulfate), and thereby enriches the concentrate in multivalent ions compared to that in the feedwater.

Chemical Cleaning (CIP) Waste. Each membrane supplier has developed its own specific solutions or formulations based on laboratory and field experience with their membrane product, and many companies catering to the membrane industry have developed proprietary cleaners in an attempt to optimize cleaning efficiency for specific fouling situations (AWWA, 2004). Table 22-9 presents a listing of standard cleaning solutions to remove various categories of foulants.

TABLE 22-9 Typical Chemical Cleaning Solutions for Desalting Membranes

Foulant type	Cleaning solution
Inorganic salts/ precipitates	<ul style="list-style-type: none"> • 0.2% HCl • 0.5% H₃PO₄ • 2% citric acid
Metal oxides	<ul style="list-style-type: none"> • 2% citric acid • 1% Na₂SO₄
Inorganic colloids (silt)	• 0.1% NaOH and 0.05% sodium dodecyl benzene sulfate at pH 12
Silica (and metal silicates)	<ul style="list-style-type: none"> • 0.1% NaOH, 0.05% sodium dodecyl benzene sulfate at pH 12 • Ammonium bifluoride
Biofilms and organics	<ul style="list-style-type: none"> • Hypochlorite, hydrogen peroxide, 0.1% NaOH, 0.05% sodium dodecyl benzene sulfate at pH 12 • 1% sodium tripolyphosphate, 1% trisodium phosphate, 1% sodium EDTA

Source: Adapted from AWWA, 2004.

The volume of cleaning solution used and the amount of generated waste are function of

- Source water characteristics (type and level of foulants present)
- Membrane process and module/system characteristics
- Size/capacity of membrane train
- System operating conditions (flux and recovery)
- Cleaning system design (piping diameter and lengths)
- Frequency of cleaning

Typically the volume of the spent cleaning solution is a small percentage of the flow treated (significantly less than 0.1 percent). The total volume of spent cleaning solution includes also the rinses between each cleaning step.

Chemical cleaning is typically a multistage process. Usually a low-pH solution is applied first, followed by a high-pH solution. The trains are also cleaned in steps. The typical approach is to clean first the modules in 1/2 of the vessels in the first stage, followed by the other half of the first stage, and finally all modules in the second stage. Spent cleaning solutions are composed of the removed foulants and the chemicals used to remove them (e.g., detergents, surfactants, acid, caustic, etc.). The spent cleaning solution may need to be treated before disposal, most often by simple pH adjustment (AWWA, 2004).

Residuals Management. In addition to capital- and operation-cost considerations, decisions regarding residuals management should include the assessment of the long-term viability of any selected approach. Regulatory changes in particular have the potential to adversely impact operation of a desalting plant. Disposal of desalination membrane residuals is generally regulated by the same guidelines governing industrial residuals, which results in a longer and costlier permitting process than if the nature of membrane concentrate were taken into consideration at the beginning of the permitting process. Unlike many industrial wastes, membrane concentrate is not characterized by process added chemicals but by the nature of the raw water fed to the process (AWWA, 2004).

Unlike residuals from MF/UF membranes, management and disposal of desalination membrane concentrate can be particularly challenging because volume and a high concentration of dissolved solids can limit the number of options permitted or cost effective, particularly in geographical regions where surface water discharge is unavailable. The most common method of NF, RO, and EDR concentrate management is surface water discharge, followed by sanitary sewer discharge and deep well injection (Mickley, 2001). The two methods typically used for spent chemical cleaning solutions are sewer disposal and blending with concentrate. Prior to blending, it may be necessary to neutralize the acidity or alkalinity of the cleaning solution to prevent unwanted reactions or to ensure that the blended residual is compatible with regulations governing the concentrate discharge. For certain ED/EDR cleaning wastes, residual chlorine may need to be neutralized with a reducing agent.

Spent cleaning solution treatment sometimes is accomplished in the cleaning tank itself at the end of each cleaning step for small facilities. However, for larger facilities, treatment is usually accomplished in separate facilities because of the relatively low cost of these facilities and the significant benefit of reducing membrane system downtime for the overall cleaning process. Commonly, one or two spent cleaning tanks are used with pumps that recirculate the spent cleaning solution from and back to the tank(s) or transfer the treated solution to the disposal point. For pH adjustment, either acid (e.g., sulfuric acid) or base (e.g., sodium hydroxide) is added to the recirculating fluid until the desired pH neutralization point is reached. This can be monitored and controlled manually or automatically (AWWA, 2004).

Surface Water Discharge. The discharge of NF, RO, and ED residuals to a surface water body (i.e., lakes, rivers, lagoons, ocean, etc.) is the most common management practice,

primarily because this method has the lowest cost (unless pipeline conveyance distances are long) and the residuals volume improves stream flow. However, the residuals must be compatible with the environment of the receiving water body. Discharge to surface waters requires an NPDES permit, which includes an assessment of potential impacts on the receiving stream from both salinity and specific concentrate constituents. Typically salinity is the limiting factor for surface water discharges, as it is unusual for discharges to be permitted if the concentrate would increase the receiving stream salinity by more than 10 percent. Some facilities address this by combining the concentrate with liquid process streams from other municipal or industrial facilities (e.g., with WWTP effluent, cooling water, etc.).

In general, toxicity is not a concern for desalting membrane system residuals because the principal effect of membrane processes is an increase in the concentration of naturally occurring constituents, which typically have no toxicity. However, concentrates from facilities treating brackish groundwater may be too saline to discharge to fresh surface waters. Therefore such plants are limited to areas with available brackish receiving streams (e.g., estuary, tidal river, etc.). In some states, whole effluent toxicity tests (bioassays) are part of the NPDES permit. The concentrate produced by some groundwaters treated by RO have been found to fail these tests on sensitive test organisms because of major ion toxicity, which is due to excessively high (or low) concentrations of common ions (Mickley, 2000). Most cases in Florida have been associated with high calcium levels. Some of these situations have been also complicated by toxicity due to high levels of fluoride. Because major ion toxicity is different from that due to contaminants such as heavy metals or pesticides, the state of Florida has made allowances in cases where only major ion toxicity is present in membrane concentrates.

Dissolved oxygen (DO) levels may also be a concern for concentrates from desalination of groundwaters, which can have low DO levels. Concentrates from such system must be re-aerated prior to discharge to avoid negative impacts on receiving stream biota. Occasionally the groundwater may also contain hydrogen sulfide, which must also be suitably removed from the concentrate prior to discharge. As mentioned earlier, ED/EDR concentrates can contain free chlorine. The free chlorine must be neutralized prior to surface water discharge, which requires that the reducing agent be compatible with the receiving stream (AWWA, 2004).

Sewer. Disposal to the sewer represents an indirect discharge to surface waters and requires permission from the receiving wastewater utility, which may impose pretreatment standards since the discharge permit of the wastewater treatment plant (WWTP) could be affected. If the concentrate has high salinity and its flow contribution is significant, impacts on the biological efficiency of the wastewater plant due to concentrate salinity should also be considered. Additionally, the capacity of the sewer line and WWTP must be addressed. These capacity and quality criteria may limit the amount of desalting residuals discharged to sewer. Sanitary sewer discharge of small volumes usually represents a low-cost disposal method with limited permitting requirements.

Land Application. Disposal of concentrate by land application is generally achieved via irrigation or through groundwater recharge measures such as percolation ponds, rapid infiltration basins, and so on. The selected land application option must be compatible with state regulations protecting groundwater and vegetation (in the case of irrigation). Factors associated with land application include the availability and cost of land, percolation rates, irrigation needs, water quality tolerance of target vegetation to salinity, and ability to meet groundwater quality standards. An assessment of the compatibility with target vegetation should be conducted, including assessment of the sodium adsorption ratio (SAR), trace metals uptake, and other vegetative and percolation factors (AWWA, 2004).

Regulations governing groundwater quality and protection of drinking water aquifers should be investigated as early as possible to confirm the acceptability of this alternative. Usually dilution of the concentrate is required to meet groundwater standards. Where salinity levels are excessive, special salt tolerant species (halophytes) could be considered for

irrigation. In general, land applications are used only for smaller volume concentrates since this disposal option is frequently limited by availability of land, dilution water, and/or climate in locations where land application is not possible year around (AWWA, 2004).

Deep Well Injection. Deep well injection and other subsurface injection alternatives such as bore holes are regulated by USEPA's UIC program, which is typically administered at the state level. Regulatory considerations include the transmissivity and salinity of the receiving aquifer and the presence of a structurally isolating and confining layer between the receiving aquifer and any overlying Underground Source of Drinking Water (USDW), which is defined as any water bearing formation containing less than 10,000 mg/L TDS (AWWA, 2004). Deep wells are not feasible in areas subject to earthquakes or where faults are present that can provide a direct hydraulic connection between the receiving aquifer and an overlying potable aquifer.

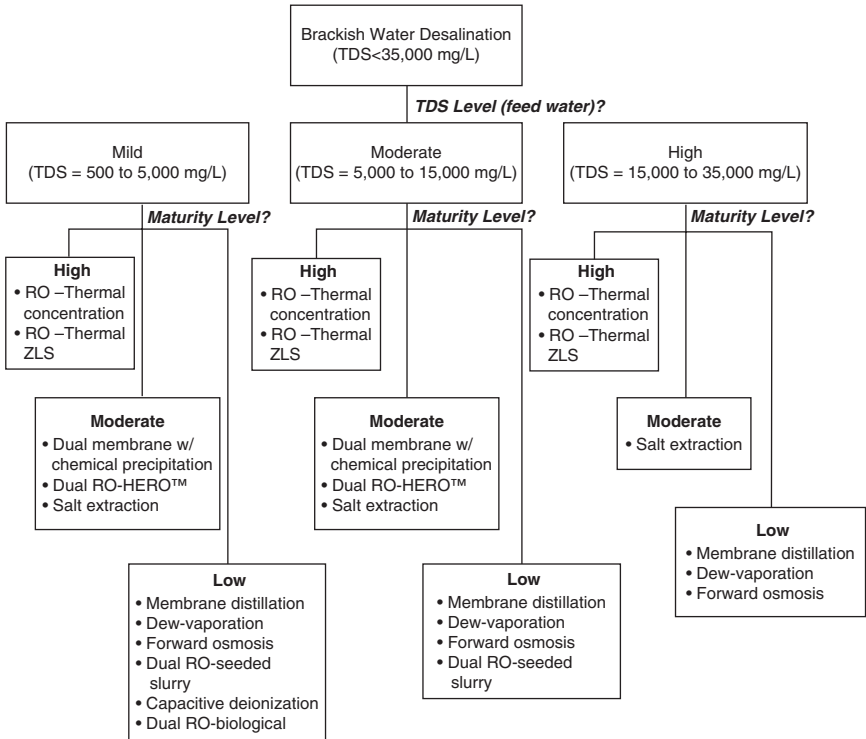

The cost for deep well injection is higher than surface water disposal, sewer disposal, and land application in cases where these alternative methods do not require long transmission pipelines. In addition to the disposal well(s), one or more small-bore monitoring wells in the local area are also typically required to confirm that vertical movement of water has not occurred. Disposal to deep wells is usually restricted to larger volume concentrates where economies of scale make the disposal option more affordable. A backup means of disposal must be available for use during periodic maintenance testing of the well. Nearly all of the plants using subsurface injection are located in the state of Florida as geologic characteristics make this option inappropriate in many areas of the United States (Mickley, 2001).

Evaporation Pond. Solar evaporation is a viable alternative in relatively warm, dry climates with high evaporation rates, flat terrain, and low land costs. Construction of evaporation ponds typically requires an impervious lining and monitoring wells, depending on state requirements. With little economy of scale, evaporation ponds are usually used only for small volume concentrates. Evaporation ponds are typically designed to accommodate concentrate for the projected life of the desalination facility, so provision for the precipitation of salts must be incorporated into the depth requirements of the pond (AWWA, 2004). In addition, the ultimate fate of the concentrated salts and the future regulatory implications should be considered for any evaporation pond project.

Other. Other concentrate management and disposal alternatives such as blending with WWTW effluent or with power plant cooling water are subsets of the alternatives presented. Blending provides a dilution effect that can support the implementation of a desalting facility.

Zero liquid discharge systems such as thermal evaporators, brine concentrators, vapor compressors, crystallizers, and spray dryers are available to reduce residuals to a solid product for landfill disposal. However, the cost for these thermal systems is typically much higher than the cost for the desalination membrane facility, both from a capital and operating (energy) perspective, making this disposal option unfeasible except for small concentrate flows (AWWA, 2004). Use of high-recovery RO systems in front of the thermal evaporators can reduce the cost for waters of limited hardness where chemical and solids disposal costs are not excessive.

Zero liquid discharge technologies other than thermal evaporation to remove dissolved solids from concentrate are currently being researched, such as fluidized bed crystallization, adsorption with activated alumina, and forward osmosis. These methods may potentially provide cost and energy savings compared to traditional zero liquid discharge systems; for example, Bond and Veerapaneni (2007) described cost savings of 50 to 70 percent and energy savings of 70 to 75 percent using a fluidized bed crystallization process to treat an RO concentrate stream rather than a benchmark zero liquid discharge approach including a brine concentrator and evaporation pond. However, many of these non-thermal concentrate treatment approaches have not yet been established as mature technologies. Figure 22-21 presents the relative maturity level of various concentrate treatment systems.

Notes:

1. Maturity is prescribed in terms of applications and experience relative to the municipal water industry. If mature and installed in other applications (e.g. industrial), the maturity relative to municipal application is considered moderate. In general, the developing/alternative desalination technologies in bench or pilot scale testing stage are considered low in maturity.
2. Dual membrane with chemical precipitation implies primary RO, followed by concentrate treatment via chemical precipitation and a secondary membrane process (i.e. RO or ED/EDR). The configuration based on secondary ED/EDR was developed and tested in this study.
3. Thermal ZLD implies thermal concentration and thermal crystallization.
4. Dual RO-HERO™ is considered mature in industrial applications.
5. Salt extraction is considered moderately mature based on existing international/industrial installations.

FIGURE 22-21 Flowchart for general guidance on relative maturity and TDS applicability of recovery enhancement and concentrate minimization technologies. (Source: Sethi et al., 2009.)

Two recent Water Research Foundation reports provide an excellent overview of the subject: *Desalination Product Water Recovery and Concentrate Volume Minimization* (Sethi et al., 2009) and *Inland Membrane Concentrate Treatment Strategies for Water Reclamation Systems* (Fox et al., 2009).

Research is ongoing to evaluate the technical and cost feasibility of beneficial use desalination membrane concentrates, including use as a feed source for sodium hypochlorite generation or for energy recovery through heat generation for solar energy ponds (AWWA, 2004). The Water Reuse Foundation report *Beneficial and Nontraditional Uses of Concentrate* (Jordahl, 2006) provides additional information on beneficial use options for desalination membrane concentrate. These and other research may ultimately provide additional alternatives for management of desalination residuals.

ION-EXCHANGE AND INORGANIC ADSORPTION PROCESS RESIDUALS

As described in Chap. 12, ion-exchange and adsorption processes can be used to remove cations, anions, and ionic complexes from water. Both ion-exchange and adsorption processes pass raw water through a vessel containing a solid media. In ion exchange, the removed ions exchange onto the media for other ions of lesser attraction to the media. These released ions end up in the finished water. The process continues until the media is exhausted, at which point the targeted contaminant begins to breakthrough to the finished water. When the concentration of the contaminant breakthrough exceeds a target finished water concentration, the media is regenerated by passing a volume of water containing a high concentration of an exchangeable ion past the media. The media releases the contaminant ions and accepts the exchangeable ions. Therefore the spent regenerant contains the contaminant ions as well as excess exchangeable ions. Ion-exchange media can be a strong acid cation (SAC) exchanger, weak acid cation (WAC) exchanger or anion exchange media (see Chap. 12).

Adsorption processes work similarly to ion-exchange processes, although the adsorption of the contaminant to the solids media does not release ions into the finished water. Adsorption media can also be regenerated to regain adsorption capacity, although occasionally it may be easier to dispose of the target contaminants through disposal of the contaminated solids; in this case, utilities may forgo the regeneration process and simply discard the exhausted media.

The primary cations removed by ion exchange or adsorption include

- Hardness using usually SAC, but occasionally WAC
- Barium using SAC
- Radium using SAC
- Radon using activated alumina, specialty resins, and GAC

The anions that are removed by ion exchange or adsorption include

- Fluoride using activated alumina
- Nitrate using anion exchange
- Arsenic using activated alumina, ion exchange, iron impregnated resins
- Perchlorate using anion exchange
- Selenium using activated alumina or anion exchange
- Chromium using anion exchange

By far the most common ion-exchange process used is softening for the removal of calcium and magnesium.

Softening

Ion exchange has been used for many years as a softening process. Most large plants in the past that utilized ion exchange for softening were located near coastal areas so that brine wastes were discharged to the ocean. Although many of these plants have been abandoned due to corrosion and high maintenance costs, ion exchange is still being practiced by small treatment systems. Its chief advantage over lime softening is the ease of operation. In areas where disposal of lime sludges is a problem, ion exchange may also be favorable if a suitable brine waste discharge point can be found. Wastes are produced from an ion-exchange

process from the three phases of bed cleaning: backwash, regeneration, and rinse. Ion-exchange contactors are normally backwashed at a rate of 12.2 to 14.7 m/h (5 to 6 gpm/ft²) for about 10 min, generating 2037 to 2444 L of backwash waste for each square meter of contactor area. The regenerate brine waste volume depends on the type of exchange media used, the amount of cation exchange capacity that is available, and the efficiency of regeneration. (The units used for ion exchange are in terms of kg of hardness expressed as CaCO₃. Hardness refers to any divalent or higher cation.) The capacity of synthetic ion-exchange resins depends on the regenerant driving force used, as shown in Table 22-10.

TABLE 22-10 Ion Exchange Softening Resin Capacity

Salt used (kg/m ³)	Exchange capacity (kg/m ³)	Regenerate use kg NaCl/kg removed
85	49.4–56.5	1.8
142	63.6–70.6	2.4
213	67.1–77.7	3.4

The theoretical salt (NaCl) demand for regeneration is 1.18 kg NaCl/kg hardness removed. Most plants operate between 114- and 142-kg/m³ (8- and 10-lb/ft³) regeneration, whereas small homeowner systems operate at 85 kg/m³ (6 lb/ft³). Therefore, for every kg of hardness removed approximately 11 to 57 L (3 to 15 gal) of brine are produced. The strength of the initial regenerant solution is normally between 8 and 18 percent NaCl. Increased regenerant strength reduces waste production, as shown in Table 22-11. This brine contains the excess salt in the brine and the cations removed from the resin.

TABLE 22-11 Volume of Spent Regenerate Produced in Ion Exchange Softening

Regenerant use kg NaCl/kg removed	Volume of regenerant used for indicated solution strength, L/kg removed			
	6 percent NaCl	10 percent NaCl	12 percent NaCl	16 percent NaCl
1.8	30.3	18.2	15.1	11.4
2.4	40.1	24.2	20.1	15.1
3.4	56.8	34.1	28.4	21.2

Following regeneration, the media is rinsed to remove any remaining regenerant. The rinse process is conducted in a downward flow mode for about 30 min and uses 2673 to 5347 L/m³ (20 to 40 gal/ft³) of resin volume.

The volume of brine solution produced can also be determined in terms of bed volumes (BV). A bed volume as its name implies is the equivalent volume occupied by the media. Therefore, 1 m³ of resin would have a BV of about 1000 L. The number of bed volumes that a column can operate prior to exhaustion can be found by dividing the exchange capacity by the hardness of the raw water.

Table 22-12 shows data collected by Snoeyink (1984) on quantities of residuals produced by softening ion-exchange plants at six sites. The amount of rinse water used at each plant was in the range of 2673 to 5347 L/m³ (20 to 40 gal/ft³) of resin. The TDS concentration of the residual can be estimated as the excess salt plus the cations removed. All of the chloride should be present and the excess sodium not used in exchange. The theoretical NaCl demand is 1.18 kg/kg, and NaCl is 40 percent sodium; therefore, the theoretical sodium demand is 0.472 kg/kg.

TABLE 22-12 Residuals Quantities Produced by Softening Ion Exchange Plants

Plant	Gallons wastewater/1,000 gal. water processed*	Raw water total hardness (mg/L as CaCO ₃)	Gallons regenerant/ft ³ resin	Gallons rinse/ft ³ resin	Concentration of brine percent	Gallons processed/ft ³ resin-cycle	Dosage (lb salt/ft ³ resin)
Crystal Lake Plant 6	21.9	233	7.3	18.4	11	1220	6.6
Crystal Lake Plant 8	17.2	244	5.1	19.0	15	1400	6.5
Eldon	71.9	75	3.9	61.7	17	750	5.6
Grinnel	49.5	388	14.5	35.0	6	1000	7.2
Holstein	53.5	885	5.7	19.7	14	475	6.6
Estherville	82.8	915	4.4	24.7	15	350	5.5

*Includes backwash water, regenerant waste and rinse water.

Fluoride Removal by Activated Alumina

As indicated earlier, there are several ions other than hardness that can be successfully removed by ion-exchange or adsorption processes. Of these, probably the use of activated alumina for fluoride removal is the most widely practiced. Activated alumina also removes arsenic and selenium. Activated alumina is a mixture of amorphous and gamma aluminum oxide prepared by low-temperature dehydration of aluminum hydroxide.

To regenerate the alumina once it is exhausted with fluoride, a dilute solution of 0.25- to 0.5-M sodium hydroxide is used. Because alumina is both a cation and anion exchanger, Na^+ is exchanged for H^+ , which immediately combines with hydroxide to form water (Clifford, 1999).

In order to restore the fluoride removal capacity, the alumina that has been regenerated with sodium hydroxide is acidified by contacting it with excess acid. As an alternative to rinsing the basic alumina with acid, the source water pH can be reduced to 5.5 to 6.0. This avoids the production of an acid rinse residual.

Table 22-13 shows a typical fluoride capacity for activated alumina as a function of the fluoride concentration in order to reach a final fluoride level of 1.4 mg/L.

TABLE 22-13 Fluoride Capacity of Activated Alumina

Raw water fluoride (mg/L)	Raw water TDS (mg/L)	Run length BV	Fluoride capacity (g/m ³)
2.0	810	2300	3700
3.0	1350	1200	3000
5.0	1210	1150	4600

Source: Clifford, 1999.

Similar to ion-exchange processes, prior to regeneration the exhausted contactor is backwashed to remove particles and to re-stratify the media. Backwashing is accomplished at a flow rate of 19.6 to 22.0 m/h (8 to 9 gpm/ft²) for 5 to 10 min. This backwash results in about eight bed volumes (BVs) of spent backwash water being produced.

A slow rinse follows both the sodium hydroxide regeneration and the acid rinse. The rinse takes place at about 1.22 m/h (0.5 gpm/ft³) and is equivalent to about two BV for each rinse. The sodium hydroxide regeneration requires about 1.22-m/h (0.5-gpm/ft³) flow rate for around 75 min, or about five BV. A 1 percent NaOH concentration is typically used. The acid rinse is also done at a flow rate of 1.22 m/h (0.5 gpm/ft³) with the use of about 1.5 BV at a 2 percent sulfuric acid concentration. A final rinse of about 30 to 50 BV is used prior to placing the activated alumina back in service.

Snoeyink (1984) presented characteristics of residuals produced at two activated alumina plants as shown in Tables 22-14 and 22-15. In both cases the sodium hydroxide regeneration was done in both an upflow and downflow mode. The acid and final rinse stages were combined by rinsing using raw water that had been lowered to a pH of about 3.2 using sulfuric acid. Also shown are the percentage each residual represents to the total volume of raw water treated.

Removal of Nitrate and Perchlorate Using Anion Exchange

Nitrate and perchlorate can be removed by anion exchange resins. Sodium chloride is used as the regenerate for these systems. Table 22-16 shows the amount of residual produced at several operating nitrate and perchlorate plants as summarized by Min et al. (2004).

Approximate values for nitrate and perchlorate in the brine residual are also shown, as well as the disposal method used.

Min et al. (2004) also reported quality analysis on a regenerate brine collected from La Puente Valley County Water District (LPVCWD), as presented in Table 22-17. The six samples presented in the table were collected consecutively from a pseudo-continuous, countercurrent, ion-exchange process operated by LPVCWD to remove perchlorate. The considerable variability in the spent brine quality could challenge subsequent treatment processes.

TABLE 22-17 Analysis of Individual La Puente Ion Exchange Effluent Brine Samples

The principal options for treating or disposing of nitrate and perchlorate brines are biological degradation followed by discharge, thermal degradation followed by discharge, or direct discharge to a wastewater plant or body of water if allowed. Significant research has been conducted on both degradation processes, but actual applications are limited.

Disposal of Brines

Economical disposal of brine and other ion-exchange and adsorption process waste streams (spent backwash and rinse water) requires a readily available disposal location. Therefore, most large plants that utilize ion-exchange softening are located in coastal communities so that ocean brine disposal is practiced. Ion exchange has been used in small water supply systems in other parts of the country, and residuals have most often been discharged to municipal wastewater systems or to receiving streams.

One of the most common methods to dispose of the residuals is to discharge to a wastewater plant. The effects of changing concentrations of salts in the wastewater due to slug discharge of high TDS brine is of considerable significance. A concentration change of 100 to 200 mg/L of NaCl is rather low and would have no impact on the biological process, whereas a concentration change of 35,000 mg/L NaCl (almost an undiluted discharge of ion-exchange brine) would cause considerable stress to the biological organisms. In terms of impact to biological treatment processes, the effects of brine discharges from water treatment plants should have an insignificant impact on the wastewater treatment process as long as some precautions for equalization and dilution are followed. Toxicity of specific compounds within the waste streams should be carefully monitored and diluted sufficiently to eliminate toxic effects.

In addition to effects on the aerobic biological process, salts can affect anaerobic digestion. Toxicity is normally associated with the cation rather than the anion of the salt. While

discussion of cation effects is beyond the scope of this chapter, for additional information a recommended source is the book by Rittmann and McCarty (2001).

Although brine discharge to wastewater systems may be feasible from a biological treatment perspective, there may be other factors that limit the feasibility of this disposal method. If the wastewater is being treated for reuse applications, wastewater utilities may be limited in their ability to accept brine discharges due to effluent TDS limits.

Discharge of the brine to brackish coastal water and to seawater is also a widely practiced method for disposal. Since the brines are primarily a high TDS residual consisting mostly of salt, the permitting process has been fairly easy. Membrane concentrates have been more difficult to permit in some states due to the requirements to pass acute toxicity tests. These tests could also be applied to ion-exchange brines which would make permitting of their disposal more difficult. Mickley (2000) has described extensively the requirements and problems related to toxicity testing on membrane concentrates.

In general, there are no economically feasible technical options for specifically removing excess ions from concentrate within the existing economics of the municipal drinking water industry. In site-specific instances, there may be means of providing enhanced dilution of the concentrate prior to or at final discharge through blending or the use of end-of-the-pipe diffusers (Mickley, 2000).

RESIDUALS CONTAINING ARSENIC

All water systems must supply finished water with less than 0.01 mg/L arsenic according to the Safe Drinking Water Act, (USEPA, 2003); see Chap. 1 on standards and Chap. 2 on health effects. For systems that utilize sources with arsenic concentrations above this regulatory limit, some form of treatment is utilized for arsenic removal. These technologies produce a number of different types of residuals, including both solids and liquids. The feasibility of certain arsenic removal treatment technologies for a given utility may be strongly influenced by the available disposal options for the arsenic residuals. When selecting treatment options, it is critical to evaluate the types of residuals that would be generated, their expected arsenic concentrations, and the residuals pretreatment strategies that would be required prior to final disposal.

Table 22-18 shows the options available to dispose of these materials produced by treatment technologies. In general, arsenic in the residual material can limit the options available for disposal. The material must be analyzed for leaching potential using the TCLP procedure (EPA Test Method 1311) (USEPA, 1991a). The arsenic in the leachate must not exceed 5 mg/L, or it will be categorized as a hazardous waste. In general, removal technologies that produce residual solids will not fail the TCLP; adsorption media will not fail because the arsenic is tightly bound, and coagulant sludges generally do not have levels high enough to fail this test. However, iron or alum coagulation processes treating waters specifically for arsenic can have high enough arsenic concentrations in the residuals to fail the TCLP. In California, the Waste Extraction Test (WET) is used to determine the toxicity of a material, and so, to determine if the waste must be handled as a hazardous material (State of California, 2005). California's WET procedure is similar to that described in the TCLP, but it uses more stringent conditions. Therefore, some sludges could pass the TCLP, but fail the WET.

If the material does fail the TCLP, then it can only be disposed of at a hazardous waste facility. It may be difficult to find such facilities that will accept small quantities of materials, and disposal costs at facilities that do accept these wastes can be high. Transportation to these facilities is regulated under the Hazardous Materials Transportation Act, which covers how the material is packaged, the manifests that must accompany it, and the records that must be kept.

TABLE 22-18 Summary of Residuals and Management Methods for Arsenic Treatment Technologies

Treatment technology	Form of residual	Type of residual	Possible disposal methods
Anion exchange	Liquid	Regeneration streams <ul style="list-style-type: none"> • Spent backwash • Spent regenerant • Spent rinse stream 	Sanitary sewer Direct discharge Evaporation ponds/lagoon
	Solid	Spent resin	Landfill Hazardous waste landfill Return to vendor

Regulations

Arsenic residuals management methods are classified into two groups depending on whether they are liquid residuals or solid/sludge residuals. In the case of liquid residuals, disposal methods may include direct discharge to a water body, indirect discharge via sanitary sewer system, underground injection, management in lagoons, and possible land application. Solid/sludge residuals may be disposed through landfill land application, storage

in lagoons, and reactivation, recovery, or disposal of spent resin. Federal and state regulations apply to handling, transportation, and disposal of arsenic-laden residuals. Most states have the administrative authority to implement federal regulations, and are then required to establish and administer regulations meeting the requirements of these acts. Waste disposal regulations are primarily the responsibility of the states, but the state regulations must meet or exceed the federal regulations.

If the water treatment residual has failed the TCLP test because of arsenic concentrations, then on-site lagoons would be regulated by RCRA. Under RCRA, USEPA has established criteria that prohibit practices that contaminate surface or groundwater (40 CFR 257) and also established comprehensive design and operation standards applicable to surface impoundments (USEPA, 1991b).

Residuals Quantities and Characteristics

Table 22-19 provides a summary of example arsenic concentrations in water treatment residuals (Amy et al., 2000). The residuals volumes and arsenic concentrations shown in the table for various types of residuals were calculated assuming a raw water arsenic content and arsenic removal for each treatment technology. Arsenic concentrations in residuals volumes generated in processes listed in Table 22-19 ranged from 0.098 mg/L for membrane technologies to approximately 10 mg/L for activated alumina and ion exchange. On a dry weight basis, theoretical arsenic concentrations ranged from 165 to more than 14,000 mg/kg.

Table 22-20 shows a summary of the key water quality results obtained in USEPA (2000) for residuals samples collected from various arsenic treatment techniques. Results showed that about 99 percent of the arsenic in the ion-exchange regenerant samples was in the dissolved form. Almost none of the arsenic in the activated alumina regenerant stream and the SFBW samples was dissolved. The concentrate samples collected from the RO and NF plants had low arsenic concentration.

The concentration factor, or degree to which arsenic levels were concentrated in the residuals by the various treatment processes, depends on the arsenic removal process utilized. USEPA (2000) reported arsenic concentration factors as low as 12 for SFBW/activated carbon filter samples and as high as 270 for ion-exchange residuals. Arsenic concentration was greater for brine streams than for waste streams from other processes.

TABLE 22-19 Summary of Example Residuals Quantity from Arsenic Processes

Treatment technology	Volume of residuals produced (gal/MG)	As concentration in residuals volume (mg/L)	Quantity of solids produced (lb/MG)	As concentration in solids (mg/kg dry weight)
Conventional coagulation	4300	9.25	180	1850
Softening	9600	4.2	2000	165

Treatment of Arsenic-Containing Liquid Residuals

Liquid wastes from arsenic removal processes often have arsenic levels higher than allowed for discharge to streams or land. In this case the arsenic must be removed prior to discharge. Figure 22-22 illustrates some of the possible treatment processes for brines generated from activated alumina and ion-exchange regenerants as well as for concentrates from NF and RO. The treatment processes for the liquid wastes are essentially the same as for treatment of the source water: either adsorption, or ion exchange, or precipitation. Extensive testing has been done to identify methods to treat these arsenic residuals (USEPA, 2000; MacPhee, 2001). A summary of the best treatment technology determined for each residual type is presented in Table 22-21.

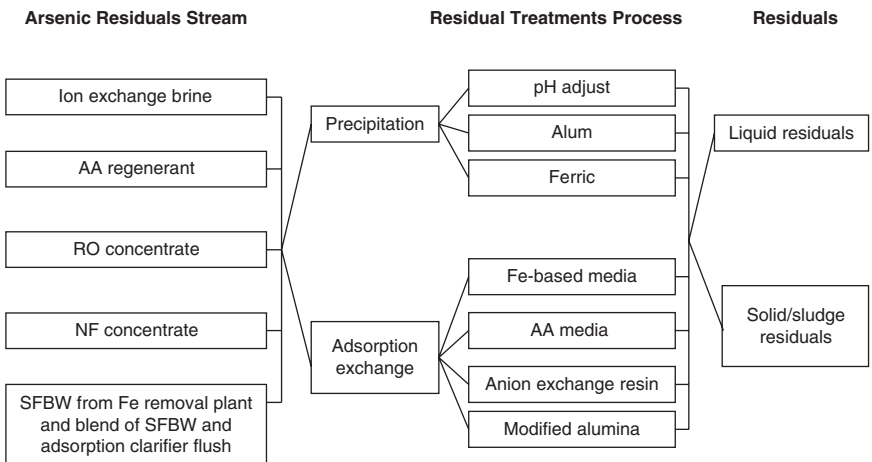

FIGURE 22-22 Arsenic residuals treatment options. (Source: Adapted from USEPA, 2000.)

TABLE 22-21 Summary of Treatment Results for Removing Arsenic from Liquid Arsenic Waste

Sample type	Best treatment conditions determined from testing ^a	Total As remaining (mg/L)
AA regenerant	None	0.154
Ion Ex (A)	None	1.28
Ion Ex (B)	None	18.7
RO (A)	Ferric chloride precipitation	0.041
RO (B)	Iron media adsorption	0.018
NF (A)	Ferric chloride precipitation, iron-based media or AA adsorption	0.009, 0.030
NF (B)	Iron media adsorption, ferric chloride precipitation	<0.002, 0.005
SFBW (A) (settled)	Ferric chloride precipitation	0.013
SFBW/ACF (B) (unsettled)	Gravity settling (no chemical addition)	0.043
(settled)	Iron media, ion exchange, or AA adsorption	<0.002

^aGoal was to reach 0.05 m/L arsenic which is the discharge standard for many states.

AA = Activated Alumina.

Source: Adapted from MacPhee et al., 2001.

Handling of Solids from Arsenic Removal

As discussed, several solid residuals can be produced by arsenic removal systems. Spent exhausted media can be produced by activated alumina and iron-based sorbents systems. Generally a contract can be established for the media vendor to take back the spent material. They will often supply replacement material at a cost less than normal. If the media cannot be returned to the vendor, then it needs to undergo TCLP or WET (for systems in California) testing and be disposed of properly.

Other solids produced can be coagulant solids from treating liquid residuals or coagulant solids from treatment processes removing arsenic from the raw water such as coagulation followed by filtration or microfiltration. These residuals can go to a sewer, be dewatered and disposed of, or be stored in a lagoon.

RESIDUALS CONTAINING RADIOACTIVITY

The revised Radionuclides Rule came into effect on December 8, 2003, mandating that all community water systems (CWSs) come into compliance with this regulation. This rule retained the maximum contaminant levels (MCLs) for combined radium-226/228, gross alpha particle activity and combined beta particle and photon radioactivity and set a new MCL for uranium. The MCLs are presented in Chap. 1.

Systems can use a number of treatment alternatives to come into compliance with this regulation. Best available technologies (BATs) for radionuclide removal, and the residuals associated with these processes, are shown in Table 22-22. Treating water for naturally occurring radionuclides will result in residual streams that are classified as “technologically enhanced naturally occurring radioactive materials” (TENORM). TENORM is defined here as naturally occurring materials, such as rocks, minerals, soils, and water whose radionuclide concentrations or potential for exposure to humans or the environment is enhanced as a result of human activities (e.g., water treatment).

TABLE 22-22 Summary of Treatment Technologies for Removal of Naturally Occurring Radionuclides in Water

Treatment technology	Contaminant removed	Removal efficiency (percent)	Wastes produced	Waste concentrations
Cation exchange	Radium	85–97	Rinse and backwash water Regenerant brine	8 to 9 pCi/L-Ra ^H 50 to 3,500 pCi/L- Ra ^H 22 to 94 pCi/L ^I

Coagulation/ Filtration	Uranium	50 to 85	Sludge	10,000 to 30,000 pCi/ L-U

^HPeak values.[†]Average for given waste forms.[‡]May be increased to 99 percent by the presence or addition of magnesium carbonate to the water.[§]May be increased to 90 percent by passing the water through a detention tank after the addition of potassium permanganate prior to filtration.**Source:** USEPA, 2005a; data extracted from USEPA 1982, 1986, 1994, 1995; Wade Miller Associates, 1991; and Reid 1985.

Characterization

The Spreadsheet Program to Ascertain Residuals Radionuclide Concentrations (SPARRC) can be used to estimate the waste volumes and concentrations of radionuclides in the residuals from water treatment plants removing naturally occurring radionuclides. The current version of SPAARC (available at www.npdespermits.com/sparrc) incorporates predictive algorithms to estimate radionuclides and cocontaminant removals and focuses on a sound estimate of residual radionuclides concentrations and cooccurring pollutants rather than sizing and designing drinking water treatment technologies. The program allows the operator to select the type of treatment process, as well as input and output parameters such as water flows, doses of coagulant and polymer, and filter capacities. Table 22-23 shows the processes considered.

TABLE 22-23 Software Program to Ascertain Residuals Radionuclide Concentration Elements

Technology	Radionuclides	Co-contaminant
Coagulation/Filtration	Uranium	Arsenic
Lime softening	Radium and uranium	None
IX	Radium, barium, and uranium	None
RO	Radium and uranium	None
Activated alumina	Uranium	Arsenic
Greensand filtration	Radium and barium	None

Regulations

No federal agency currently has the legislative authority to regulate the disposal of wastes generated by water treatment facilities on the basis of the residuals' naturally occurring radionuclide content. The U.S. Nuclear Regulatory Commission (USNRC) regulates licensed radionuclide materials such as would be generated from a nuclear power plant. The Atomic Energy Act (AEA) of 1954 and its subsequent amendments provided the legislative authority for this agency to do so. The USNRC regulates the handling and disposal of both high-level and low-level radioactive wastes that are generated by various human-made processes. High-level radioactive waste includes such things as spent fuel rods from nuclear power plants. Low-level radioactive waste includes such things as clothing and building materials used in nuclear processes. The regulations governing both high-level and low-level radioactive wastes deal only with human-made radioactivity and source material.

Uranium and thorium are considered source material (42 USC 2014(z)) and so are subject to NRC or Agreement State licensing and regulation. Water treatment systems that produce residuals containing uranium or thorium must comply with this licensing requirement. However, source material of an unimportant quantity (10 CFR 40.13) is *exempt* from NRC or Agreement State regulation if the uranium or thorium makes up less than 0.05 percent by weight (or approximately 335 pCi/g for natural uranium) of the material. These limits apply to both liquid and solid residuals.

The USEPA regulates the disposal of hazardous solid waste under the Resource Conservation and Recovery Act (RCRA). But radioactivity in solid wastes is not one of the classifications used by RCRA to determine if a particular substance is hazardous. Activated carbons and sludges from water treatment could not be categorized as hazardous under RCRA because of radionuclide activity. No other federal law specifically regulates disposal of waste containing elevated levels of naturally occurring radioactive materials at this time.

State TENORM Regulations

Most states do not specifically regulate water plant wastes on the basis of elevated levels of radioactivity. A few states have enacted restrictions on the disposal of solid wastes containing specific naturally occurring radionuclides.

The states of Illinois and Wisconsin have developed disposal criteria of water treatment plant wastes containing radium. Other states, including New Hampshire, have disposal criteria for wastes containing high levels of NORM and TENORM radiation from uranium and radium. *Naturally occurring radioactive materials* (NORM) include primordial radionuclides that are naturally present in the rocks and minerals of the Earth's crust and cosmogenic radionuclides produced by interactions of cosmic nucleons with target atoms in the atmosphere

and in the Earth. TENORM refers to NORM that has been concentrated or changed due to the exposure to the environment and by processes such as water treatment.

Most states do not have specific TENORM regulations and regulate it the same ways as all other sources of radiation. In the absence of specific regulations or guidance, water suppliers would be required to dispose of radioactive residuals in accordance with existing solid waste or, where applicable, hazardous waste requirements.

The U.S. Department of Transportation (USDOT) regulates the shipment of any radioactive waste (USDOT, 1976). DOT is a possible regulatory authority if the waste is shipped off-site for disposal. The waste can be considered radioactive by USDOT if (1) a state authority has designated the waste as radioactive or (2) the radioactivity exceeds USDOT established levels. DOT defines a radioactive waste as a material that has a specific activity greater than 2000 pCi/g. Also, if a state designates a waste as radioactive then USDOT regulations apply. In such cases, shipment must be according to 49 CFR Part 172.392, which requires that the waste be packaged in leak-proof containers with acceptable levels of external radiation and transported in appropriately marked vehicles.

Ultimate Disposal Options

Table 22-24 summarizes the disposal options for radioactive wastes and notes possible constraints for these methods due to radionuclides.

TABLE 22-24 Common Disposal Considerations for Residuals Containing Radioactivity

Direct discharge	<ul style="list-style-type: none"> • System must have a NPDES permit. • Systems must meet state radionuclides limits.
Discharge to a POTW	<ul style="list-style-type: none"> • Systems must meet the requirements of the POTW and meet state permitting requirements.
Underground injection	<ul style="list-style-type: none"> • Class I hazardous injection wells may be a disposal option for radioactive or hazardous wastes. • Systems should check with their state to determine whether the state has more stringent UIC requirements. • USEPA has the authority to take action on any residential waste disposal system if the system introduces contaminants into a USDW whose presence or likely presence causes an imminent and substantial endangerment to public health.
Landfill disposal	<ul style="list-style-type: none"> • Systems must check with their states to determine whether landfilling is an acceptable means of disposal for hazardous and nonhazardous solid waste containing radionuclides.

Source: USEPA, 2005a.

Mixed Waste

Mixed waste is regulated under RCRA and the Atomic Energy Act (AEA) of 1954. Mixed waste “contains both hazardous waste and source . . . or byproduct material subject to the Atomic Energy Act of 1954” (42 USC 6903.41). Therefore, systems generating waste containing uranium or thorium (source material) as well as hazardous waste could potentially have a mixed waste. If wastes contain licensable amounts of source material (any concentration exceeding the “unimportant quantity” in 10 CFR 40.13 (a)) and hazardous waste, these wastes must be disposed of at a facility authorized to accept mixed waste. Because there are limited disposal pathways, generation of a mixed waste should be avoided if at all possible. (USEPA, 2005).

ULTIMATE DISPOSAL AND UTILIZATION OF SOLIDS

The treatment and disposal of water treatment plant residuals are rapidly becoming integral parts of operating water treatment plant facilities as local, state, and federal regulations are requiring more stringent standards for traditionally practiced residuals management programs. The discharge of untreated residuals to most surface waters is severely restricted under the National Pollutant Discharge Elimination System (NPDES) of the Clean Water Act. Discharge of residuals to the sanitary sewer is equally becoming more restrictive through wastewater pretreatment standards, wastewater treatment plant available capacity, digester ability to handle the mostly inorganic residuals, and the wastewater plants' effluent standards. Sanitary landfill disposal of dewatered residuals has become costly, and the residuals take up valuable space in a disposal system that is already predicting severe shortages in the near future. As a result, beneficial use programs for residuals are increasingly being considered by utilities, not only as a cost-effective alternative but also as a publicly acceptable management practice.

The desired residuals management goal for any water utility is to operate an economically efficient and environmentally attractive residuals management plan by developing one or more long-term agreements that will allow for the proper utilization of residuals in a beneficial application. The beneficial use markets that have exhibited the greatest potential for success are the following:

- *Commercial products.* The use of residuals in the making of commercial products has been successful in such areas as turf farming and topsoil blending. In both cases, the residuals are a substitute for natural soil material and offer economical benefits to the producer. Details on beneficial use options for water plant residuals is found in Cornwell et al. (2000).
- *Co-use with biosolids.* Incorporating residuals in biosolids management programs such as land application and composting can be beneficial. Blended products tend to have lower metal concentrations making the product more marketable. Also, for utilities that operate both a water and wastewater facility, permitting, record keeping, and monitoring requirements are reduced when all the residuals are managed under one program. Co-composting of biosolids and residuals has been successfully practiced at blends up to 25 percent residuals.
- *Land application.* Land application of residuals to agricultural or forested land is a feasible beneficial use alternative. Land application of lime residuals has been practiced for many years due to the value of lime addition to farmland (Russell, 1975). Land application of coagulant residuals has also been successful whether blended with biosolids or applied alone.

Application of residuals to turf farms provides a residuals management option which can benefit a farmer's harvest and supplements the farmed areas with a new soil base. Turf grass has a relatively low nutrient demand but requires significant moisture levels, particularly for initial growth phases. Dewatered residuals applied to a turf farm at the beginning of the seeding process can provide excellent water retention capabilities. The preferred method of application is with a manure-type spreader. The application rate is a function of the type of grass, supplemental fertilization, and residuals quality. A 25-mm (1-in) application depth of residuals at 20 percent solids concentration equals a solids loading rate of 38.1 dry metric tons per hectare (17 dry tons per acre) or a mass loading rate of 1.7 percent.

Greenhouse and leaching experiments undertaken by the University of Buffalo (Van Benschoten et al., 1991) showed the success of using residuals in grass growing. Residuals

FIGURE 22-23 University of Buffalo greenhouse study: Grass mass versus percent residuals loading. Note: each bar shows the sum of three harvests and represents a unique test. (Source: Van Benschoten et al., 1991.)

mixed with native soils at 25, 50, 75, and 100 percent loadings clearly enhanced turf grass growth in the greenhouse studies. As shown in Fig. 22-23, measured turf grass growth in residuals/soil mixtures was up to 3 to 4 times the growth observed in native soils. This improvement in yield translates into a turf farmer being able to bring his fields to harvest sooner and therefore provide a marketable turf product sooner than experienced under current harvesting conditions. Increases in labile phosphorus (as determined in Bray-1 phosphorus tests), indicative of a beneficial increase in soil of phosphorus available to plants, followed the recorded increases in grass mass.

Commercial producers of topsoil utilize a variety of raw soil products to develop a marketable product for nurseries, homeowners, professional landscapers, and so on. In this process, the raw soils are screened and blended with some organic material before being sold as a product. Residuals can be blended during the topsoil production process to increase the nutrient value and water retention capabilities. To a topsoil producer, the residuals are a raw material that can be obtained at little or no cost and increases the profit margin on the final product. The amount of residuals added to the topsoil may be 10 percent or less and is a function of consistency, quality, and availability. The acceptable quality of the residuals is determined by individual topsoil producers. Earthgro Corporation in Pennsylvania is a commercial topsoil producer and has established various classes of quality at which residuals can be accepted as shown in Table 22-25.

TABLE 22-25 Topsoil Blending: Metal Content Limits (ppm)

Parameter	Preapproved	Requires review	Not accepted
Cadmium	<2.0	2.0–25.0	>25.0
Chromium	<1000	—	>1000
Copper	<100	100–1000	>1000
Lead	<200	200–400	>400
Mercury	<0.3	0.3–10.0	>10.0
Nickel	<200	—	>200
Zinc	<300	300–1200	>1200

Blending residuals with topsoil can be a mutually beneficial operation for the utility and the producers. Key elements for long-term success are reasonably consistent solids quality, reliable delivery of dewatered residuals, and a strong contractual arrangement between all parties.

Residuals can be mixed with biosolids and subsequently be a coproduct in the overall end-use management strategy of the biosolids. For a utility that operates both water and wastewater facilities, this type of residuals management program has certain benefits including (1) it avoids separate permitting and monitoring of the residuals, (2) it provides a beneficial and often cost-effective end-use avenue for the residuals, and (3) it reduces most of the metal concentrations in the biosolids product because of the diluting effect of the residuals. Even in situations where the water and wastewater facilities are owned and operated by separate entities, the residuals can enhance the quality of the biosolids product and provide a source of revenue. Residuals can be incorporated with biosolids in a variety of methods, including

- Discharge of liquid residuals to the sanitary sewer
- Discharge of liquid residuals at the wastewater plant influent
- Discharge of liquid residuals at the wastewater plant solids handling stage
- Blending of dewatered residuals with dewatered biosolids

Inorganic water plant residuals can significantly impact primary settler overflow quality, digester space, and digester efficiency. Residuals should also not degrade the end-use biosolids product quality such as lowering nutrient values or increasing/introducing higher metal concentrations. This is particularly true for land application and composting processes.

The land application of residuals can be an environmentally safe and cost-effective method for residuals management. Due to the variable characteristics of different raw water sources, allowable residuals application rates must be considered according to each individual residuals composition. The primary concerns associated with land application of coagulant residuals are due to the presence of heavy metals and the potential for phosphorus binding. Alum residuals, when added to soil, have the capabilities to absorb inorganic P which prohibits plants to extract P from the soil for plant growth. However, with good soil management and crop selection, P depletion can be prevented with proper loading rates and P fertilization. The aluminum concentration of WTP residuals can range from 5 to 15 percent of the total dry solids mass, which is 50 to 100 percent higher than the concentration of the aluminum in most soils (Elliott and Dempsey, 1991). Elliott and Dempsey (1991) determined that a 22.4 metric ton per hectare (10 ton per acre) residuals loading rate with residuals Al concentration of 30 percent, the soil Al level was reported to only increase by 0.3 percent. Aluminum phytotoxicity is dependent on Al solubility and is not a problem when the pH range in the soils is maintained between pH 6 and 6.5 (Elliott and Dempsey, 1991).

The addition of alum residuals to soils could also change the soils physical structure, or bulk density. A soil with a high bulk density is more compact which is unfavorable to plant growth because root penetration is restricted. A low bulk density (less compacted soil) has more pore space for air and water which is beneficial for plant growth (Tisdale and Nelson, 1975). Rengasamy et al. (1980) found that soil mixed with alum residuals increased soil aggregation and moisture retention and, as a result, increased the dry yield of maize. Bugbee and Frink (1985) demonstrated that improvements in aeration and moisture retention promoted by the addition of alum residuals were made to offset the phosphorus deficiency in lettuce.

The impact of land application on various crops has been investigated by Virginia Polytechnic Institute and State University. Novak (1993) studied the impact of alum and PACl residuals on corn when applied at 1.3 to 2.5 percent by dry weight (29.1 to 56.0 metric tons per hectare (13 to 25 tons per acre)). Crop yields from the treated plots were not statistically different from the untreated plots. Mutter et al. (1994) studied the impact of

PACI residuals on wheat when applied at 2, 4, and 8 percent. No negative effects on wheat grain or biomass yield were observed at these loading rates. Although soil aluminum levels were significantly increased at these loading rates, after two crop rotations the soil Al concentrations were found to be similar to background Al levels. The wheat leaf tissue was increased slightly in Al concentration as compared with the control. This increase in Al concentration, however, was not found to be significant.

A detailed description of the processes involved for land application of water residuals are outlined in *Land Application of Water Treatment Plant Sludges* (Elliott et al., 1990). The AwwaRF land application guide provides a good source of technical information concerning the principles and design associated with land-applying residuals. Implementation logistics and residuals quality requirements are also summarized in the report. A number of land application research studies conducted using coagulant residuals have demonstrated neutral or slightly positive impacts on crop growth (Lin and Green, 1990; Geertsema, 1994). Some of the benefits associated with the addition of coagulant residuals to agronomic soils include

- Improvement to soil structure
- Soil pH adjustment
- Addition of trace minerals
- Increased moisture holding capacity
- Soil aeration

Land application of softening sludge has been practiced for years. Farmers were allowed to cart away dewatered softening sludge from a plant in Ohio as early as the 1950s (Reeves, 1980).

In farming regions, the application of nitrogen fertilizers causes a reduction in soil pH. If optimum pH conditions do not exist, crop yields are reduced. Therefore, farmers must apply sufficient quantities of calcium carbonate as a means of counteracting the fertilizer applications. For each 45.4 kg (100 lb) of ammonia fertilizer, 1.4 to 1.8 kg (3 to 4 lb) of limestone must be applied (Russell, 1980).

Several state agencies have evaluated the neutralizing power of softening sludges versus commercial limestone. In 1969, the Ohio Department of Health reported that the total neutralizing power of lime sludge is greater than that of marketed liming materials (Ohio, 1969). To bring the soil pH into the desirable range, 2721 kg/4047 m² (3 tons/acre) lime, or about 9070 kg (10 tons) of lime sludge at a 30-percent solids concentration, are required. Subsequent lime applications are required to maintain the desired pH. In Illinois, a calcium carbonate equivalent test (CCE) performed on several softening sludges indicated that the softening sludges were superior to agricultural limestones available locally. Since softening sludges contain a high quantity of calcium carbonate and offer a high degree of neutralization, this resource should be used when it is practical for soil conditioning. The addition of softening sludge also increases the porosity of tight soils, making them more workable for agricultural purposes (Russell, 1980).

Landfilling of water plant solids is the disposal choice when beneficial options cannot be obtained. Landfilling of water plant residuals has three basic categories.

- Sludge monofills
- Codisposal in a municipal or industrial landfill
- Hazardous waste landfills

Since water plant solids are usually not found to be hazardous, the last category is not used. Codisposal into a municipal or industrial waste landfill is a matter of contacting the available landfills in the area and determining these requirements and their tipping fee. Generally landfills will require that the sludge be tested to prove it is nonhazardous, and it

must be of a high enough solids concentration that there is no free water. Due to the costs of codisposal landfills, some utilities are building monofills. Monofills are disposal sites specifically constructed to hold water plant residuals. The two major types of sludge monofills are trench filling and area filling.

In trench landfills, sludge is placed entirely below the original ground surface. The trench depth is dependent typically on the depth to groundwater and bedrock to maintain sufficient soil buffers between the sludge and substrata. Trench depth is a function of sidewall stability and equipment limitations as well. The trenching method encompasses both narrow and wide trench type disposal areas, which range in width from about 1 to 15 m (several ft to 50 ft).

Unlike the trench landfilling technique, where sludge is placed below ground, in area filling techniques sludge is generally placed above the original surface. Area filling may be accomplished in one of three ways.

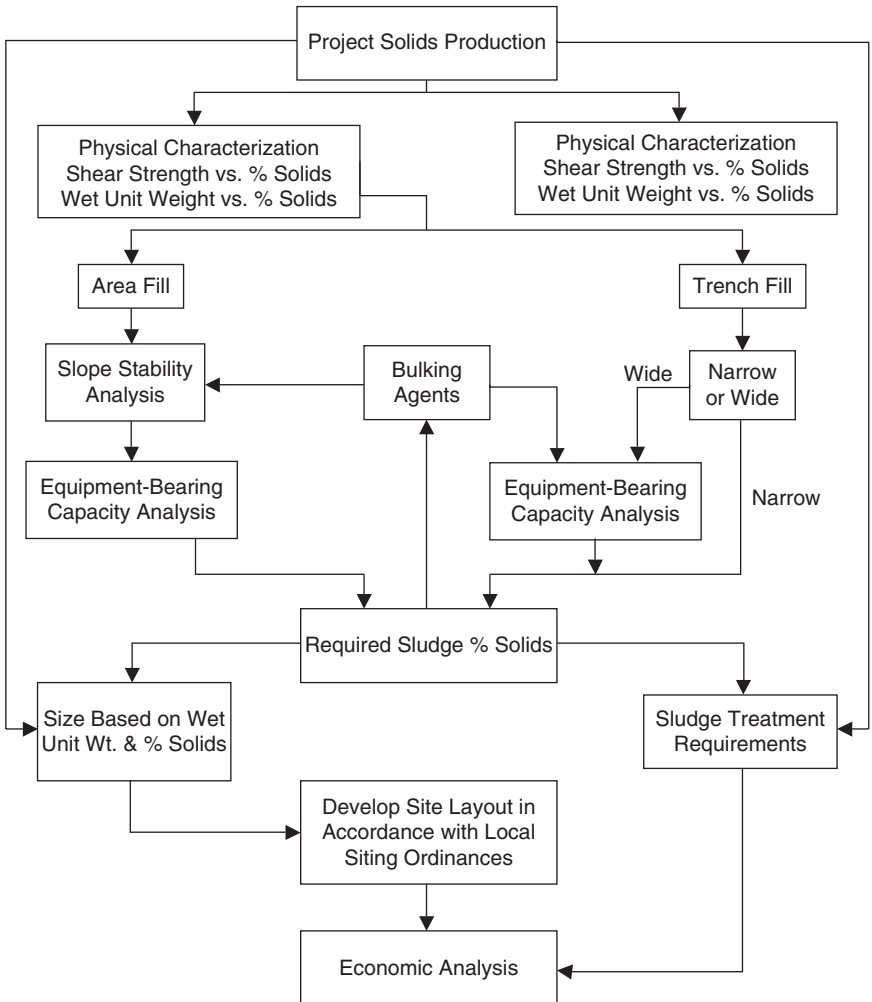

FIGURE 22-24 Considerations for sludge monofill design.

- *Area mound.* Sludge is mixed with soil such that it becomes stable enough to be stacked in mounds.
- *Area layer.* Sludge is spread evenly in layers over a large tract of land.
- *Diked containment.* Earthen dikes are constructed above ground to form a containment structure into which the sludge can be disposed.

Although solids content is not limited in area fill landfills, the requirement that sludge must be capable of supporting equipment due to the lack of sidewall containment necessitates reasonably good sludge stability and bearing capacity. These characteristics are typically achieved through good dewatering, dewatering followed by air drying, or mixing sludge with bulking agents. A combination of these methods can also be employed. Areas with high water tables and those with bedrock close to the surface are particularly amenable to area fill methods of sludge monofilling.

In the area fill layer disposal method, sludge is spread in 15.2- to 30.5-cm (6- to 12-in) layers. This in turn allows additional air drying of the sludge to achieve higher solids concentration and shear strengths. This method would seem favorable for coagulant sludges, which are typically difficult to dewater. The layering method eliminates the need for a separate air-drying area outside the monofill, provided the monofill cell is large enough. The area fill layering technique usually results in relatively stable fill areas when completed and, therefore, requires less extensive equipment and manpower efforts for maintenance than the area fill mound technique.

Figure 22-24 presents a schematic diagram that highlights the essential planning considerations for disposal of water plant sludge in a monofill. The diagram shows the determining factors and the effects of each decision in the planning process as indicated on the figure. Sludge treatment requirements and project economics are affected not only by the quantity of sludge produced but also by the sludge's physical and chemical characteristics.

ABBREVIATIONS

AEA	Atomic Energy Act
BAT	best available technology
BOD	biochemical oxygen demand
BV	bed volume
CEBW	chemically enhanced backwash
CIP	clean-in-place
CST	capillary suction time
CWS	community water systems
DAF	dissolved air flotation
DO	dissolved oxygen
DOC	dissolved organic carbon
ED	electrodialysis
EDR	electrodialysis reversal
EQ	equalization
FBRR	Filter Backwash Recycling Rule
GAC	granular activated carbon
IPP	Industrial Pretreatment Program
MCL	maximum contaminant level
MDL	method detection limit
MF	microfiltration
NF	nanofiltration

NOAA	National Oceanic and Atmospheric Administration
NORM	naturally occurring radioactive materials
NPDES	National Permit Discharge Elimination System
ntu	nephelometric turbidity unit
PAC	powdered activated carbon
PACl	polyaluminum chloride
POTW	publicly owned treatment works
RCRA	Resource Conservation and Recovery Act
RO	reverse osmosis
SAC	strong acid cation
SAR	sodium adsorption ratio
SFBW	spent filter backwash water
SPARRC	Spreadsheet Program to Ascertain Radionuclides Residuals Concentration
SR	specific resistance
TCLP	toxicity characteristic leach procedure
TDS	total dissolved solids
TENORM	technologically enhanced naturally occurring radioactive materials
TOC	total organic carbon

USNRC	U.S. Nuclear Regulatory Commission
WAC	weak acid cation
WET	waste extraction test
WQBEL	water quality based effluent limit

NOTATION FOR EQUATIONS

A	additional chemicals added such as polymer, clay or activated carbon
Al	alum dose as 17.1 percent Al_2O_3
$CaCH$	calcium carbonate hardness removed as $CaCO_3$
$CaNCH$	calcium noncarbonate hardness removed as $CaCO_3$
d	particle diameter
D	total bowl diameter
D_d	drained depth
ΔD_e	required depth change due to evaporation
D_i	initial depth of residuals at loading
$d(z)$	thickness of the sludge layer
$D(z)$	total depth of sludge that can be frozen
DOC_r	dissolved organic carbon removed
E	net pan evaporation
F	latent heat of fusion
Fe	iron dose as Fe
h	convection coefficient
K	conductivity coefficient
M	mass of dry solids

$MgCH$	magnesium carbonate hardness removed as $CaCO_3$
$MgNCH$	magnesium noncarbonate hardness removed as $CaCO_3$
N	number of leads
P	percent solids expressed as a decimal
Q	plant flow
r_1	radius from centerline of centrifuge to pool level
r_2	radius from centerline of centrifuge to bowl
s	specific gravity of the sludge
S	sludge production
S_b	pitch of blades
SS	raw water suspended solids
SS_d	drained solids concentration
SS_f	desired final solids concentration
SS_i	initial solids concentration
$t(f)$	freezing time
T	average ambient temperature
T_f	freezing point temperature
Tu	raw water turbidity
V	volume of sludge
V	volume of sludge/water in the pool of a centrifuge
ΔW	bowl/conveyor differential speed
Y	sand bed yield
z	pool depth in a centrifuge
μ	viscosity
ρ	fluid density
ρ_p	particle density
ρ_f	density of frozen sludge
χ	filterability constant
Φ	dimensionless instrument constant
ω	radial velocity of centrifuge (radians)

APPENDIX A

CHEMICAL ELEMENTS

TABLE A.1 Atomic Numbers and Masses from IUPAC[†]

Actinium	Ac	89	(227)	Krypton	Kr	36	83.798
Aluminum	Al	13	26.9815386	Lanthanum	La	57	138.90547
Americium	Am	95	(243)	Lawrencium	Lr	103	(262)
Antimony	Sb	51	121.760	Lead	Pb	82	207.2
Argon	Ar	18	39.948	Lithium	Li	3	6.941
Arsenic	As	33	74.92160	Lutetium	Lu	71	174.967
Astatine	At	85	(210)	Magnesium	Mg	12	24.305
Barium	Ba	56	137.327	Manganese	Mn	25	54.9380
Berkelium	Bk	97	(247)	Mendelevium	Md	101	(258)
Beryllium	Be	4	9.012182	Mercury	Hg	80	200.59
Bismuth	Bi	83	208.98040	Molybdenum	Mo	42	95.94
Boron	B	5	10.811	Neodymium	Nd	60	144.242
Bromine	Br	35	79.904	Neon	Ne	10	20.1797
Cadmium	Cd	48	112.411	Neptunium	Np	93	(237)
Calcium	Ca	20	40.078	Nickel	Ni	28	58.693
Californium	Cf	98	(251)	Niobium	Nb	41	92.9064
Carbon	C	6	12.0107	Nitrogen	N	7	14.0067
Cerium	Ce	58	140.116	Nobelium	No	102	(259)
Cesium	Cs	55	132.90541	Osmium	Os	76	190.23
Chlorine	Cl	17	35.453	Oxygen	O	8	15.9994
Chromium	Cr	24	51.996	Palladium	Pd	46	106.42
Cobalt	Co	27	58.933195	Phosphorus	P	15	30.97376
Copper	Cu	29	63.546	Platinum	Pt	78	195.084
Curium	Cm	96	(247)	Plutonium	Pu	94	(244)
Dysprosium	Dy	66	162.500	Polonium	Po	84	(209)
Einsteinium	Es	99	(252)	Potassium	K	19	39.0983
Erbium	Er	68	167.259	Praseodymium	Pr	59	140.9077
Europium	Eu	63	151.964	Promethium	Pm	61	(145)
Fermium	Fm	100	(257)	Protactinium	Pa	91	231.0359
Fluorine	F	9	18.998403	Radium	Ra	88	(226)
Francium	Fr	87	(223)	Radon	Rn	86	(222)
Gadolinium	Gd	64	157.25	Rhenium	Re	75	186.207
Gallium	Ga	31	69.723	Rhodium	Rh	45	102.9055
Germanium	Ge	32	72.64	Rubidium	Rb	37	85.4678
Gold	Au	79	196.96658	Ruthenium	Ru	44	101.07
Hafnium	Hf	72	178.49	Samarium	Sm	62	150.36
Helium	He	2	4.00260	Scandium	Sc	21	44.9559
Holmium	Ho	67	164.9303	Selenium	Se	34	78.96
Hydrogen	H	1	1.0079	Silicon	Si	14	28.0855
Indium	In	49	114.818	Silver	Ag	47	107.8682
Iodine	I	53	126.9045	Sodium	Na	11	22.989769
Iridium	Ir	77	192.217	Strontium	Sr	38	87.62
Iron	Fe	26	55.847	Sulfur	S	16	32.065

Thallium	Tl	81	204.383	Ytterbium	Yb	70	173.04
Thorium	Th	90	232.0381	Yttrium	Y	39	88.9059
Thulium	Tm	69	168.9342	Zinc	Zn	30	65.409
Tin	Sn	50	118.71	Zirconium	Zr	40	91.224
Titanium	Ti	22	47.867				

[†]IUPAC, *Pure Applied Chemistry*, vol. 75, no. 8, pp. 1107–1122, 2003, and revisions, August 2005. A value in parentheses is the mass number of the longest-lived isotope of the element.

APPENDIX B

USEFUL CONSTANTS

TABLE B.1 Physical and Chemical Constants

Avogadro's number	$6.022 \times 10^{23} \text{ mol}^{-1}$
Boltzmann's constant, k_B	$1.3805 \times 10^{-23} \text{ J K}^{-1}$
Dielectric constant (water, 25°C, ϵ)	78.54
Earth gravitation, g	9.806 m s^{-2}
Einstein	1 mole of photons = 6.022×10^{23} photons
Electron charge	$1.602 \times 10^{-19} \text{ C}$
Faraday constant, F	$96.485 \text{ kJ equiv}^{-1} \text{ V}^{-1} = 9.6485 \times 10^4 \text{ C equiv}^{-1}$
Gas constant, R	$1.987 \text{ cal mol}^{-1} \text{ K}^{-1} = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}, 0.08206 \text{ L atm mol}^{-1} \text{ K}^{-1}$
Ice point	273.15 K
Molar volume of ideal gas at 273.15 K, 1 atm	$22.414 \text{ L mol}^{-1}$
Speed of light in vacuum	$2.998 \times 10^8 \text{ m s}^{-1}$
Planck constant, h	$6.626 \times 10^{-34} \text{ J s}$

APPENDIX C

CONVERSION FACTORS

TABLE C-1 Unit Conversion Factors, SI Units to U.S. Customary Units, and U.S. Customary Units to SI Units

SI unit name	To convert, multiply in direction shown by arrows				U.S. customary unit name
	Symbol	→	←	Symbol	
Acceleration					
Meters per square second	m/s ²	3.2808	0.3048	ft/s ²	Feet per square second
Meters per square second	m/s ²	39.3701	0.0254	in/s ²	Inches per square second
Area					
Hectare (10,000 m ²)	ha	2.4711	0.4047	ac	Acre
Square centimeter	cm ²	0.1550	6.4516	in ²	Square inch
Square kilometer	km ²	0.3861	2.5900	mi ²	Square mile
Square kilometer	km ²	247.1054	4.047 × 10 ⁻²	ac	Acre
Square meter	m ²	10.7639	9.2903 × 10 ⁻²	ft ²	Square foot
Square meter	m ²	1.1960	0.8361	yd ²	Square yard
Energy					
Kilojoule	kJ	0.9478	1.0551	Btu	British thermal unit
Joule	J	2.7778 × 10 ⁻⁷	3.6 × 10 ⁶	kW·h	Kilowatt-hour
Joule	J	0.7376	1.356	ft·lb _f	Foot-pound (force)
Joule	J	1.0000	1.0000	W·s	Watt-second
Joule	J	0.2388	4.1876	cal	Calorie
Kilojoule	kJ	2.7778 × 10 ⁻⁴	3600	kW·h	Kilowatt-hour
Kilojoule	kJ	0.2778	3.600	W·h	Watt-hour
Megajoule	MJ	0.3725	2.6845	hp·h	Horsepower-hour
Force					
Newton	N	0.2248	4.4482	lb _f	Pound force
Flow rate					
Cubic meters per day	m ³ /d	264.2	3.785 × 10 ⁻³	gal/d	Gallons per day
Cubic meters per day	m ³ /d	2.642 × 10 ⁻⁴	3.785 × 10 ³	mgd	Million gallons per day
Cubic meters per second	m ³ /s	35.3147	0.02832	ft ³ /s	Cubic feet per second
Cubic meters per second	m ³ /s	22.827	0.0438	mgd	Million gallons per day
Cubic meters per second	m ³ /s	15850.3	6.3090 × 10 ⁻⁵	gal/min	Gallons per minute
Liters per second	L/s	22827	4.381 × 10 ⁻⁵	gal/d	Gallons per day
Liters per second	L/s	2.2825 × 10 ⁻²	43.8126	mgd	Million gallons per day
Liters per second	L/s	15.852	0.0631	gal/min	Gallons per minute

 color removal by, 7.42–7.43
 of cyanotoxins, 7.45
 for DBP control, 19.28–19.31, 19.29f.–19.31f.
 electrochemical potentials in, 7.2–7.4, 7.3t.
 of hydrogen sulfide, 7.42, 7.42t.
 ionic reactions in, 7.11–7.12, 7.12t.
 of iron, 7.31–7.36, 7.32t., 7.34f.
- Chemical oxidation (*Cont.*):
 of manganese, 7.31–7.36, 7.32t., 7.34f.
 mixed oxidants, 5.7, 7.31
 molecularity and, 7.9
 of MTBE, 7.46
 oxidation state in, 7.4
 oxidation-reduction reactions in, 7.4–7.8
 pH dependence in, 7.10–7.11, 7.11f.
 radical reactions in, 7.12–7.13, 7.13t.
 reaction kinetics and, 7.8–7.10
 reaction pathways in, 7.14–7.15
 reaction rate constant and, 7.9
 of SOCs, 7.43–7.46
 standard half-cell potentials for, 7.3t.
 taste and odor destruction with, 7.37–7.39, 7.41
 temperature dependence in, 7.10
 thermodynamic principles of, 7.2–7.8
 treatment process selection and, 5.5–5.7
 uses of, 7.1–7.2
- Chemical precipitation. *See* Precipitation
- Chemical warfare, 2.76
- Chemically enhanced backwash (CEB), 11.91
- Chemicals. *See also* Dissolved chemicals; Inorganic constituents; Organic constituents; Volatile organic chemicals
 acid-base chemistry, 3.11–3.13
 anthropogenic, 3.24, 3.25t., 3.33–3.34
 carcinogenicity of, 2.25–2.26
 classifying, 2.28
 dose-response in, 2.23–2.24
 electroneutrality of, 3.5–3.6
 equilibrium of, 3.7–3.17
 genotoxicity of, 2.25, 2.27
 inorganic carbon chemistry, 3.17–3.21
 IPR assessing unidentified, 16.19
 mutagenicity of, 2.25, 2.27
 naturally occurring, 3.24, 3.25t.
 oncogenicity of, 2.25
 perfluorinated, 2.57–2.58
 principles/concepts of, 3.2–3.24
 redox chemistry, 3.14–3.17
 stoichiometry of, 3.6–3.7
 teratogenicity of, 2.25
 in treatment additives, linings and coatings, 2.58–2.59
- Chick's law, 17.21–17.23, 17.22f.

- Chitin, 8.48

- Chloramine/chloramination, 2.64
 application of, 17.33–17.34
 bacteria inactivation by, 17.28
 breakpoint reaction in, 17.11–17.13, 17.12f.
 chlorine reaction with ammonia in, 7.19–7.20,
 17.10–17.15, 17.12f., 17.15t.
 chlorine reaction with inorganic constituents
 in, 17.16, 17.17t.
 chlorine reaction with organic constituents in,
 7.18–7.19, 17.16
 DBP formation and impact of, 19.38,
 19.38f.–19.39f.
 DBPs and, 19.4t.–19.6t., 19.10–19.13,
 19.10f., 19.12f.
 formation of, 7.19–7.20
 free available chlorine compared to, 21.24,
 21.25f.
 history of, 17.3
Legionella control with, 21.24–21.25
 NDMA and, 19.11, 19.12f.
- Chlorate, 2.64–2.65
 formation of, 7.21–7.23
 GAC reactions with, 14.59
- Chloride
 calcium hypochlorite, 7.17–7.18
 corrosion from, 20.29–20.30
- Chlorinated volatile organic chemicals,
 2.46–2.49
- Chlorine dioxide, 5.6–5.7, 7.34f.
 application of, 17.36
 bacteria inactivation by, 17.28
 basic chemistry of, 17.9–17.10
 chlorate formation, 7.21–7.23
 chlorite formation, 7.21–7.23
 DBPs and, 2.64–2.65, 19.4t.–19.6t., 19.13,
 19.29, 19.29f.
 demand reactions of, 17.18
 GAC reactions with, 14.59
 generation of, 7.21, 17.35–17.36
 Henry's law and, 17.9
 history of, 17.3
 in taste and odor control, 7.21
- Chlorine/chlorination, 2.64, 5.6
 ammonia reactions with, 7.19–7.20,
 17.10–17.15, 17.12f., 17.15t.
 bacteria inactivation by, 17.27–17.28
 basic chemistry of, 17.5–17.8
 biological growth in treatment plants
 controlled by, 7.47
 breakpoint reaction in, 17.11–17.13, 17.12f.
 bromide reactions with, 7.20
 chlorine demand kinetics, 17.17–17.18
 Chlorine/chlorination (*Cont.*):
 chlorine-chlorite process, 17.35–17.36
 contact tank hydraulics in, 17.34
 contact time in, 17.33t.
 DBPs and, 19.4t.–19.6t., 19.7–19.10,
 19.8f.–19.9f.
 DBPs and delaying addition of, 19.36, 19.37f.
 dechlorination, 17.33
 design/application of, 17.31–17.34, 17.32t.
 disinfection, UV disinfection compared to,
 18.3, 18.3t.
 disinfection efficiency and speciation of,
 17.10–17.11, 17.11f.
 forms of, 7.15–7.16
 free available chlorine, 7.16, 17.6, 21.24,
 21.25f.
 in GAC adsorption systems, 14.44
 GAC reactions with, 14.58–14.59
 gaseous, 7.17–7.18
 Henry's law and, 17.6–17.7
 history of, 17.3
 hypochlorite ion, 7.16–7.17, 7.16f.
 hypochlorous acid, 7.16–7.17, 7.16f.
 inorganic constituent reactions with, 17.16,
 17.17t.
 iodide reactions with, 7.20
 liquid, 7.17–7.18
 molecular chlorine, 7.16–7.17, 7.16f.
 NOM studies with, 19.23
 organic constituents reactions with,
 7.18–7.19, 17.16
 pH and, 17.6–17.8, 17.7f., 20.30, 20.31f.
 postchlorination, 17.33
 prechlorination, 17.32–17.33
 residuals of, 17.30–17.31
 sodium hypochlorite, 7.17–7.18
 source water and, 17.32–17.33
 species of, 7.16–7.17, 7.16f.
 superchlorination, 17.33
 TOC and decay of, 17.17–17.18
 total available chlorine, 17.10
 UV/Cl₂ AOP mechanism, 18.33
- Chlorite, 2.64–2.65
 chlorine-chlorite process, 17.35–17.36
 formation of, 7.21–7.23
 GAC reactions with, 14.59

 monitoring and control of, 13.60–13.61
 noncarbonate hardness removal by, 13.19–13.20
 pH adjustment in, 13.21
 process variations facilitating lime recovery in, 13.50–13.52
 process variations for, 13.29–13.30, 13.30f.
 radionuclides removed by, 13.72, 13.73f.
 rapid mixing and, 13.56
 recarbonation of, 13.21–13.22
 recirculation and, 13.53–13.54
 silica removed by, 13.72, 13.73f.
 with sodium hydroxide, 13.20
 split-treatment softening, 13.47–13.50
 stoichiometry basis for dose estimates of, 13.23–13.24
 straight, 13.30–13.31
 straight lime-soda softening, 13.30f., 13.31–13.34
 three-stage, 13.51
 TOC removal by, 13.65–13.69, 13.65f., 13.68t., 13.69f.
 two-stage, 13.46–13.47, 13.51
- Limestone contactors, 20.75
- Limiting current density, 11.51–11.52

 TOC removal by, 13.64–13.69, 13.65f.,
 13.69f.
- Precoat filtration, 10.2, 10.87–10.88
 advantages of, 10.88–10.89
 applications of, 10.88–10.89
 body feed and, 10.87, 10.92
 body feed concentration and, 10.93–10.94,
 10.94f.
Cryptosporidium removal with, 10.88–10.89
 disadvantages of, 10.89
 filter elements in, 10.87, 10.89, 10.90f.–10.91f.
 filter media in, 10.91–10.92
 filtration rate effecting, 10.94
Giardia lamblia removal with, 10.88–10.89
 grades of filter media for, 10.88
 mathematical model for, 10.94–10.95
 performance of, 10.88–10.89
 precoating in, 10.92, 10.92f.
 pressure filter vessels in, 10.91, 10.91f.
 schematic of, 10.88f.
 septum in, 10.87, 10.89, 10.90f.
 spent cake removal in, 10.92–10.93
 SWTR and, 10.87
 theoretical aspects of, 10.93–10.95
 vacuum filter vessels in, 10.90–10.91
- Prehydrolyzed metal salts, 8.20–8.21
- Premix clarifiers, 9.32–9.33
- Premix-recirculation clarifiers, 9.32–9.33, 9.33f.
- Pressure
 equilibrium constant and effects of, 3.9, 6.5
 low/negative-pressure transients in
 distribution systems, 21.30
 membrane processes and low, 22.43–22.47
 packed towers and drop in, 6.26f.
- Pressure filtration, 10.3
 applications of, 10.76
 configuration of, 10.74–10.75, 10.74f.
Cryptosporidium and *Giardia lamblia*
 removal by, 10.8
 gravity filters compared with,
 10.75–10.76
 operation of, 10.75
 rate control of, 10.75–10.76
 in small water systems, 10.76
- Pressure flotation, 9.46
- Primary coagulant polymers, 8.46
- Probability density functions (PDFs),
 16.21–16.22, 16.22f.
- Process integrity monitoring, 11.36
- Prometon, 2.52–2.53
- Protozoa, 2.15–2.18. *See also Cryptosporidium*;
Giardia lamblia
Acanthamoeba, 2.17–2.18
Cyclospora, 2.17
Entamoeba histolytica, 2.16–2.17
 free-living, 2.17–2.18, 2.18
Isospora, 2.16
Naegleria fowleri, 2.17
 parasitic, 2.15–2.17
Toxoplasma, 2.16
Pseudomonas aeruginosa, 21.10–21.12
- Public Notification Rule, 1.31–1.32
- pX notation, 3.3, 3.4t.
- Quantum yield, 18.20–18.21, 18.21t.
- Quaternary amines, 8.46
- Quats, 12.10
- Radical reactions, 7.12–7.13, 7.13t.
- Radioactive residuals, 22.66–22.69,
 22.67t.–22.69t.
 characterization of, 22.67, 22.68t.
 disposal options for, 22.69, 22.69t.
 regulations for, 22.68
- Radionuclides
 health effects of, 2.70–2.71
 lime softening removing, 13.72, 13.73f.
 particle types of, 2.69
 radium, 2.71
 radon, 2.72
 standards for, 2.71
 uranium, 2.72
- Radium, 2.71
 IX removal of uranium combined with,
 12.72–12.73
 IX removing, 12.34–12.35

- Radon, 2.72
 regulations, 1.19
- Rainwater, 3.28–3.29, 3.28t.
- Rapid granular bed filtration
 air binding in, 10.49
 air scour delivery systems in, 10.56
 air-scour assisted backwashing of, 10.54t.,
 10.55–10.57
 available head loss in, 10.11
 backwash in, 10.11
 backwash water and air scour flow rates in,
 10.56–10.57, 10.57t.
 backwashing and expansion of filter bed in,
 10.60–10.62
 backwashing methods for, 10.53–10.57,
 10.54t.
 backwashing troughs in, 10.57
 backwashing wash water required for,
 10.57–10.58
 bed depth and media size in, 10.18
 Brownian diffusion, 10.31
 configurations for, 10.15–10.21, 10.16f.
 continuous turbidity monitoring and, 10.43,
 10.44f.
Cryptosporidium and, 10.22
 diffusion mechanism in, 10.31–10.32, 10.31f.
 dirty filter, restarting, and, 10.45–10.46
 dirty filter media and, 10.66–10.68
 dirty filter rate increases and, 10.45, 10.46f.
 dual-media filters in, 10.18–10.20
 effluent quality pattern in, 10.39–10.40,
 10.40f.
 fabricated self-supporting underdrain system
 for, 10.24
 false-floor underdrain with nozzles for, 10.25,
 10.25f.
 filter cycle, 10.11
 filter run in, 10.11
 filtering-to-waste in, 10.41–10.42
 filtration rates and, 10.21–10.22
 GAC in, 10.20–10.21
Giardia lamblia and, 10.22
 grain sizes in, 10.16–10.17, 10.17t.
 gross production per filter run in,
 10.23–10.24, 10.23f.
 head loss development in, 10.46–10.48,
 10.47f.–10.48f.
 initial performance of, 10.40–10.41, 10.41f.
 interception mechanism in, 10.31–10.32,
 10.31f.
 intermixing of adjacent layers during
 backwashing in, 10.63
- Rapid granular bed filtration (*Cont.*):
 macroscopic (phenomenological) approach
 to, 10.29–10.31
 manifold-lateral underdrain system, 10.24,
 10.24f.
 media properties in, 10.12–10.15, 10.14t.
 media types in, 10.11
 microscopic (fundamental) approach to,
 10.31–10.35
 microscopic/macrosopic models combined
 for dirty media in, 10.36
 mineral deposits and, 10.66–10.68
 models for, 10.26–10.39
 movement of gravel during backwashing in,
 10.64–10.65, 10.65f.
 mudballs and, 10.65f., 10.66
 negative head effects in, 10.49, 10.49f.
 particle size for removal efficiency in,
 10.32–10.35, 10.33f.–10.34f.
 particle-counting instruments and, 10.43, 10.44f.
 performance of, 10.9, 10.10f., 10.11
 polymers aiding, 10.21
 pre-treatment coagulation for, 10.43–10.45,
 10.44f.
 run length in, 10.23–10.24, 10.23f.
 schematic of, 10.9f.–10.10f.
 sedimentation mechanism in, 10.31–10.32,
 10.31f.
 single collector efficiency in, 10.32, 10.33t.
 single-media filters in, 10.18–10.20
 skimming during backwashing in,
 10.62–10.63
 steady state period in, 10.42
 stratification during backwashing in,
 10.62–10.63
 support gravel in, 10.26
 surface wash plus fluidized-bed backwash in,
 10.54–10.55
 terminal head loss in, 10.11
 transport mechanisms for, 10.31–10.32,
 10.31f.
 triple-media filters in, 10.19–10.20
 UFRV in, 10.23–10.24, 10.23f.
 underdrain failures in, 10.65–10.66
 underdrain systems in, 10.24–10.26
 upflow filter in, 10.15–10.16
 upflow wash with full fluidization in,
 10.53–10.54
- Rapid mixing, 5.8. *See also* Flocculation
 jar tests for, 8.64–8.66
 lime softening and, 13.56
 purpose of, 8.50

- Treatment systems. *See* Natural treatment systems
- Triazine herbicides, 2.52–2.53
- Trichloroacetic acid (TCA), 2.68
 packed towers calculating, 6.29–6.36
- Trichloroethane, 2.49
- 1,1,1-Trichloroethane, 2.48–2.49
- Trichloroethylene (TCE), 2.49
- Trihalomethanes (THMs), 2.44–2.45, 2.59,
 2.66–2.67, 19.7–19.8
 adsorption of, 14.53
 ammonia's impact on formation of, 19.38,
 19.38f.
 bromide reactions with, 19.20–19.22, 19.20f.
 bromine/iodine and, 19.21–19.22, 19.21f.–
 19.22f.
 discovery of, 1.4
 haloform reaction and, 7.14–7.15, 7.15f.
 in IPR, 16.15
 reaction time and, 19.16–19.17, 19.16f.
 regulations for, 19.45–19.46
 spatial temporal variability of, 19.46
 stability of, 19.43–19.45, 19.44f.
 TOC and formation potential of, 19.24
 TTHM Rule, 1.4
 UV controlling precursors to, 19.30–19.31,
 19.31f.
- TTF test. *See* Time to filter test
- TTHM Rule. *See* Total Trihalomethanes Rule
- Tuberculation, 20.4, 20.8
- Turbidimeter, 8.4
- Turbidity
 aesthetic concerns with, 2.74–2.75
 DAF and, 9.83–9.84, 9.84f.
 direct filtration and effluent, 10.73
 flocculation, 8.66–8.67, 8.67f.
 GAC reducing, 14.57–14.58
 as indicator, 2.22–2.23
 in natural treatment systems, 15.15–15.16
 of particles, 3.49, 3.50f., 8.4–8.5
 rapid granular bed filtration and continuous
 monitoring of, 10.43, 10.44f.
 of raw waters, 9.41
- Turbulent transport, 8.52–8.53
- UDF. *See* Unidirectional flushing
- UF. *See* Ultrafiltration
- UFRV. *See* Unit filter run volume
- Ultrafiltration (UF), 5.13–5.15, 11.2, 16.5
 coagulants removing arsenic with, 11.61,
 11.61f.
 coagulation, flocculation, sedimentation
 integration with, 11.58–11.60,
 11.58f.–11.59f.
 configuration of, 11.12–11.15,
 11.15f.–11.17f., 11.17t.
 crossflow operation in, 11.13, 11.14f.
Cryptosporidium removed by, 11.33–11.34,
 11.33f.
 dead end operation in, 11.13, 11.14f.
 floc-blanket reactor-PAC-UF process,
 14.80–14.81, 14.80f.
 flow patterns of, 11.13, 11.14f.–11.15f., 11.15
Giardia lamblia removed by, 11.33–11.34,
 11.33f.
 mechanical sieving in, 11.44–11.45
 MF integrated process design/applications
 with, 11.57–11.65
 NF/RO/EDR integration with, 11.59–11.60,
 11.59f.
 oxidation reactions integrated with,
 11.60–11.61, 11.60f.
 PAC with, 14.80
 pilot plant testing for, 11.95
 process residuals of, 11.91–11.92
 residuals removed by, 22.3–22.4
 seawater RO integrated with, 11.61–11.62
 uses of, 11.4, 11.8

- Ultraviolet light (UV). *See also* UV disinfection;
 UV photolysis
 absorbance of, 18.14
 Beer-Lambert law and, 18.7–18.8
 bench-scale testing for, 18.8–18.9
 biosimetry test for, 18.9–18.10, 18.9f.
 collimated beam and, 18.8–18.9, 18.8f.
 DBPs and, 19.4t.–19.6t., 19.14–19.15
