Water Quality & Treatment

A Handbook on Drinking Water

James K. Edzwald, Editor

American Water Works
Association

WATER QUALITY & TREATMENT

ABOUT THE AMERICAN WATER WORKS ASSOCIATION

American Water Works Association is the authoritative resource for knowledge, information, and advocacy to improve the quality and supply of water in North America and beyond. AWWA is the largest organization of water professionals in the world. AWWA advances public health, safety, and welfare by uniting the efforts of the full spectrum of the entire water community. Through our collective strength we become better stewards of water for the greatest good of the people and the environment.

McGraw-Hill's
AccessEngineering
 Authoritative content · Immediate solutions

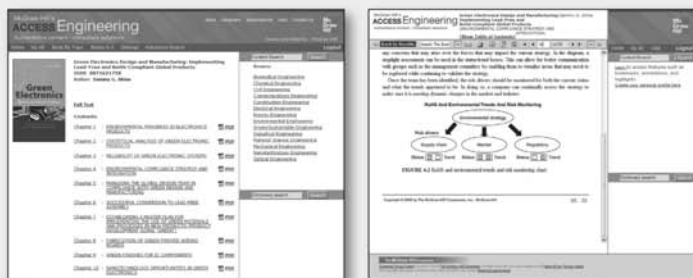

AccessEngineering offers the complete contents of hundreds of outstanding McGraw-Hill books, including *Marks' Standard Handbook for Mechanical Engineers*, *Perry's Chemical Engineers' Handbook*, and *Roark's Formulas for Stress and Strain*, with new books added biweekly. This dynamic source of world-renowned engineering content supports all levels of scientific and technical research in the corporate, industrial, government, and academic sectors.

Focused around 14 major areas of engineering, **AccessEngineering** offers comprehensive coverage and fast title-by-title access to our engineering collection in the following subject areas:

- / Biomedical
- / Chemical
- / Civil
- / Communications
- / Construction
- / Electrical
- / Energy
- / Environmental
- / Green/Sustainable
- / Industrial
- / Material Science
- / Mechanical
- / Nanotechnology
- / Optical

In addition, sophisticated personalization tools allow content to be easily integrated into user workflow. A science and engineering dictionary containing more than 18,000 terms is included in a fully searchable, taxonomically organized database.

ABOUT THE EDITOR

James K. Edzwald is Professor Emeritus of the Department of Civil and Environmental Engineering at the University of Massachusetts, Amherst. He earned his B.S. and M.S. degrees in Civil Engineering and Environmental Health Engineering from the University of Maryland, and a Ph.D. in Water Resources Engineering from the University of North Carolina, Chapel Hill. He also held faculty positions at the University of Missouri, Clarkson University, and Rensselaer Polytechnic Institute. His research interests include water supply, drinking water treatment, and aquatic chemistry. Professor Edzwald has authored or coauthored over 150 publications on water quality and treatment. He is a recipient of the 2004 A.P. Black Award from AWWA for his contributions in water supply research and a recipient of the 2009 Founders' Award from the Association of Environmental Engineering and Science Professors for his contributions to environmental engineering education and practice. He is a registered professional engineer in New York.

Chapter 1. Drinking Water Standards, Regulations, and Goals

J. Alan Roberson, PE., and Eric G. Burneson, PE.

1.1

Regulatory History Prior to the 1974 SDWA	/ 1.2
Evolution of the SDWA	/ 1.3
The Risk Management and Standard-Setting Processes	/ 1.8
Current Drinking Water Regulations	/ 1.19
Role of State Agencies	/ 1.26
Peer Review, Outside Consultation, and Public Involvement	/ 1.30
Other Countries and International Standards	/ 1.32
Outlook for the Future	/ 1.33
The Internet as a Resource	/ 1.34
Disclaimer	/ 1.35
Abbreviations	/ 1.35
References	/ 1.37

Chapter 2. Health and Aesthetic Aspects of Drinking Water

*Gloria B. Post, Ph.D., D.A.B.T., Thomas B. Atherholt, Ph.D.,
and Perry D. Cohn, Ph.D., M.P.H.*

2.1

Waterborne Disease	/ 2.3
Pathogenic Organisms	/ 2.6
Indicators of Water Quality	/ 2.19
Toxicological Evaluation of Drinking Water Contaminants	/ 2.23
Risk Assessment of Drinking Water Contaminants	/ 2.27
Inorganic Constituents	/ 2.33
Organic Constituents	/ 2.44
Disinfectants and Disinfection By-Products	/ 2.59
Radionuclides	/ 2.69
Aesthetic Quality	/ 2.72
Preparedness and Health	/ 2.75
Final Comment	/ 2.76
Internet Resources	/ 2.76
Abbreviations	/ 2.77
Acknowledgments	/ 2.78
References	/ 2.79

Chapter 3. Chemical Principles, Source Water Composition, and Watershed Protection *James K. Edzwald, Ph.D., B.C.E.E., and John E. Tobiason, Ph.D., B.C.E.E.* **3.1**

Introduction	/	3.2
Chemical Principles and Concepts	/	3.2
Source Water Composition	/	3.24
Particles	/	3.42
Natural Organic Matter	/	3.58
Source Water Selection and Protection	/	3.67
Abbreviations	/	3.71
Notation for Equations	/	3.72
References	/	3.72

Chapter 4. Hydraulic Characteristics of Water Treatment Reactors and Their Effects on Treatment Efficiency *Desmond F. Lawler, Ph.D., PE.* **4.1**

Introduction	/	4.2
Continuous Flow Reactors: Ideal and Non-Ideal Flow	/	4.2
Tracer Studies	/	4.3
Choosing a Step or Pulse Input Tracer Test	/	4.11
Mathematical Models for Non-Ideal Flow	/	4.16
Computational Fluid Dynamics	/	4.24
Reaction Rate Expressions	/	4.26
Reactions in Continuous Flow Systems at Steady State: Combining Hydraulics and Reaction Kinetics	/	4.33
Reactors in Water Treatment and Their Hydraulics Characteristics	/	4.43
Summary	/	4.47
Abbreviations	/	4.47
Notation for Equations	/	4.47
References	/	4.49

Chapter 5. Overview of Water Treatment Processes *Doug Elder, P.E., and George C. Budd, Ph.D., PE.* **5.1**

Introduction	/	5.2
Source Water Quality Considerations (Chap. 3)	/	5.2
Characteristics and General Capabilities of Unit Processes	/	5.4
Distribution System Considerations (Chaps. 19–21)	/	5.25
Treatment Process Residuals Management (Chap. 22)	/	5.27
Other Considerations	/	5.28
Treatment Process Configurations	/	5.29
Abbreviations	/	5.36
References	/	5.38

Chapter 6. Gas–Liquid Processes: Principles and Applications *David W. Hand, Ph.D., David R. Hokanson, M.S., P.E., and John C. Crittenden, Ph.D., P.E., D.E.E., N.A.E.* **6.1**

Introduction	/	6.1
Theory of Gas Transfer	/	6.2
Packed Towers	/	6.14
Diffused or Bubble Aeration	/	6.41

Surface Aeration / 6.52
 Spray Aerators / 6.56
 Notation for Equations / 6.61
 References / 6.63

Chapter 7. Chemical Oxidation *Philip C. Singer, Ph.D., P.E., B.C.E.E., and David A. Reckhow, Ph.D.* 7.1

Introduction / 7.1
 Principles of Oxidation / 7.2
 Oxidants Used in Water Treatment / 7.15
 Applications of Oxidation Processes to Water Treatment Processes / 7.31
 Abbreviations / 7.47
 Notations for Equations / 7.48
 References / 7.48

Chapter 8. Coagulation and Flocculation *Raymond D. Letterman, Ph.D., P.E., and Sotira Yiacoumi, Ph.D.* 8.1

Introduction / 8.2
 Contaminants / 8.3
 Stability of Particle Suspensions / 8.6
 Destabilization Mechanisms / 8.14
 Coagulants / 8.15
 The Rapid Mixing and Flocculation Processes / 8.50
 Abbreviations / 8.71
 Equation Notation / 8.71
 References / 8.72

Chapter 9. Sedimentation and Flotation *Ross Gregory, MPhil, C.Eng., C.WEM, and James K. Edzwald, Ph.D., B.C.E.E.* 9.1

Modern History of Sedimentation / 9.2
 Sedimentation Theory / 9.3
 Operational and Design Considerations for Sedimentation / 9.26
 Introduction to Dissolved Air Flotation / 9.45
 Fundamentals of Dissolved Air Flotation / 9.48
 Operational and Design Considerations for Flotation / 9.65
 Applications / 9.84
 Abbreviations / 9.89
 Notation for Equations / 9.89
 References / 9.92

Chapter 10. Granular Media Filtration *John E. Tobiason, Ph.D., P.E., B.C.E.E., John L. Cleasby, Ph.D., P.E., B.C.E.E., Gary S. Logsdon, D.Sc., P.E., B.C.E.E., and Charles R. O'Melia, Ph.D., P.E.* 10.1

Overview of Particle Filtration Processes / 10.2
 Granular Media Filtration Process Description / 10.9
 Media Filtration Theory and Modeling / 10.26

Rapid-Rate Filter Performance /	10.39
Flow Control in Filtration /	10.49
Backwashing and Maintenance of Filter Media /	10.53
Direct Filtration /	10.70
Pressure Granular Bed Filters /	10.74
Slow Sand Filtration /	10.76
Precoat Filtration /	10.87
Dedication /	10.95
Abbreviations /	10.95
Equation Notation /	10.96
References /	10.97

Chapter 11. Membranes *Steven J. Duranceau, Ph.D., P.E., and James S. Taylor, Ph.D., P.E.*

11.1

Size Ranges for Membrane Processes /	11.4
Classifications and Configurations of Membrane Processes /	11.9
RO-NF Configuration /	11.18
Membrane Properties and Rejection Characteristics /	11.26
Bubble-Point Direct Testing /	11.35
Mass Transport and Separation /	11.37
Integrated MF and UF Process Applications and Process Design /	11.57
NF and RO Process Concepts and Design Criteria /	11.65
Residuals Disposal and Concentrate Management /	11.91
Pilot Plant Testing /	11.94
Abbreviations /	11.96
Notation for Equations /	11.98
References /	11.99

Chapter 12. Ion Exchange and Adsorption of Inorganic Contaminants *Dennis Clifford, Ph.D., P.E., B.C.E.E., Thomas J. Sorg, P.E., B.C.E.E., and Ganesh L. Ghurye, Ph.D., P.E., B.C.E.E.*

12.1

Overview /	12.2
Introduction and Theory of Ion Exchange /	12.2
Applications of IX and Adsorption /	12.27
IX Modeling Using EMCT /	12.74
Waste Disposal /	12.82
Summary /	12.82
Abbreviations /	12.87
Notation for Equations /	12.89
References /	12.90

Chapter 13. Precipitation, Coprecipitation, and Precipitative Softening *Stephen J. Randtke, Ph.D., P.E.*

13.1

Introduction /	13.1
Principles /	13.2
Precipitative Softening /	13.12
Other Applications /	13.70
Acknowledgments /	13.74
Abbreviations /	13.74
Notation for Equations /	13.75
References /	13.76

Chapter 14. Adsorption of Organic Compounds by Activated Carbon *R. Scott Summers, Ph.D., Detlef R. U. Knappe, Ph.D., and Vernon L. Snoeyink, Ph.D.* **14.1**

Adsorption Overview / 14.2
 Adsorbent Characteristics / 14.4
 Adsorption Theory / 14.8
 GAC Adsorption Systems / 14.37
 Performance of GAC Systems / 14.39
 GAC Performance Estimation / 14.59
 Powdered Activated Carbon (PAC) Adsorption / 14.77
 Thermal Reactivation of GAC / 14.85
 Adsorption of Organic Matter by Other Adsorbents / 14.87
 Abbreviations / 14.89
 Notation for Equations / 14.91
 References / 14.91

Chapter 15. Natural Treatment Systems *Saroj K. Sharma, Ph.D. and Gary Amy, Ph.D.* **15.1**

Introduction / 15.2
 River (RBF) and Lake (LBF) Bank Filtration / 15.3
 Artificial Recharge and Recovery (ARR) / 15.7
 Subsurface Groundwater Treatment / 15.10
 Soil Aquifer Treatment (SAT) for Indirect Potable Reuse / 15.12
 Water Quality Improvements in Natural Treatment Systems / 15.15
 Design and Operation of Natural Water Treatment Systems / 15.20
 Selected Case Studies of Natural Treatment Systems / 15.23
 Abbreviations / 15.28
 References / 15.29

Chapter 16. Water Reuse for Drinking Water Augmentation *Jörg E. Drewes, Ph.D., and Stuart J. Khan, Ph.D.* **16.1**

Introduction to Potable Reuse / 16.2
 Source Water Characteristics / 16.5
 System Reliability and Health Risk Considerations / 16.17
 Design of Potable Reuse Schemes / 16.23
 Monitoring Strategies for Process Performance and Compliance / 16.33
 Regulations and Guidelines for Drinking Water Augmentation / 16.36
 Public Perception to Indirect Potable Reuse / 16.39
 Abbreviations / 16.42
 References / 16.43

Chapter 17. Chemical Disinfection *Charles N. Haas, Ph.D.* **17.1**

Introduction / 17.1
 History of Disinfection / 17.3
 Regulatory Issues for Disinfection / 17.4
 Disinfectants and Theory of Disinfection / 17.5
 Assessment of Microbial Quality (Indicators) / 17.19
 Disinfection Kinetics / 17.21
 Mode of Action of Disinfectants / 17.27

Disinfectant Residuals for Posttreatment Protection	/ 17.30
Design and Application of Technologies	/ 17.31
Relative Comparisons	/ 17.41
Abbreviations	/ 17.42
Notation for Equations	/ 17.43
References	/ 17.43

Chapter 18. Ultraviolet Light Processes *Karl G. Linden, Ph.D., and Erik J. Rosenfeldt, Ph.D., PE.*

18.1

Introduction to Ultraviolet Light Processes	/ 18.1
Fundamentals of UV Light	/ 18.4
UV Disinfection	/ 18.10
UV Photolysis	/ 18.17
UV Advanced Oxidation Processes (AOPS)	/ 18.24
Abbreviations	/ 18.34
Notation for Equations	/ 18.36
References	/ 18.36

Chapter 19. Formation and Control of Disinfection By-Products *David A. Reckhow, Ph.D., and Philip C. Singer, Ph.D., PE., B.C.E.E.*

19.1

Introduction	/ 19.1
Formation of Disinfection (and Oxidation) By-Products	/ 19.2
Control of Oxidation/Disinfection By-Products	/ 19.27
Disinfection By-Products in the Distribution System	/ 19.43
Abbreviations	/ 19.46
References	/ 19.48

Chapter 20. Internal Corrosion and Deposition Control *Michael R. Schock and Darren A. Lytle*

20.1

Introduction	/ 20.2
Corrosion, Passivation, and Immunity	/ 20.3
Physical Factors Affecting Corrosion and Metals Release	/ 20.20
Chemical Factors Affecting Corrosion	/ 20.25
Corrosion of Specific Materials	/ 20.40
Direct Methods for the Assessment of Corrosion	/ 20.66
Corrosion Control Alternatives	/ 20.73
Water Sampling for Corrosion Control	/ 20.77
Acknowledgments	/ 20.81
Disclaimer	/ 20.82
Abbreviations	/ 20.82
Notation for Equations	/ 20.82
References	/ 20.83

Chapter 21. Microbiological Quality Control in Distribution Systems *Mark W. LeChevallier, Ph.D., Marie-Claude Besner, Ph.D., Melinda Friedman, PE., and Vanessa L. Speight, Ph.D., PE.*

21.1

Microbial Risks from Distribution System Contamination	/ 21.2
Microbes in Distribution Systems	/ 21.7

Factors Contributing to Microbial Occurrences in Distribution Systems /	21.21
Monitoring Distribution Systems /	21.34
Engineering and Design of Distribution Systems /	21.43
Controlling Microbial Occurrences in Distribution Systems /	21.47
Final Comments /	21.65
Abbreviations /	21.66
References /	21.67

Chapter 22. Water Treatment Plant Residuals Management

David A. Cornwell, Ph.D., P.E., B.C.E.E., and Damon K. Roth, P.E.

22.1

Introduction /	22.2
Coagulation and Lime-Softening Residuals /	22.4
Thickening /	22.16
Non-Mechanical Dewatering /	22.21
Mechanical Dewatering /	22.29
Spent Filter Backwash Treatment /	22.37
Recycle /	22.40
Membrane Residuals /	22.43
Ion Exchange and Inorganic Adsorption Process Residuals /	22.54
Residuals Containing Arsenic /	22.62
Residuals Containing Radioactivity /	22.66
Ultimate Disposal and Utilization of Solids /	22.70
Abbreviations /	22.75
Notation for Equations /	22.76
References /	22.77

PREFACE

This sixth edition of *Water Quality & Treatment: A Handbook on Drinking Water* serves as a handbook for scientists, engineers, and other professionals who study and work in drinking water—particularly the quality of water supplies, the quality of treated drinking water, and water treatment processes. It is meant as a resource for those in academics (professors and students), consulting engineering practice, water utilities, federal and state regulatory agencies, and the water process and chemical industries. The book emphasizes principles (theory) and applications (practice). It serves as a companion to the book on design, AWWA-ASCE, *Water Treatment Plant Design* (the fifth edition is in preparation, with expected publication in late 2011).

This book is an activity of the American Water Works Association's (AWWA's) Water Quality and Technology Division (WQTD). James K. Edzwald served as the technical editor and worked with the authors of the chapters in preparing the book. An ad hoc committee of the WQTD consisting of James P. Malley, Jr., Marilyn M. Marshall, and Dixie Fanning provided advice to the technical editor throughout the preparation of this book.

Water Quality & Treatment, sixth edition, differs greatly from the fifth edition—published in 1999; it contains significant revisions, updating of material, and new chapters. Five new chapters expand the scope of this book: Chapter 4, “Hydraulic Characteristics of Water Treatment Reactors and Their Effects on Treatment Efficiency,” Chapter 15, “Natural Treatment Systems,” Chapter 16, “Water Reuse for Drinking Water Augmentation,” Chapter 18, “Ultraviolet Light Processes,” and Chapter 19, “Formation and Control of Disinfection By-Products.” A sixth chapter, Chapter 3, “Chemical Principles, Source Water Composition, and Watershed Protection,” replaces one from the fifth edition on source water quality management, and it is essentially another new chapter in that it contains new material on chemical principles and additional material on source water quality.

Since publication of the fifth edition, the drinking water field has faced new regulations and concerns about the health effects of some new and previously known contaminants. Furthermore, in the last 10 years we have seen the development of new technologies and refinements of older technologies that are now covered in this edition. The sixth edition covers the health effects and treatment technologies to remove some contaminants not covered previously, such as nanoparticles, endocrine disrupting compounds, and pathogens; it contains updated material on many other contaminants, such as disinfection by-products, arsenic, and pathogens, including viruses and protozoan cysts such as *Cryptosporidium*; and it addresses subjects not adequately covered in the prior edition, such as water reuse, ultraviolet light processes, and natural treatment systems.

Several other new features are notable in this sixth edition. The International System of Units (SI) is used with U.S. units in parenthesis where appropriate. This makes the book useful to professionals outside the United States and to those within the United States working on water projects around the world. Each chapter has its own table of contents to aid readers in finding subject matter within chapters. Four new appendices provide quick references for atomic numbers and masses, physical and chemical constants, unit conversion factors, and the physical properties of water and gases.

The book is organized beginning with five foundation chapters that contain material on drinking water standards and regulations (Chap. 1); health effects (Chap. 2); chemical principles, source water composition, and watershed protection (Chap. 3);

hydraulics of treatment processes (Chap. 4); and an overview of water treatment processes (Chap. 5). This is followed by coverage of various water treatment processes in Chapters 6 through 14 that present principles and applications of the removal of various contaminants from water supplies. Chapter 15 covers natural treatment systems such as river bank filtration, and Chapter 16 deals with water reuse. Chapters 17 and 18 follow with disinfection and ultraviolet light processes, including disinfection and advanced oxidation processes. Chapters 19, 20, and 21 cover disinfection by-products, corrosion, and microbiological quality in distribution systems, respectively. Chapter 22 ends the book with the properties, treatment, and management of water treatment residuals.

James K. Edzwald

Editor

Professor Emeritus, University of Massachusetts

James P. Malley, Jr.

Chairman of the Board of Trustees, AWWA Water Quality and Technology Division

Professor, University of New Hampshire

ACKNOWLEDGMENTS

The sixth edition of *Water Quality & Treatment: A Handbook on Drinking Water* is a valuable resource for the drinking water field that is made possible through the efforts of many people. First and foremost, the quality of the book is due to the efforts of the 45 authors who prepared 22 chapters in the book.

Revision of the book began with an assessment of the fifth edition. Several professionals from water utilities, consulting engineering firms, and academics were asked to review the fifth edition and to make recommendations for new material for inclusion in the sixth edition. I wish to thank the following: William C. Becker (Hazen and Sawyer), William D. Bellamy (CH2M Hill), Steve Bishop (Metcalf and Eddy), Howard Dunn (Vice President of Operations and Technology, Aquarion Water Company of Connecticut), Harold T. Glaser (Kennedy Jenks), Raymond D. Letterman, (Syracuse University and Technical Editor of the fifth edition), Michael J. MacPhee (Malcolm Pirnie), Charles R. O'Melia (Johns Hopkins University), Vernon L. Snoeyink (University of Illinois), and John P. Walsh (formerly, Director of Operations and Distribution, Aquarion Water Company of Connecticut, now with Environmental Partners Group).

I am grateful to the reviewers who commented on draft chapters and provided comments for the authors for improving their chapters. They are Robert Andrews, Brian Arbuckle, Takashi Asano, Khalil Z. Atasi, Benoit Barbeau, William Ball, Tim Bartrand, William Becker, Ernest Blatchley III, James Bolton, Anne Camper, Sarah Clark, Joseph Cotruvo, James Crook, Brian Dempsey, Francis DiGiano, Bruce Dorvak, Jörg E. Drewes, Nicholas Dugan, Marc Edwards, Doug Elder, Tom Gillogly, Thomas Grischek, Johannes Haarhoff, Robert Howd, Kerry Howe, Michael Kavanaugh, William Knocke, Yann Le Gouellec, France Lemieux, Gary Logsdon, Michael J McGuire, James P. Malley, Jr., Margaret H. Nellor, Eva C. Nieminski, John Novak, David Pernitsky, David Reckhow, Michael Semmens, Sukalyan Sengupta, Robert Sharp, Jim Taft, Ian Watson, Paul Westerhoff, and Yuefeng Xie.

This book project was initiated by James P. Malley, Jr., Marilyn, M. Marshall, and Dixie Fanning, members of the ad hoc committee representing the Water Quality and Technology Division of AWWA. Their advice was invaluable, and I thank them. I am particularly indebted to Jim Malley for his leadership. He was also always there to give advice and help me over the hurdles. Finally, I thank the staff with AWWA Publications and with McGraw-Hill for their work in producing the book. A special thanks goes to Gay Porter De Nileon, AWWA Publications Manager, who provided essential support from AWWA; without her assistance the book could not have been completed.

The initial Safe Drinking Water Act (SDWA) was signed into law on Dec. 16, 1974 (PL 93-523). The 1974 SDWA established the national regulatory structure by which the U.S. Environmental Protection Agency (USEPA), state and local regulatory agencies, and water utilities work together to ensure safe drinking water. This chapter presents the history of drinking water regulations leading to the 1974 SDWA, subsequent SDWA amendments in 1986 and 1996, and the history of the drinking water regulations that resulted from the 1974 SDWA and the 1986 and 1996 amendments. The current risk management and standard-setting processes are discussed, along with the roles of the states and the public in the standard-setting process. Standards developed at the state level, as well as international standards, are also discussed.

REGULATORY HISTORY PRIOR TO THE 1974 SDWA

Early History

Protection of drinking water quality goes back several hundred years. Scientific and medical advances in the 1800s, along with the need to provide basic sanitation in the rapidly urbanizing cities, laid the foundation for today's drinking water field. Philadelphia was one of the first cities in the United States to provide piped drinking water; drinking water first flowed through mains of the Philadelphia Water Department in 1801 (Philly H₂O, 2008).

Connecting disease epidemics with centralized water systems was a major step in public health protection (McGuire, 2006). As part of the major cholera outbreak in London and the investigation into the area surrounding the Broad Street Pump in 1854, Dr. John Snow concluded that cholera was a waterborne disease. He removed the pump handle and no further epidemics occurred in the area surrounding that well. At that point, safe drinking water and basic sanitation started to become part of basic public health protection (Johnson, 2006). The Centers for Disease Control and Prevention (CDC) has recognized conventional drinking water treatment, i.e., the traditional multibarrier approach of using the best available source, treating the water appropriately by using filtration and disinfection, and maintaining distribution system integrity, as one of the 10 great public health improvements of the twentieth century (under the umbrella of infectious disease control) (CDC, 1999).

The first federal action taken regarding drinking water quality was passage of the Interstate Quarantine Act in 1893 (U.S. Statutes, 1893). This legislation gave the Surgeon

General of the U.S. Public Health Service (USPHS) the authority to develop and enforce regulations to prevent the introduction and transmission of communicable diseases. Interstate quarantine regulations followed the next year.

The first national drinking water regulation was adopted in 1912, a result of the nation's growing railroad network, and prohibited the use of the "common cup" on interstate train carriers (Roberson, 2006). Bringing the interstate transport challenges into current times for airlines, USEPA conducted a stakeholder effort in 2006–2007 to develop and aircraft drinking water rule. As a result of this effort, USEPA finalized a regulation for drinking water on aircraft (USEPA, 2009a).

The U.S. Public Health Standards

The "common cup" regulatory framework was soon found to be deficient, as the "common cup" regulation could only protect public health if the water placed in the cup was safe. The task of developing these standards fell to the USPHS, which at that time was an agency within the U.S. Treasury Department. On Oct. 14, 1914, the Secretary of the Treasury promulgated Standards for Purity of Drinking Water Supplied to the Public by Common Carriers in Interstate Commerce, the first national drinking water standards (AWWA, 1990). These standards, known as the "Treasury Standards," were limited to the bacteriological quality of the water.

Even though the Treasury Standards were legally binding on interstate carriers, many state and local governments adopted these standards as guidelines for their water systems. States used these standards to develop their own regulations and provided regulatory oversight for systems in their states. These standards were the start of federal, state, and local cooperation in protecting drinking water quality at the community level that continues to this day.

The Treasury Standards were revised in 1925 by the USPHS to strengthen the bacteriological quality requirements and to add basic physical and chemical standards (USPHS, 1925). These standards were revised again in 1942, 1946, and 1962 (USPHS, 1943, 1946, 1962). The 1962 standards were the most comprehensive, covering 28 constituents, and were used by all 50 states either as standards or guidelines. However, depending on the state regulations, these standards were not legally enforceable for many systems and were only legally binding for those systems that supplied water to the interstate carriers.

EVOLUTION OF THE SDWA

Setting the Stage for the SDWA

Public concern and media attention about the presence of contaminants in the environment continued to grow in the late 1960s and early 1970s. The modern environmental movement began at this time, and the public concern and media attention translated to pressure on the federal government to act. From a federal perspective, the government wanted to keep up to date with the newest scientific developments in drinking water research and incorporate the latest results into the USPHS standards.

In 1969, the USPHS Bureau of Water Hygiene started the Community Water System Survey (CWSS) in an effort to revisit the 1962 standards and conducted a review of water systems to determine how many met these standards. The USPHS surveyed approximately 1000 public water systems (PWSs) that, at the time, served approximately 12 percent of the population. Released in 1970, the survey results showed that 41 percent of the systems did not meet the 1962 guidelines (USPHS, 1970). Many systems were deficient in one or more

components of the multibarrier approach (source water protection, filtration, disinfection, and protecting the integrity of the distribution system).

Soon thereafter, drinking water researchers in both the United States and Europe were conducting their own surveys that began to raise public awareness. Analytical methods that allowed for better separation and quantification of organic chemicals had improved. A 1972 study of the Mississippi River, which supplies New Orleans, found 36 synthetic organic chemicals (SOCs) (USEPA, 1972). In addition, researchers in the United States and the Netherlands published their seminal work on disinfection by-products (DBPs) with the discovery of trihalomethanes (THMs) (Bellar et al., 1974; Rook, 1974).

Building on these scientific reports, several national media stories raised consumers' concern about drinking water safety and put pressure on Congress for legislative action. The initial congressional hearings on drinking water were held in 1971 and 1972. Like most major legislation, there was substantial debate on the best legislative approach, and more than one session of Congress was needed to pass the initial SDWA. After four years of work, Congress passed the first SDWA in November 1974, which was signed into law on Dec. 16, 1974 (PL 93-523).

The First 1974 SDWA

The 1974 SDWA established a partnership between the states and the federal government for the implementation of the drinking water program that continues to the present. This legislation dramatically changed the federal-state regulatory relationship. Under the SDWA, USEPA conducts the necessary research and analyses and establishes National Primary Drinking Water Regulations (NPDWRs). NPDWRs are legally enforceable standards that apply to PWSs, which are defined by the SDWA as having at least 15 service connections or regularly serving 25 residents. It should be noted that systems with fewer than 15 service connections and private wells are not covered by the SDWA and the resultant NPDWRs. These regulations protect public health by limiting the levels of contaminants in drinking water using maximum contaminant levels (MCL) or treatment techniques (TT) if analytical techniques are not economically or technologically feasible for the specific contaminant.

If individual states or American Indian tribal nations pass their own regulations that are at least as stringent as the federal regulations and have programs and enforcement authorities to ensure that PWSs within the state are in compliance with the regulations, USEPA will delegate primacy to the state or tribe. Currently, 49 states and 1 tribe have primacy and oversee PWSs (with some federal assistance and oversight).

PWSs have the ultimate responsibility for compliance with these regulations, including specific requirements for monitoring and reporting. Failure to meet any of these requirements can result in enforcement actions and, in some cases, penalties. Before the 1974 SDWA was passed, national drinking water standards were not enforceable, except for the coliform standard for interstate carriers, i.e., trains, airplanes, buses, and ships.

Soon after passage of the 1974 SDWA, USEPA published the first two national drinking water regulations (Table 1-1): the National Interim Primary Drinking Water Regulations (NIPDWRs), using the USPHS standards as the starting point; and the Total Trihalomethanes (TTHM) Rule. These two rules increased the number of regulated contaminants to 23 (Fig. 1-1).

The TTHM Rule was the first national primary drinking water regulation for which USEPA prepared detailed assessments of toxicology and health risk, occurrence and exposure, analytical methods, treatment technologies, and economic impacts. Many of the policies and procedures used to develop the economic analyses, occurrence estimates, and technologies and costs for the TTHM Rule formed the foundation of the current regulatory development process.

*FR – Federal Register

FIGURE 1-1 Number of regulated contaminants from 1976 through 2000. (Source: www.epa.gov/safewater/contaminants/pdfs/contam_timeline.pdf)

However, these analyses require a significant amount of data, and many complex technical and policy issues must be debated and resolved in order to complete these analyses. To effectively utilize taxpayer dollars and adhere to the SDWA goals, USEPA should target its drinking water research and regulatory development efforts on the contaminants that present the greatest health risk. Consequently, in 1983, USEPA, in collaboration with the Awwa Research Foundation (AwwaRF, now known as the Water Research Foundation), conducted a series of workshops with a variety of national drinking water experts to discuss the following questions (AwwaRF, 1983):

- What are the most important contaminants to regulate?
- Are there robust and reliable analytical methods for analyzing these contaminants?
- What are the health effects of these contaminants and what is the exposure?
- What treatment technologies work for these contaminants and what do these technologies cost?
- How would water utilities monitor and report compliance to the states?

Answering these questions with limited data for a large number of potential contaminants is not easy (these questions are still relevant today for drinking water risk management and regulatory development). After these workshops, USEPA continued to collect data on health effects, analytical methods, occurrence, and treatment technologies but did not issue any new national drinking water regulations until 1986.

The 1986 SDWA Amendments

Frustrated by USEPA's lack of regulatory progress (progress being defined as an increasing number of regulations), Congress amended the SDWA in 1986 (PL 99-339). The amendments placed USEPA on a "regulatory treadmill" with requirements to regulate a specific list of 83 contaminants in the first five years and then 25 new contaminants every three years thereafter. On the basis of these statutory requirements, the number of regulated contaminants would have exceeded 250 in 2007.

USEPA increased its regulatory development process in the late 1980s and early 1990s. Seven new NPDWRs were promulgated between 1986 and 1992 (see Table 1-1). These regulations increased the number of regulated contaminants to 84 (see Fig. 1-1). The number of regulated contaminants increased sharply in 1991 and 1992, and the financial burden for utilities to monitor these contaminants also increased substantially.

Despite its best efforts, USEPA was unable to meet multiple regulatory deadlines and was sued by the Bull Run Coalition (Bull Run Coalition v. Reilly, 1993). USEPA negotiated new regulatory deadlines, then missed those new deadlines, and had to renegotiate again. This process frustrated everyone involved in the regulatory development process, including:

- Water utilities, because they never knew when new regulations were coming out and did not know how to plan for capital investments for treatment improvements that would last 50 to 100 years
- USEPA, because it was continually being sued
- Congress, because statutory deadlines were continually being missed

Throughout the early 1990s, pressure increased to amend the SDWA and allow USEPA to jump off the regulatory treadmill and more appropriately focus its limited resources. Congress began holding hearings and debating potential SDWA amendments in the

103rd Congress in 1993 and 1994 and ultimately passed the 1996 SDWA Amendments (PL 104-208) in the 104th Congress.

The 1996 SDWA Amendments

The 1996 SDWA Amendments can be divided into the following areas:

- A new standard-setting process with specific statutory language on how to select contaminants for potential regulation and then how to set the regulation.
- Priority regulations with specific deadlines for contaminants such as arsenic, sulfate, and radon and the Microbial/Disinfection By-Product (M/DBP) cluster.
- New state programs for source water assessments, capacity development, operator certification, and a drinking water state revolving loan fund.
- New public information programs, such as the Consumer Confidence Report (CCR) for utilities, and revision of the Public Notification Regulation (PNR) by USEPA.

USEPA promulgated nine new or revised NPDWRs between 1998 and 2006 (see Table 1-1). These regulations increased the number of regulated contaminants to 91 (see Fig. 1-1). The nine NPDWRs promulgated by USEPA since the 1996 SDWA Amendments are primarily new or expanded treatment technique requirements. Therefore, although the number of contaminants with MCLs has not increased significantly, the complexity of the treatment techniques, i.e., the more complex turbidity requirements in the Interim and Long Term 1 Enhanced Surface Water Treatment Rules, and more advanced compliance treatment technologies, i.e., ion exchange for arsenic removal, have significantly increased costs for many PWSs.

The Bioterrorism Act of 2002

Prior to September 11, 2001, water security had not been a significant problem for water utilities and there were no legislative or regulatory requirements. After 9/11, Congress reacted to address security concerns for critical infrastructure (CI), with the water sector (both drinking water and wastewater) being one of the CI sectors. To address water security concerns, the SDWA was amended through the Public Health Security and Prevention Preparedness Act of 2002 (the Bioterrorism Act, PL 107-188). The legislation required water utilities serving more than 10,000 people to meet five new statutory requirements: (1) conduct a vulnerability assessment (VA); (2) submit the VA to USEPA (USEPA had statutory requirements to develop policies and procedures for protection of the VAs that were submitted); (3) certify to USEPA that the VA was properly conducted and met the requirements of the Bioterrorism Act; (4) conduct or revise the utility emergency response plan (ERP) based on the knowledge derived from the VA; and (5) certify to USEPA that the new or revised ERP has been completed.

Although not part of the SDWA, the Homeland Security Act (PL 107-296) was also passed in 2002 and created the Department of Homeland Security (DHS) by merging parts of 22 different federal agencies into one. DHS has the overall responsibility for homeland security, and USEPA has been designated as the lead agency for the water sector. DHS created an overall risk management framework for critical infrastructure through the National Infrastructure Protection Plan (NIPP) (DHS, 2006). Under the NIPP framework, the water sector developed its own Water Sector-Specific Plan (SSP). The Water SSP, along with the other SSPs, was released by DHS in 2007 (DHS, 2007). See other publications for more detail on water security issues (States, 2010; Roberson and Morley, 2006; Mays, 2004).

THE RISK MANAGEMENT AND STANDARD-SETTING PROCESSES

The 1996 SDWA Amendments established a scientific, risk-based approach to targeting, assessing, and managing health risks from contaminants in PWSs. This approach targets research, assessment, and regulatory activities on the contaminants that have the greatest likelihood of presenting health risks from drinking water. The amendments also recognized that over time, better information becomes available and requires USEPA to regularly reassess and reprioritize its risk management efforts.

The mechanisms required by the SDWA for USEPA to gather and assess data to prioritize contaminants for risk management actions include: (1) the Contaminant Candidate List (CCL), (2) the Unregulated Contaminant Monitoring Rules (UCMRs), (3) regulatory determinations, and (4) the review of NPDWRs (six-year review). The risk management actions that SDWA authorizes include: (1) NPDWRs, (2) National Secondary Drinking Water Regulations, and (3) Health Advisories and Other Actions.

This section discusses each of these targeting and risk management processes. Figure 1-2 provides an overview of how these different processes fit together in the development of regulations.

Contaminant Candidate List

The Contaminant Candidate List (CCL) is developed by USEPA as a listing of priority contaminants for regulatory decision making and information collection. The SDWA requires that every five years, USEPA publish a list of unregulated contaminants that are known or anticipated to occur in PWSs and that may require regulation. In developing a CCL, USEPA must consider the contaminants identified in section 101(14) of the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA, or Superfund) and substances registered as pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). USEPA must also consult with the scientific community and request and consider public comment on a draft list.

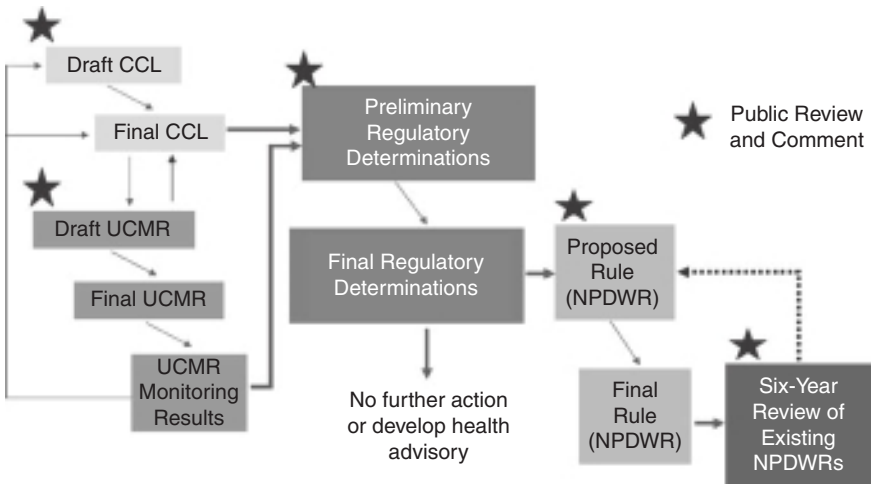

FIGURE 1-2 Overview of SDWA regulatory processes.

USEPA published the first CCL (CCL1) in 1998 (USEPA, 1998a). CCL1 contained 50 chemicals and 10 microbial contaminants. USEPA consulted with the scientific community to develop a process to identify CCL1 contaminants. The process used a combination of expert judgment for microbial contaminants and screening and evaluation criteria to identify chemical contaminants.

In response to comments that a more comprehensive and reproducible approach was needed for selecting contaminants for future CCLs, USEPA sought advice from the National Academies of Science–National Research Council (NRC). The NRC recommended that USEPA continue to use expert judgment and public involvement to identify future contaminants for the CCLs (NRC, 2001a). The NRC also recommended that USEPA first screen a broad universe of contaminants of potential concern to identify a preliminary CCL (PCCL) based on available health risk data and likelihood of occurrence in drinking water. Then USEPA would assess the PCCL contaminant data in a more detailed manner, using classification tools and expert judgment to evaluate the likelihood that specific contaminants could occur in drinking water at levels and at frequencies that pose a public health risk.

To ensure broad stakeholder input, USEPA also consulted with the National Drinking Water Advisory Council (NDWAC) on its implementation of the NRC-recommended CCL process. The NDWAC endorsed the NRC recommendations, which it described as a three-step process, as depicted in Fig. 1-3 (NDWAC, 2004). The NDWAC provided specific recommendations for implementing each step. Because of differences in the information available for microbes and chemicals, the NDWAC recommended these contaminants be evaluated in parallel procedures. The NDWAC also recommended that USEPA move forward using a step-wise adaptive management approach to build upon advances in technology and the experience it has gained in developing previous CCLs.

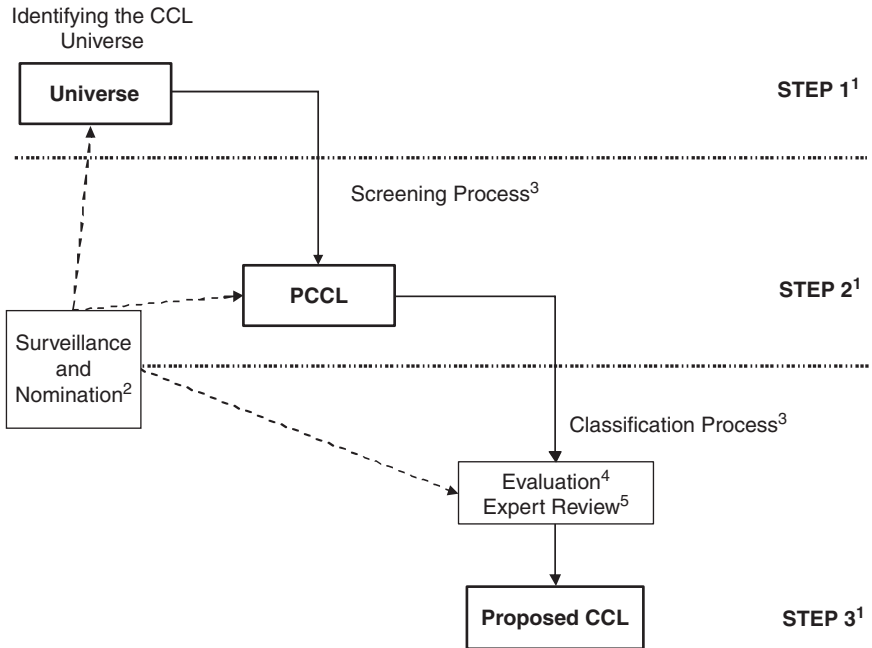

USEPA did not implement the NRC and NDWAC recommendations for the second CCL (CCL2) published in 2005 because the recommended processes would not have been completed in time (USEPA, 2005a). However, the agency described the improved process it would implement for future CCLs. CCL2 consisted of the 51 (42 chemical and 9 microbial) contaminants for which USEPA had not yet made regulatory determinations.

USEPA published the draft of the third CCL (CCL3) for public comment in February 2008 (USEPA, 2008a). This draft included 104 contaminants—93 chemicals and 11 microbiological contaminants. The draft CCL3 was developed using the NRC/NDWAC-recommended process to evaluate approximately 7500 chemical and microbial contaminants. USEPA also considered the contaminant nominations and information received from the public in preparing the draft CCL3. The final CCL3 was published in October 2009 and included 116 contaminants (104 chemicals and 12 microbiological contaminants), as listed in Table 1-2 (USEPA, 2009b).

Research plays a significant role in filling the data gaps identified in the CCL process. The final CCL3 contained a table on regulatory determination data/information needs for each contaminant, broken down into health effects, occurrence, and need for analytical methods (USEPA, 2009b). This table shows the depth and breadth of the potential research agenda for USEPA's drinking water program, as there are numerous data/information needs for the CCL3 contaminants.

Regulatory Determinations

A regulatory determination is a decision made by USEPA on whether to initiate a national primary drinking water rulemaking for a contaminant. The SDWA requires that every five years USEPA make regulatory determinations for at least five contaminants on the CCL. Section 1412(b)(1) of the SDWA specifies three criteria that must be met for USEPA to make a determination to develop a national regulation for a contaminant: "(1) the contaminant may

Notes:

1. Steps are sequential, as are components of each step, with the exception of surveillance and nomination. This generalized process is applicable to both chemical and microbial contaminants, though the specific execution of particular steps may differ in practice.
2. Surveillance and nomination provide an alternative pathway for entry into the CCL process for new and emerging agents, in particular. Most agents would be nominated to the CCL Universe. Depending on the timing of the nomination and the information available, a contaminant could move onto the PCCL or CCL, if justified.
3. Expert judgment, possibly including external expert consultation, will be important throughout the process, but particularly at key points, such as reviewing the screening criteria and process from the Universe to the PCCL; assessing the training data set and classification algorithm performance during development of the PCCL to CCL classification step.
4. After implementing the classification process, the prioritized list of contaminants would be evaluated by experts, including a review of the quality of information.
5. The CCL classification process and draft CCL list would undergo a critical Expert Review by us EPA and by outside experts before the CCL is proposed.

FIGURE 1-3 Overview of CCL process recommended by NDWAC Work Group and incorporated by USEPA into CCL3. (Source: *National Drinking Water Advisory Council, 2004; www.epa.gov/safewater/ndwac/pdfs/report_ccl_ndwac_07-06-04.pdf.*)

have an adverse effect on the health of persons; (2) the contaminant is known to occur or there is a substantial likelihood the contaminant will occur in public water systems with a frequency and at levels of public health concern; and (3) in the sole judgment of the Administrator, regulation of the contaminant presents a meaningful opportunity for health risk reductions for persons served by public water systems.”

^aChemical Abstracts Service Registry Number

USEPA developed a comprehensive approach for evaluating these criteria with significant input from the NRC (NRC, 1999a, 1999b) and the NDWAC (USEPA, 2003a). To evaluate the first criterion, USEPA evaluates best available, peer-reviewed assessments² to characterize the health effects that may result from consuming the contaminant in drinking water (USEPA, 2008b). From this information, USEPA estimates a health reference level (HRL) that takes into account the potential for other routes of exposure (e.g., food). To evaluate the second criterion, USEPA analyzes data from nationally representative occurrence studies³ and compares these data to the HRL to determine the frequency at which PWSs exceed this level of concern. To evaluate the third statutory criterion, USEPA evaluates the potential health risks in the populations above the health reference level. USEPA also evaluates the nondrinking water route of exposure to determine if removing the contaminant from drinking water will significantly reduce the population's exposure to the contaminant.

USEPA has made regulatory determinations for 20 contaminants, 9 from CCL1 and 11 from CCL2, as listed in Table 1-3 (USEPA, 2000, 2008b). For all of these contaminants, USEPA has made a determination not to regulate them because they did not occur frequently in PWSs at levels of health concern and/or there was not a meaningful opportunity for health risk reduction through a national primary drinking water rule.

USEPA requested comment on a preliminary regulatory determination to not regulate perchlorate in October 2008 (USEPA, 2008c). In August 2009, USEPA published a supplemental request for comments on alternative analysis of the perchlorate regulatory determination (USEPA, 2009c). In this notice, USEPA presented a broader range of alternatives for interpreting the available data on: (1) the level of concern, (2) the frequency of occurrence of perchlorate in drinking water, and (3) the opportunity for health-risk reduction through a national perchlorate standard.

²USEPA has relied upon peer-reviewed risk assessments from the agency's Integrated Risk Information System (IRIS) or the pesticide reregistration eligibility decisions (RED), as well as from the National Academy of Sciences (NAS) or the Agency for Toxic Substances and Disease Registry (ATSDR).

³USEPA has relied on data from the Unregulated Contaminant Monitoring (UCM) Program, the National Inorganic and Radionuclide Survey (NIRS), and the first Unregulated Contaminant Monitoring Rule (UCMR1) in making its regulatory decisions for CCL1 and CCL2 contaminants.

TABLE 1-3 Contaminants Not Regulated by First and Second Regulatory Determinations

First regulatory determinations (9)	Second regulatory determinations (11)
Manganese	Boron
Sodium	Dactical mono-acid degradate
Sulfate	Dactical di-acid degradate
Aldrin	1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene
Dieldrin	1,3-dichloropropene
Metribuzin	2,4-dinitrotoluene
Hexachlorobutadiene	2,6-dinitrotoluene
Naphthalene	s-ethyl dipropylthiocarbamate
<i>Acanthamoeba</i>	Fonofos
	Terbacil
	1,1,2,2-tetrachloroethane

Unregulated Contaminant Monitoring Regulations

Unregulated contaminant monitoring regulations (UCMRs) require the collection of drinking water contaminant occurrence data that can be used by USEPA to identify contaminants for the CCL, to support regulatory determinations, and to develop national primary drinking water regulations. The 1986 SDWA Amendments provided authority for USEPA to gather information on unregulated contaminants. USEPA included unregulated contaminant monitoring (UCM) requirements in the Phase I and Phase II regulations. The UCM monitoring continued until the 1996 SDWA Amendments required substantial revisions to the program. Under the 1996 SDWA Amendments, USEPA is required to: (1) publish a list of not more than 30 unregulated contaminants every five years, i.e., the UCMR; (2) identify a representative sample of PWSs serving 10,000 or fewer people to monitor, with USEPA paying the cost of analyzing samples from those systems; (3) place the monitoring data in the National Contaminant Occurrence Database; and (4) notify consumers that the monitoring results are available.

USEPA selects contaminants for the UCMR by evaluating contaminants that have been targeted through prioritization processes (i.e., the CCL). The agency identifies additional contaminants through an evaluation of current research on occurrence and health-effects risk factors. USEPA does not list contaminants that do not have an analytical reference standard or contaminants whose analytical methods are not ready for widespread use under UCMR.

The first UCMR (UCMR1), which was promulgated in 1999 (USEPA, 1999a), listed 12 contaminants for assessment monitoring (List 1) at all large water systems (serving more than 10,000 people) and a representative sample of 800 small water systems (serving fewer than 10,000 people). UCMR1 also listed 14 contaminants for screening monitoring (List 2) at 300 randomly selected large and small water systems. Surface water systems were required to collect four quarterly samples, and groundwater systems were required to collect two semiannual samples. Monitoring data for UCMR1 were reported to USEPA from 2001 to 2005 and are available on the Internet at www.epa.gov/safewater/ucmr/data.html#2.

USEPA promulgated the second UCMR (UCMR2) in 2007 (USEPA, 2007a). The UCMR2 lists 10 contaminants for assessment monitoring (List 1) at all large systems and

at 800 selected small systems. UCMR2 also requires screening monitoring (List 2) for 15 contaminants from all very large systems (serving more than 100,000 people) and from 600 selected medium and small systems. Monitoring for the UCMR2 is to be performed during a 12-month period from January 2008 to December 2010.

National Primary Drinking Water Regulations

National Primary Drinking Water Regulations (NPDWRs), which are legally enforceable standards that apply to PWSs, protect public health by limiting the levels of contaminants in drinking water. NPDWRs take the form of MCLs or TTs. An MCL is the maximum permissible level of a contaminant in water that is delivered to any user of a PWS. A treatment technique is an enforceable procedure or level of technological performance that PWSs must follow to ensure control of a contaminant. Examples of TT rules are the Surface Water Treatment Rule (disinfection and filtration for inactivation/removal of target pathogens) and the Lead and Copper Rule (optimized corrosion control). More details on the individual rules are found in the next section.

To propose a new or revised NPDWR, the 1996 SDWA Amendments require USEPA to undertake a number of steps, including:

- Establish a maximum contaminant level goal (MCLG). The MCLG is the maximum level of a contaminant in drinking water at which no known or anticipated adverse effect on the health of persons would occur, allowing for an adequate margin of safety. MCLGs are nonenforceable public health goals.
- Set the MCL as close as feasible to the MCLG. The feasible level is the level that may be achieved with the use of the best available technology, TTs, and other means that USEPA finds (after examination for efficiency under field conditions and not solely under laboratory conditions) are available, taking cost into consideration. When there is no reliable method that is economically and technically feasible to measure a contaminant, USEPA establishes a TT for control of that contaminant.
- Prepare a health-risk reduction cost analysis (HRRCA) that includes estimates of the quantifiable and nonquantifiable costs and benefits of the regulatory alternatives, including the feasible level that is closest to the MCLG.
- Determine if the costs justify the benefits at the feasible level. If not, USEPA may set the MCL at a level that maximizes health risk reduction benefits at a cost that is justified by the benefits.
- List the technologies that achieve compliance with the MCL or TT. USEPA can update the list at any time after promulgating a standard to list new or innovative technologies that achieve compliance with a standard.
- Identify affordable small-system compliance technologies. If none are available, USEPA must identify small-system variance technologies that remove the contaminant to the maximum extent affordable and are protective of public health.

The SDWA specifies that USEPA use the “the best available, peer-reviewed science” in the decision-making processes (i.e., CCL, regulatory determinations, and developing NPDWRs). The SDWA also specifies that USEPA must propose a NPDWR within 24 months of making a determination to regulate a contaminant and promulgate a final regulation within 18 months of proposal. At the Administrator’s discretion and public notification, USEPA can extend this deadline for the final rule by up to nine months.

Although USEPA has not yet made a determination to regulate a CCL contaminant because none of the CCL contaminants have met the three SDWA criteria previously discussed, the agency has implemented the standard-setting processes required by the 1996 SDWA Amendments in developing the priority regulations (e.g., Arsenic, Radionuclides, The Microbial and Disinfection By-Products Rules).

National Primary Drinking Water Regulation Review

The National Primary Drinking Water Regulation Review, or six-year review, is an evaluation by USEPA of the available information on health effects, analytical methods, treatment technologies, and any other factors for existing NPDWRs to determine if revisions are appropriate. The SDWA requires that USEPA review and revise as appropriate each NPDWR every six years. The SDWA also requires that each revision shall maintain or provide for greater protection of public health.

USEPA has developed a protocol based upon input from the NDWAC to systematically evaluate NPDWRs to determine if a revision presents a meaningful opportunity to improve the level of public health protection or to achieve cost savings while maintaining or improving the level of health protection, as shown in Fig. 1-4 (USEPA, 2003b). In carrying out the six-year review, USEPA compiles the available, peer-reviewed information on health effects, analytical feasibility, and treatment for regulated contaminants to determine if the data indicate a need to reevaluate a contaminant's NPDWR. If no new data are available, USEPA assumes the existing NPDWRs remain appropriate. However, if new data are available, USEPA determines whether changes in the NPDWR for that contaminant are warranted.

For example, if the current MCL for a contaminant was set at the level of analytical feasibility and a new or improved analytical method is now available for a contaminant, USEPA then determines if the lower analytical quantitation level is feasible. USEPA also determines if there is a meaningful opportunity to improve public health by changing the standard. For example, based on contaminant occurrence data collected from states, USEPA will estimate the population served by systems where the concentration of the contaminant exceeds the potentially lower new standard.

USEPA completed the first six-year review in 2003 (USEPA, 2003c); the agency reviewed NPDWRs for 69 contaminants and concluded that it was appropriate to revise one NPDWR, the Total Coliform Rule (TCR) at that time. The TCR revisions are discussed later in this chapter.

National Secondary Drinking Water Regulations

National Secondary Drinking Water Regulations, referred to as secondary maximum contaminant levels (SMCLs), are nonenforceable guidelines for contaminants that may cause cosmetic effects in consumers (e.g., skin discoloration) or aesthetic effects in drinking water (e.g., taste, odor, or color) (USEPA, 1992). PWSs are not required to comply with SMCLs unless their states have chosen to adopt them as an enforceable standard. The SDWA defines an SMCL as a regulation that USEPA determines is "requisite to protect the public welfare." USEPA has established SMCLs for 15 contaminants, as shown in Table 1-4 (USEPA, 1979, 1986, 1991).

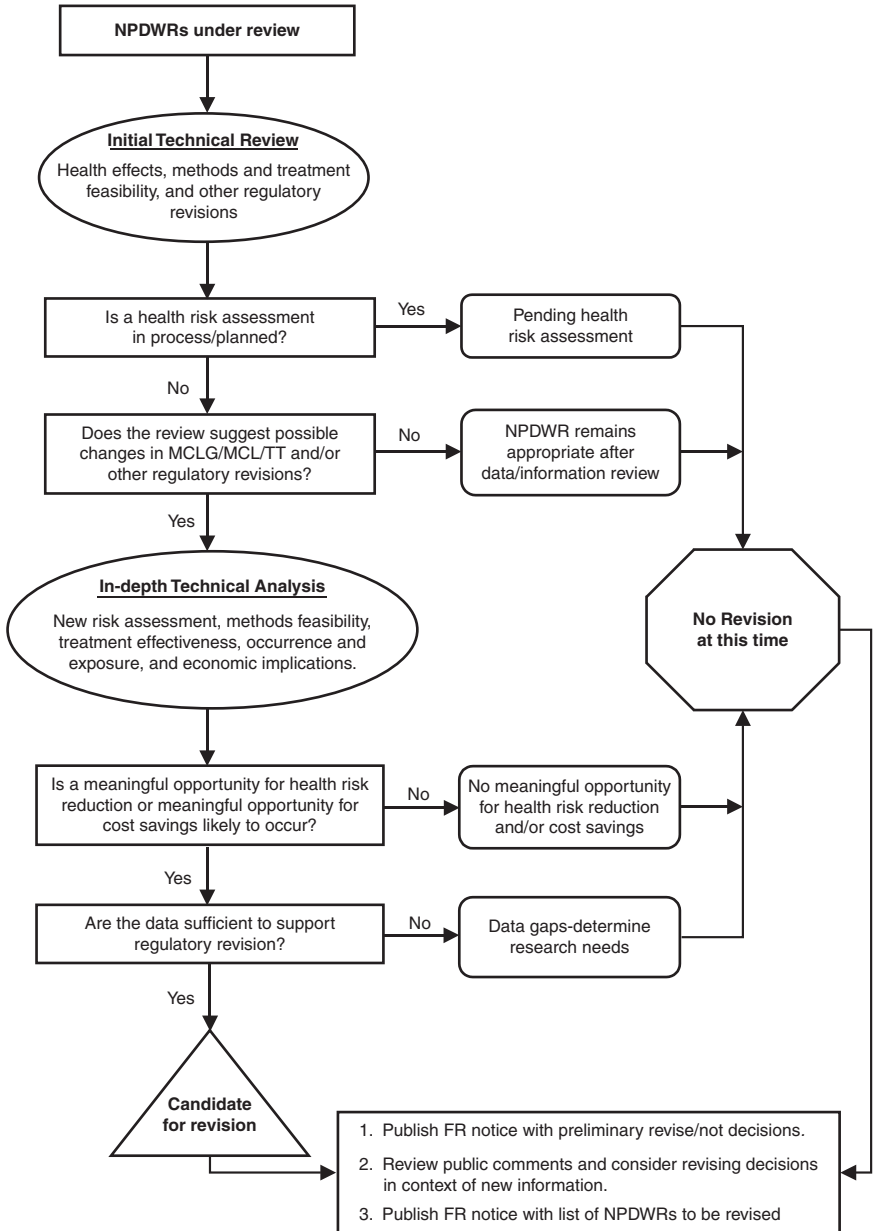

FIGURE 1-4 Overview of the six-year review protocol and making the revise/not revise decision. (Source: EPA Protocol for the Review of Existing National Primary Drinking Water Regulations, EPA-815-R-03-002, 2003; www.epa.gov/safewater/standard/review/pdfs/support_6yr_protocol_final.pdf.)

TABLE 1-4 National Secondary Drinking Water Standards

Contaminant	Effect(s)	SMCL, mg/L
Aluminum	Colored water	0.05–0.2
Chloride	Salty taste	250
Color	Visible tint	15 color units
Copper	Metallic taste; blue-green stain	1.0
Corrosivity	Metallic taste; corrosion; fixture staining	Noncorrosive
Fluoride	Tooth discoloration	2
Foaming agents	Frothy, cloudy; bitter taste; odor	0.5
Iron	Rusty color; sediment; metallic taste; reddish or orange staining	0.3
Manganese	Black to brown color; black staining; bittermetallic taste	0.05
Odor	“Rotten egg,” musty, or chemical smell	3 TON
pH	Low pH: bitter metallic taste, corrosion high pH: slippery feel, soda taste, deposits	6.5–8.5
Silver	Skin discoloration; greying of the white part of the eye	0.10
Sulfate	Salty taste	250
Total dissolved solids (TDS)	Hardness; deposits; colored water; staining; salty taste	500
Zinc	Metallic taste	5

Health Advisories and Other Actions

Health advisories are documents prepared by USEPA that provide information on contaminants that can cause human health effects and are known or anticipated to occur in drinking water. Health advisories provide nonenforceable guidance values (HA values) based on noncancer health effects for different durations of exposure (e.g., 1-day, 10-day, and lifetime). Health advisories also provide technical guidance on health effects, analytical methodologies, and treatment technologies associated with drinking water contaminants. These advisories were first developed in 1987 before USEPA had established many of the NPDWRs in effect today. USEPA has issued health advisories in association with its regulatory determinations, and has recently issued or revised health advisories for more than 170 contaminants (USEPA, 2006a).

In addition to health advisories, USEPA takes other actions to address concerns associated with drinking water contaminants. These actions include issuing drinking water advisories (DWAs), which are similar to a health advisories in that they provide a nonenforceable guidance value. However, the DWA value is based on aesthetic values (taste, odor, and color). USEPA has published DWAs for sulfate, methyl-*tert*-butyl-ether (MTBE), and sodium (USEPA, 2006a).

CURRENT DRINKING WATER REGULATIONS

Individual Rules

USEPA finalized 18 NPDWRs between 1975 and 2006 (see Table 1-1). Typically, minor technical corrections are needed after final rule promulgation, and a separate *Federal Register* notice is issued for these corrections. The number of regulated contaminants has varied from 90 to 91 since the 1996 SDWA Amendments (see Fig. 1-1). The secondary standards are listed in Table 1-4, and the MCLGs and MCLs for the primary drinking water standards are listed in Table 1-5.

The 1996 SDWA Amendments mandated specific deadlines for a handful of regulations that were known as the “priority” regulations. These regulations address the following:

- *Disinfectants and disinfection by-products*. This set of regulations was to be finalized in accordance with the regulatory schedule listed in the 1994 proposed Information Collection Rule (ICR). The Stage 1 Disinfection By-Product Rule (DBPR) and Interim Enhanced Surface Water Treatment Rule (IESWTR) were promulgated in 1998, the Long Term 1 Enhanced Surface Water Treatment Rule (LT1ESWTR) was promulgated in 2002, and the Stage 2 DBPR and Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) were promulgated in 2006.
- *Arsenic*. The arsenic regulation was to be proposed by Jan. 1, 2000, and finalized by Jan. 1, 2001. The arsenic regulation was promulgated in 2001.
- *Sulfate*. Regulatory determination was to be made for sulfate by August 2001 as part of the first regulatory determinations. USEPA made a final determination not to regulate sulfate in July 2003 (USEPA, 2003a).
- *Filter backwash*. A regulation to address filter backwash was to be finalized by August 2000. This rule was promulgated in 2001.
- *Radon*. The radon regulation was to be proposed by August 1999 and finalized by August 2000. USEPA proposed a radon in drinking water rule in November 1999 but has not promulgated a final rule (USEPA, 1999b).
- *Groundwater*. A rule to address potential groundwater contamination was to be finalized sometime between August 1999 and publication of the final Stage 2 DBPR. The Ground Water Rule (GWR) was promulgated in 2006.

USEPA has also promulgated other national drinking water regulations that are not NPDWRs. Many of these regulations mandate specific monitoring, such as the ICR, and the first and second Unregulated Contaminant Monitoring Rule (UCMR1 and UCMR2). This category of regulations also includes the Consumer Confidence Report (CCR), a report on water quality that must be sent annually to customers. The CCR is an important part of the improved public education component of the 1996 SDWA Amendments. Table 1-6 lists other significant national drinking water regulations.

As previously discussed, USEPA has taken other regulatory actions, such as CCLs and regulatory determinations, that are not regulations in the sense that compliance by PWSs is not required. However, these actions form the foundation of the regulatory development process by identifying contaminants that may require regulation.

For most regulations, USEPA develops a variety of publications in order to provide compliance assistance for water utilities and state agencies. These publications typically include fact sheets on the regulations and a variety of guidance manuals that provide detailed information on technical issues that cannot be found in USEPA’s regulatory language and preamble. It should be noted that these guidance manuals are suggestions and

TABLE 1-5 National Primary Drinking Water Standards

Contaminant	MCLG, mg/L	MCL, mg/L	Potential health effects	Sources of drinking water contamination
Fluoride Rule				
Fluoride	4.0	4.0	Skeletal and dental fluorosis	Natural deposits; fertilizer, aluminum industries; drinking water additive
Phase I Volatile Organics				
Benzene	zero	0.005	Cancer	Some foods; gas, drugs, pesticide, paint, plastic industries
Carbon tetrachloride	zero	0.005	Cancer	Solvents and their degradation products
<i>p</i> -Dichlorobenzene	0.075	0.075	Cancer	Room and water deodorants and mothballs
1,2-Dichloroethane	zero	0.005	Cancer	Leaded gas, fumigants, paints
1,1-Dichloro-ethylene	0.007	0.007	Cancer, liver, kidney effects	Plastics, dyes, perfumes, paints
Trichloro-ethylene	zero	0.005	Cancer	Textiles, adhesives, metal degreasers
1,1,1-Tri-chloroethane	0.2	0.2	Liver, nervous system effects	Adhesives, aerosols, textiles, paints, inks, metal degreasers
Vinyl chloride	zero	0.002	Cancer	May leach from PVC pipe; formed by solvent breakdown
Surface Water Treatment Rule and Total Coliform Rule				
<i>Giardia lamblia</i>	zero	TT	Gastroenteric disease	Human and animal fecal wastes
<i>Legionella</i>	zero	TT	Legionnaire's disease	Natural waters; can grow in water heating systems
Heterotrophic plate count	N/A	TT	Indicates water quality, effectiveness of treatment	
Total coliform	zero	< 5%+	Indicates gastroenteric pathogens	Human and animal fecal wastes
Turbidity	N/A	TT	Interferes with disinfection	Soil runoff
Viruses	zero	TT	Gastroenteric disease	Human and animal fecal wastes
Phase II Rule Inorganics				
Asbestos (>10 µm)	7 MFL	7 MFL	Cancer	Natural deposits; asbestos cement in water systems
Barium	2	2	Circulatory system effects	Natural deposits; pigments, epoxy sealants, spent coal
Cadmium	0.005	0.005	Kidney effects	Galvanized pipe corrosion; natural deposits; batteries, paints
Chromium 0.1 (total)	0.1	0.1	Liver, kidney, circulatory disorders	Natural deposits; mining, electroplating, pigments
Mercury (inorganic)	0.002	0.002	Kidney, nervous system disorders	Crop runoff; natural deposits; batteries, electrical switches
Nitrate	10	10	Methemoglobinemia	Animal waste, fertilizer, natural deposits, septic tanks, sewage

Nitrite	1	1	Methemoglobinemia	Same as nitrate; rapidly converted to nitrate
Nitrate + nitrite	10	10		
Selenium	0.05	0.05	Liver damage	Natural deposits; mining, smelting, coal/oil combustion
Phase II Rule Organics				
Acrylamide	zero	TT	Cancer, nervous system effects	Polymers used in sewage/waste-water treatment
Alachlor	zero	0.002	Cancer	Runoff from herbicide on corn, soybeans, other crops
Aldicarb	delayed	delayed	Nervous system effects	Insecticide on cotton, potatoes, other crops; widely restricted
Aldicarb sulfone	delayed	delayed	Nervous system effects	Biodegradation of aldicarb
Aldicarb sulfoxide	delayed	delayed	Nervous system effects	Biodegradation of aldicarb
Atrazine	0.003	0.003	Mammary gland tumors	Runoff from use as herbicide on corn and noncropland
Carbofuran	0.04	0.04	Nervous, reproductive system effects	Soil fumigant on corn and cotton; restricted in some areas
Chlordane	zero	0.002	Cancer	Leaching from soil treatment for termites
Chlorobenzene	0.1	0.1	Nervous system, liver effects	Waste solvent from metal degreasing processes
2,4-D	0.07	0.07	Liver and kidney damage	Runoff from herbicide on wheat, corn, rangelands, lawns
<i>o</i> -Dichloroethylene	0.1	0.1	Liver, kidney, blood cell damage	Paints, engine cleaning compounds, dyes, chemical
<i>cis</i> -1,2-Dichloroethylene	0.07	0.07	Liver, kidney, nervous, circulatory system effects	Waste industrial extraction solvents
<i>trans</i> -1,2-Dichloroethylene	0.1	0.1	Liver, kidney, nervous, circulatory system effects	Waste industrial extraction solvents
1,2-Dibromo-3-chloropropane	zero	0.0002	Cancer	Soil fumigant on soybeans, cotton, pineapple, orchards
1,2-Dichloropropane	zero	0.005	Liver, kidney effects; cancer	Soil fumigant; waste industrial solvents
Epichlorohydrin	zero	TT	Cancer	Water treatment chemicals; waste epoxy resins, coatings
Ethylbenzene	0.7	0.7	Liver, kidney, nervous system effects	Gasoline; insecticides; chemical manufacturing wastes
Ethylene dibromide	zero	0.00005	Cancer	Leaded gas additives; leaching of soil fumigant
Heptachlor	zero	0.0004	Cancer	Leaching of insecticide for termites, very few crops
Heptachlor epoxide	zero	0.0002	Cancer	Biodegradation of heptachlor
Lindane	0.0002	0.0002	Liver, kidney, nervous system, immune system, circulatory system effects	Insecticide on cattle, lumber, gardens; restricted in 1983
Methoxychlor	0.04	0.04	Growth; liver, kidney, nervous, system effects	Insecticide for fruits, vegetables, alfalfa, livestock, pets

(Continued)

TABLE 1-5 National Primary Drinking Water Standards (*Continued*)

Contaminant	MCLG, mg/L	MCL, mg/L	Potential health effects	Sources of drinking water contamination
Pentachlorophenol	zero	0.001	Cancer; liver, kidney effects	Wood preservatives, herbicide, cooling tower wastes
PCBs	zero	0.0005	Cancer	Coolant oils from electrical transformers; plasticizers
Styrene	1	1	Liver, nervous system effects	Plastics, rubber, resin, drug damage industries; leachate from city landfills
Tetrachloroethylene	zero	0.005	Cancer	Improper disposal of dry cleaning and other solvents
Toluene	1	1	Liver, kidney, nervous system, circulatory system effects	Gasoline additive; manufacturing and solvent operations
Toxaphene	zero	0.003	Cancer	Insecticide on cattle, cotton, soybeans; cancelled in 1982
2,4,5-TP (Silvex)	0.05	0.05	Liver, kidney damage	Herbicide on crops, rights-of-way, golf courses; cancelled in 1983
Xylenes (total)	10	10	Liver, kidney, nervous system effects	By-product of gasoline refining; paints, inks, detergents
Lead and Copper Rule				
Lead	zero	TT [#]	Kidney, nervous system effects	Natural/industrial deposits; plumbing solder, brass alloy faucets
Copper	1.3	TT ^{##}	Gastrointestinal irritation	Natural/industrial deposits; wood preservatives, plumbing
Phase V Inorganics				
Antimony	0.006	0.006	Cancer	Fire retardants, ceramics, electronics, fireworks
Beryllium	0.004	0.004	Bone, lung damage	Electrical, aerospace, defense industries
Cyanide	0.2	0.2	Thyroid, nervous system damage	Electroplating, steel, plastics, mining, fertilizer
Nickel	0.1	0.1	Heart, liver damage	Metal alloys, electroplating, batteries, chemical production
Thallium	0.0005	0.002	Kidney, liver, brain, intestinal effects	Electronics, drugs, alloys, glass
Phase V Organics				
Adipate, (di(2-ethylhexyl))	0.4	0.4	Decreased body weight	Synthetic rubber, food packaging, cosmetics
Benzo(a)pyrene (PAHs)	zero	0.0002	Cancer	Coal tar coatings; burning organic matter; volcanoes, fossil fuels
Dalapon	0.2	0.2	Liver, kidney effects	Herbicide on orchards, beans, coffee, lawns, roads, railways
Di(2-ethylhexyl) phthalate	zero	0.006	Cancer	PVC and other plastics
Dichloromethane	zero	0.005	Cancer	Paint stripper, metal degreaser, propellant, extractant

Di(2-ethylhexyl) phthalate	zero	0.006	Cancer	PVC and other plastics
Dinoseb	0.007	0.007	Thyroid, reproductive organ damage	Runoff of herbicide from crop and noncrop applications
Diquat	0.02	0.02	Liver, kidney, eye effects	Runoff of herbicide on land and aquatic weeds
Dioxin	zero	3×10^{-8}	Cancer	Chemical production by-product; impurity in herbicides
Endothall	0.1	0.1	Liver, kidney, gastrointestinal effects	Herbicide on crops, land/aquatic weeds; rapidly degraded
Glyphosate	0.7	0.7	Liver, kidney damage	Herbicide on grasses, weeds, brush
Hexachlorobenzene	zero	0.001	Cancer	Pesticide production waste by-product
Hexachlorocyclopentadiene	0.05	0.05	Kidney, stomach damage	Pesticide production intermediate
Oxamyl (Vydate)	0.2	0.2	Kidney damage	Insecticide on apples, potatoes, tomatoes
Picloram	0.5	0.5	Kidney, liver damage	Herbicide on broadleaf and woody plants
Simazine	0.004	0.004	Cancer	Herbicide on grass sod, some crops, aquatic algae
1,2,4-Trichlorobenzene	0.07	0.07	Kidney, liver damage	Herbicide production; dye carrier
1,1,2-Trichloroethane	0.003	0.003	Kidney, liver, nervous system damage	Solvent in rubber, other organic products; chemical production wastes

Disinfectants and Disinfection By-Products

Bromate	zero	0.010	Cancer	Ozonation by-product
Bromodichloromethane	zero	see TTHMs	Cancer, kidney, liver, reproductive effects	Chlorination by-product
Bromoform	zero	see TTHMs	Cancer, kidney, liver, nervous system effects	Chlorination by-product
Chlorine	4 (as Cl ₂) (MRDLG)	4.0 (as Cl ₂) (MRDL)		
Chloramines	4 (as Cl ₂) (MRDLG)	4.0 (as Cl ₂) (MRDL)		
Chlorine dioxide	0.8 (as ClO ₂) (MRDLG)	0.8 (as ClO ₂) (MRDL)		
Chloral hydrate	0.04	TT	Liver effects	Chlorination by-product
Chlorite	0.08	1.0	Developmental neurotoxicity	Chlorine dioxide by-product
Chloroform	zero	see TTHMs	Cancer, kidney, liver reproductive effects	Chlorination by-product
Dibromochloromethane	0.06	see TTHMs	Nervous system, kidney, liver, reproductive effects	Chlorination by-product
Dichloroacetic acid	zero	see HAA5	Cancer, reproductive, developmental effects	Chlorination by-product

TABLE 1-5 National Primary Drinking Water Standards (*Continued*)

Contaminant	MCLG, mg/L	MCL, mg/L	Potential health effects	Sources of drinking water contamination
Disinfectants and Disinfection By-Products				
Haloacetic acids (HAA5)**	zero	0.060	Cancer and other effects	Chlorination by-product
Trichloroacetic acid	0.3	see HAA5	Liver, kidney, spleen, mental effects	Chlorination by-product
Total trihalomethanes (TTHMs)	zero	0.010	Cancer and other effects	Chlorination by-product
Radionuclides				
Beta/phonon emitters	zero	4 mrem/yr	Cancer	Natural and man-made deposits
Alpha particles	zero	15 pCi/L	Cancer	Natural deposits
Radium 226 and 228	zero	5 pCi/L	Bone cancer	Natural deposits
Uranium	zero	0.03	Cancer	Natural deposits
Arsenic				
Arsenic	zero	0.010	Skin, nervous system toxicity; cancer	Natural deposits; smelters, glass, electronics wastes; orchards

Notes:

Action level = 0.015 mg/L

Action level = 1.3 mg/L

TT = treatment technique requirement

MFL = million fibers per liter

*For water systems analyzing at least 40 samples per month, no more than 5.0 percent of the monthly samples may be positive for total coliforms. For systems analyzing fewer than 40 samples per month, no more than one sample per month may be positive for total coliforms.

**Sum of the concentrations of mono-, di-, and trichloroacetic acids and mono- and dibromoacetic acids.

Alternatives allowing public water systems the flexibility to select compliance options appropriate to protect the population served were proposed.

*FR – *Federal Register*

guidance and do not have the same enforcement implications as the regulatory language. More information on USEPA guidance manuals can be found on the USEPA Web site listed in the section “The Internet as a Resource.”

The Traditional and Negotiated Rulemaking Processes

In the traditional rulemaking process, USEPA publishes the proposed regulation in the *Federal Register* and accepts comments from the public on various aspects of the regulation. Then, USEPA evaluates the comments, develops a comment response document, and finalizes the regulation. The 1996 SDWA Amendments allow PWSs three years after the regulation has been finalized for compliance, and the compliance deadline can be extended, in conjunction with the state primacy agency, by an additional two years if additional time is needed for capital improvements.

For some of its more recent and more complex rulemakings, USEPA has used a negotiated rulemaking process to develop the substance of the regulation. In the late 1980s and early 1990s, USEPA considered revising the 1979 TTHM Rule but realized the enormous regulatory challenge in simultaneously balancing the risks from DBPs against the microbial risks. This risk–risk balancing did not lend itself to the traditional rulemaking process in which the national standard is set at the appropriate risk level.

From 1992 to 1993, USEPA used a negotiated rulemaking process to develop the proposed ICR, the proposed Stage 1 DBPR, and the proposed IESWTR. Later, for more regulatory negotiations, a Federal Advisory Committee was formed under the auspices of the Federal Advisory Committee Act (FACA) to provide regulatory recommendations through additional Agreement in Principles (AIPs) to USEPA. The members of these committees represented a broad range of stakeholders in the drinking water community including utilities, USEPA, state regulators, tribes, local government, public health authorities, consumer advocates, and environmental advocates. To marshal the widely divergent views, a facilitator was hired by USEPA to run the face-to-face meetings.

For the Microbial/Disinfection By-Product (M/DBP) cluster of regulations, USEPA used negotiated rulemaking/FACA processes in:

- 1992 to 1993 for the proposed ICR, the proposed Stage 1 DBPR, and the IESWTR
- 1997 for finalizing the Stage 1 DBPR and the IESWTR because the ICR was not completed in time for those regulations as originally anticipated in 1992 to 1993
- 1999 to 2000 for the proposed Stage 2 DBPR and the LT2ESWTR

As previously discussed, USEPA decided in 2003 to revise the TCR in its first six-year review of existing drinking water regulations. Due to the inherent complexities with the

myriad of distribution systems, USEPA, in 2007, elected to form the Total Coliform Rule Distribution System Advisory Committee (TCRDSAC). The TCRDSAC met from July 2007 to September 2008 to develop proposed revisions to the TCR and to develop recommendations for distribution system research. In September 2008, the members of the TCRDSAC signed the AIP that will be used as the foundation for proposed TCR revisions (TCRDSAC AIP, 2008).

These Federal Advisory Committees are both time and resource intensive for all committee members. The face-to-face meetings typically take two days and are sometimes preceded by a Technical Work Group (TWG) meeting. The TWG typically provides substantial data analysis and technical support for the committee. For example, the TWG conducted many variations of analyses of the ICR data that were used to support the development of the Stage 2 DBPR and the LT2ESWTR. The output from some of these analyses was eventually compiled into an ICR data analysis book that was edited by three TWG members (McGuire et al., 2002). Even in cases where USEPA serves as a Federal Advisory Committee (FAC) and signs the AIP, USEPA still has the responsibility for developing the proposed preamble and regulatory language, conducting the analyses previously discussed, and considering public comments before issuing a final regulation.

Going Beyond the Regulations

Systems sometimes develop their own water quality goals that are stricter than the regulations. These goals might be for particular contaminants that occur in their source water. One reason that systems adopt this approach is because they want to be leaders in the drinking water community and serve their customers the highest quality water possible. Another reason is that systems do not want to have any violations for any reason and want to have a considerable margin of safety relative to the standards.

Programs have been developed to assist utilities in going beyond the regulations to work toward optimizing treatment. The Partnership for Safe Water is a voluntary cooperative effort between USEPA, AWWA, and other drinking water organizations (AWWA, 2009). More than 200 surface water utilities serving more than 85 million people involved in the Partnership have improved the quality of their drinking water by optimizing system operations and improving filtration performance. Another similar collaborative program between USEPA and several state primacy agencies is the Area-Wide Optimization Program (AWOP) (Barr, 2007). AWOP started in 1989 and now operates in 21 states and focuses on treatment optimization.

ROLE OF STATE AGENCIES

State Agencies and USEPA as Co-regulators

USEPA and states are co-regulators under the SDWA. USEPA assesses contaminants and establishes NPDWRs. State agencies that obtain primacy ensure water systems comply with the drinking water standards. USEPA provides technical assistance and oversight to states in their efforts to ensure compliance with the regulations. States' experience in implementing NPDWRs provide a valuable perspective when developing new regulations. State agencies work closely with USEPA in a state-USEPA workgroup in the initial drafting of a proposed regulation, but USEPA is ultimately responsible for issuing both the proposed and final regulations.

Primacy

If state and tribal regulations are passed that are at least as strict as the federal standards and oversight programs and enforcement mechanisms are in place, primacy for PWS supervision is retained by the state or tribe. Some state agencies further delegate these responsibilities to county or local health departments. All states except Wyoming have primacy. For each new regulation, states and tribes must submit a primacy package on those regulations to USEPA for review and approval.

State agency oversight of PWSs goes beyond simply ensuring compliance with the numerous standards. Sanitary surveys are a critical oversight activity that entails looking at all aspects of a utility's operations and management proactively in order to get ahead of any potential compliance problems. The identification and correction of significant deficiencies are now required under the IESWTR, LT1ESWTR, and GWR and provide a significant new tool for state regulators to use in bringing systems back into compliance.

Other state oversight activities include: (1) review and approval of construction plans and specifications, typically for treatment plants and larger transmission and distribution piping; (2) technical assistance, ranging from assisting with treatment evaluation and selection to assisting with evaluation of water rates to filling out the required paperwork and everything in between; and (3) sample collection and analysis (in some states). These activities help move the PWSs towards compliance.

The primacy agencies make the initial compliance determination. Systems may incur violations not only for MCLs and TTs but also for monitoring and reporting (M&R). The primacy agency works with systems to bring them back into compliance. However, if the systems remain out of compliance, USEPA can step in to enforce the regulations.

The violations listed in the state-level data management system are transferred to the USEPA data system, or Safe Drinking Water Information System—Federal (SDWIS-FED). From 1997 to 2007, national compliance with the NPDWRs, based on population served, has increased slightly from 86.5 percent in 1997 to 91.5 percent in 2007 (USEPA, 2008d). The highest rate was in 2003 with 93.6 percent compliance. The national compliance rate is important to USEPA, because USEPA uses this metric to meet its obligations under the Government Performance and Results Act (GPRA) to measure how well they are performing. USEPA set an objective in its strategic plan that by 2008, 95 percent of the population served by community water systems would meet all applicable health-based standards.

USEPA's regional offices also play a role in the national drinking water program. USEPA divides the states and territories into 10 regions, as shown on Fig. 1-5. These regional offices assist state and tribal agencies that hold primacy with their regulatory oversight. In USEPA Region 3 (the District of Columbia) and USEPA Region 8 (Wyoming), the regional office directly implements the drinking water program.

USEPA provides funding to the primacy agencies for their drinking water programs through Public Water System Supervision (PWSS) grants. Since 2004, the total amount of PWSS grants has effectively been held constant (USEPA, 2008e), despite the increasing complexity of regulations such as the Filter Backwash Recycling Rule (FBRR), the IESWTR, and the LT1ESWTR. While some state agencies charge a fee for service to the utilities and/or their consultants for some of the previously mentioned activities, other states are prohibited from charging any fees. States agencies' resources continue to be challenged. In 2003, the Association of State Drinking Water Administrators (ASDWA) released a report on the funding gap for the states' drinking water programs (ASDWA, 2003). This report found a gap in 2002 of approximately \$230 million between the funds expended at the state level for drinking water programs and the estimated \$535 million needed. The funding shortfall was estimated to increase to approximately \$369 million by 2006, and this shortfall will continue to grow as the number of regulations increases, the population increases, and water systems expand.

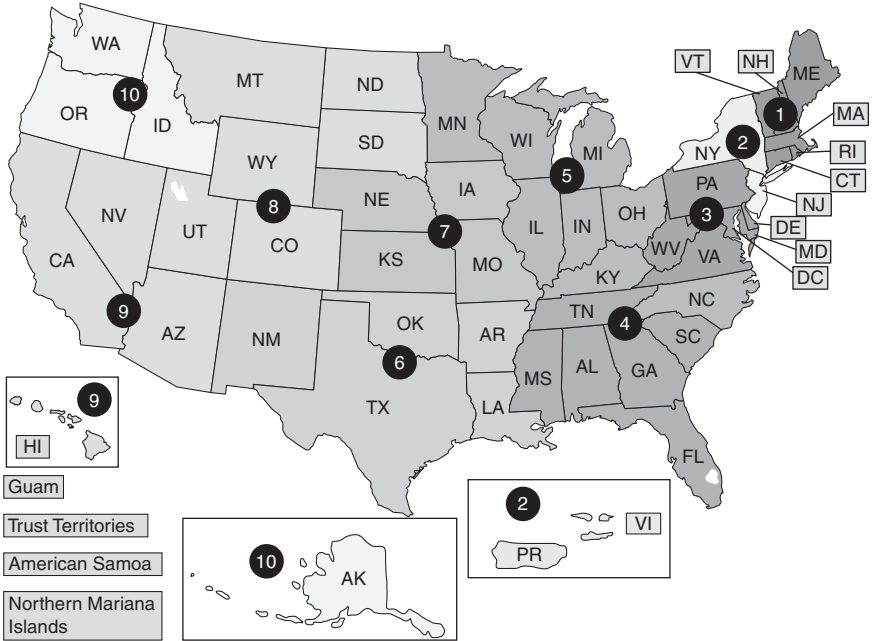

FIGURE 1-5 Map of USEPA regions. (Source: www.epa.gov/epafiles/samples/map.html#eparegions.)

New State Programs from the 1996 SDWA Amendments

State agencies' resources have been squeezed further by four new state programs that resulted from the 1996 SDWA Amendments: (1) source water assessments, (2) capacity development, (3) Drinking Water State Revolving Funds, and (4) operator certification.

As part of the 1996 SDWA Amendments, USEPA was required to develop source water protection guidance. Within 18 months of publication of this guidance, state agencies were required to develop source water assessment programs. The programs were to delineate the source water areas for PWSs, identify potential sources of contamination, and assess the susceptibility of the system to contamination. State agencies were required to complete all source water assessments by 1999. State agencies and utilities were further encouraged to develop voluntary source water protection programs.

USEPA was also required to review existing state assessment programs of the technical, financial, and managerial capacity of PWSs, and to publish guidance on how to strengthen these programs. State agencies must have the legal authority to require systems to demonstrate adequate capacity and a strategy to identify and assist systems that have capacity deficiencies. The objective of these capacity development programs is to ensure system viability for the long term.

The creation of the Drinking Water State Revolving Fund (DWSRF) provided a new funding mechanism for PWSs to construct necessary improvements. Most state agencies established drinking water state SRFs that are parallel to their existing Wastewater SRFs. Congress, which annually appropriates funding for the DWSRFs, started the fund with an appropriation of \$1.2 billion. Between 1997 and 2007, the DWSRF provided \$12.6 billion in funding for 5,555 projects; 39 percent of this funding has gone to systems serving fewer than 10,000 people (USEPA, 2007b). The American Recovery and Reinvestment Act

(ARRA) of 2009 provided additional funding of \$2 billion for the DWSRF program on a one-time basis (USEPA, 2009d).

USEPA is required by the 1996 SDWA Amendments to conduct a national needs survey every four years that is used to establish the percent allocated to each state for its SRF. The 2007 Drinking Water Needs Survey identified a 20-year (2007–2026) capital investment need of \$334.8 billion for PWSs eligible for SRF funding, noting that private systems and projects resulting from population and system growth are not eligible for SRF funding (USEPA, 2005b). The majority, approximately 60 percent (\$200.8 billion), of the total national need is for transmission and distribution projects. Approximately \$52 billion (16 percent) can be attributed to the NPDWRs. Each state agency develops its own process for identifying and prioritizing projects for potential SRF funding by developing a state-level intended use plan (IUP).

One notable feature of the drinking water SRF is the ability of state agencies to use a portion of their SRF funding for these new programs. State agencies can use up to 10 percent for source water protection, capacity development, and operator certification, as well as for the overall drinking water program. Up to another 15 percent can be used by systems for preparation of source water assessments, source water protection loans, capacity development, and wellhead protection. It should be noted that these “set-asides” take funding away from needed construction improvements. Between 1997 and 2007, state agencies “set aside” \$1.4 billion from the DWSRF.

Most state agencies have had operator certification programs for many years, but these programs varied significantly from state to state. In 1999, USEPA developed guidelines for these programs, with eight elements that operator certification programs must contain. The objective was to not have any state agencies lower their standards for operator certification but rather to establish a national base level for these programs. These guidelines also mandated the development of programs for certifying distribution system operators, which was an expansion of traditional certification programs for treatment plant operators. The 1996 SDWA Amendments also provided for grants to state agencies to reimburse operators of systems serving fewer than 3300 people for training and certification costs.

The 1996 SDWA Amendments provided for some type of earmarked allocation to states for these programs. These allocations helped the states meet the requirements of these new programs. However, combined with the new regulations and their increasing complexity, state resources continue to be challenged.

State Standards

States and tribes must pass their own regulations that are at least as strict as the federal standard in order to retain primacy, but some states pass stricter standards or develop their own standards that are not regulated by USEPA. California, New York, New Jersey, and Massachusetts are some of the states that have more or stricter standards than those of USEPA. Tracking the development of state standards across all states can be a substantial effort. ASDWA has links to each state’s drinking water program on its Web site (see “The Internet as a Resource”) (ASDWA, 2008). For information about a drinking water standard for a particular state or tribe, the appropriate state drinking water program agency should be contacted directly.

Even when the regulations adopted by primacy agencies are no more stringent than the federal regulations, differences in implementation at the state level can make them operationally different from the system’s perspective. For example, under the TCR, the state of Ohio used to report missing repeat samples as an MCL violation as opposed to an M&R violation, which caused them to have a disproportionately high number of MCL violations. Other states have differing definitions of significant deficiencies under sanitary surveys previously

discussed; consequently, in many cases, even when the numerical standards are the same, variation in implementation can make regulations look different from state to state.

PEER REVIEW, OUTSIDE CONSULTATION, AND PUBLIC INVOLVEMENT

USEPA regularly conducts peer review of its reports and assessments and also consults with outside parties to provide recommendations on specific technical and science policy issues to incorporate into its regulatory development process. The parties that USEPA uses for each consultation and the specific technical and science policy issues USEPA asks for input on are specific to each regulation. The intent of these outside consultations is to provide recommendations and advice to USEPA in meeting the SDWA requirement and to use the "...best available, peer-reviewed science..." in its regulations, as required by Section 1412(b)(3)(A) of the SDWA. USEPA also has to meet its own internal guidelines for peer review and information quality (USEPA, 2002, 2006b).

The National Academy of Sciences

USEPA has repeatedly gone to the National Academy of Sciences (NAS) for advice and recommendations on scientific and technical issues to apply into its regulatory development process. Some NAS studies have been mandated by Congress, while others were solely at USEPA's request. As a result of the 1974 SDWA, the NRC of the NAS conducted a study to assess human exposure via drinking water and the toxicology of contaminants in drinking water. USEPA published the NAS study recommendations in 1977 and used this report as the basis for revising its drinking water regulations (USEPA, 1977).

More recently, the NRC provided recommendations to USEPA on the CCL and regulatory determination processes (NRC, 1999a, 1999b, 2001a). The NRC has also assessed the health effects of fluoride, radon, arsenic, and copper and reviewed and provided recommendations for USEPA's fluoride standards (NRC, 1993, 1999c, 1999d, 2000, 2001b, 2005, 2006).

The Science Advisory Board

Congress established USEPA's Science Advisory Board (SAB) in 1978 to provide guidance regarding scientific and technical issues to support the agency throughout its regulatory development process. The SAB develops reports and advisories that review the approaches to regulatory science, reviews research programs, critiques analytical methods such as mathematical modeling, and provides other science policy and technical advice as necessary.

The USEPA Administrator appoints members of the SAB and nominations from the public are solicited for the SAB and the SAB standing committees. The SAB currently has six standing committees, including a Drinking Water Committee. Ad hoc committees and panels are formed as needed to address specific topics. Section 1412 of the SDWA mandates USEPA to consult with the scientific community, including the SAB, as part of its development of draft CCLs. USEPA regularly consults with the SAB Drinking Water Committee on a wide variety of drinking water regulatory issues.

The National Drinking Water Advisory Council

Section 1446 of the SDWA mandates the formation of the NDWAC. This section also details representation of the general public, state and local agencies, and private groups for the 15 NDWAC members; the members' terms; and the rotation of the members' terms.

NDWAC members are appointed by the USEPA Administrator. The NDWAC provides policy guidance to USEPA on individual regulations and other regulatory issues.

The NDWAC typically sends letters to the USEPA Administrator after its review of a specific issue. The council often forms a working group to review more complex issues and make more detailed policy recommendations to USEPA. These working groups are usually comprised of two to four NDWAC members plus additional subject matter experts representing a broad range of stakeholders' perspectives. Past NDWAC working groups included Benefits, CCR, Drinking Water SRF, Health Care Providers, Occurrence and Contaminant Selection, Operator Certification, Right-to-Know, Small Systems, Small System Affordability, Source Water, Arsenic Cost, CCL and Six-Year Review, CCL Classification Process, Research, Water Security, and Public Education Requirements of the LCR.

The Office of Management and Budget

Under Executive Order (EO) 12866, the Office of Information and Regulatory Affairs (OIRA) in the Office of Management and Budget (OMB) conducts a regulatory review of each proposed and final regulation by any federal agency, including USEPA. These reviews are typically conducted with a 90-day deadline, and completion of these reviews typically signifies that the proposed or final regulations will be published soon thereafter in the *Federal Register*. These reviews are conducted to ensure that the agencies are following other Executive Orders (EOs) that provide guidance on the use of benefit–cost analysis (BCA) in the regulatory development process.

Public Involvement

The public plays an important role in the provision of safe drinking water. Because the public is the ultimate consumer of the treated drinking water, it has a vested interest in the USEPA regulatory development process, as well as state and USEPA oversight of the utilities. At the national level, the public can play a role and have some influence on Congress in future SDWA reauthorizations and other legislation that might impact drinking water quality. Members of Congress are always willing to listen to the public regarding issues (such as drinking water) that are important to their constituents that ultimately vote to elect or re-elect them to office. The public can play a role in USEPA's regulatory development process by participating in USEPA's stakeholder efforts as previously described. The public can also submit comments on USEPA's proposed regulatory actions; these comments are published in the *Federal Register* (see the stars in Fig. 1-2). The public can also play a role in the development of state-level drinking water regulations by providing input at public hearings and providing comments on the states' proposed regulations. At the local level, the public can attend board meetings of their local utility and provide input during any public comment period at rate hearings.

The Consumer Confidence Report and the Public Notification Rule

Increased consumer education was one improvement that resulted from the 1996 SDWA Amendments. One important component of that increased consumer education was that USEPA must develop a new regulation that requires utilities to prepare annual water quality reports and for these reports to be delivered to their customers. These reports are known as Consumer Confidence Reports (CCRs), and the initial CCR regulation was based on a report from an NDWAC workgroup (USEPA, 1998b).

The CCR regulation requires utilities to develop a water quality report that includes the following:

- Identification of water source and treatment characterization
- Susceptibility of the source water to contamination based on the source water assessment and how to get a copy of the assessment
- Contaminants that are found in the water and their likely sources
- The levels of the contaminants, a comparison to the standard, and the health effects
- An educational statement for vulnerable populations about *Cryptosporidium* and additional information statements on nitrate, arsenic, and lead
- Sources of additional information, such as the utility's main phone number and USEPA's SDWA Hotline

The CCR regulation also requires utilities to send the CCR to customers annually, by July 1 of each year, and to provide methods to get the report in languages other than English if English is not the primary language for a significant portion of customers.

Revisions of the PNR provide another avenue for consumer education. Public notification has always been a part of the NPDWRs; however, over the years, this component has evolved with each new NPDWR. USEPA conducted a stakeholder effort from 1998 to 1999 to revise to the PNR and published the revised PNR in 2000 (USEPA, 2000). The objectives of the revised PNR are to provide faster notice in the event of an emergency, provide fewer notices overall in order to minimize confusion, and ensure that public notices are easy to understand by using clearer language and less scientific and technical jargon. USEPA and the stakeholders developed new guidance for the revised PNR that includes several templates that utilities can use for compliance.

OTHER COUNTRIES AND INTERNATIONAL STANDARDS

Canada

In Canada, drinking water guidelines are developed by Health Canada; if they choose to, the provinces and territories use these guidelines as a basis for developing enforceable standards. This regulatory approach is different from the U.S. regulatory approach in that the provinces and territories are not required to adopt the Health Canada guidelines. Health Canada's Water Quality and Health Bureau takes the lead by developing *Guidelines for Canadian Drinking Water Quality* through a collaborative effort with the provinces, territories, utilities, and the public. Development of the Guidelines generally parallels USEPA's regulatory development process, with the initial identification of substances that have been found in source waters and are known or suspected to be harmful. A maximum acceptable concentration (MAC), which is comparable to USEPA's MCL, is then established. More information on the Canadian guidelines can be found at the Web site listed in the section "The Internet as a Resource."

Australia

Australia's regulatory approach warrants discussion because it is based on a preventive risk management approach for water supplies. This approach was jointly developed by the Cooperative Research Centres and the National Health and Medical Research Council

(NHMRC). The 2004 *Australian Drinking Water Guidelines* (ADWG) were developed by the NHMRC, in collaboration with the Natural Resource Management Ministerial Council (NRMCC). The guidelines incorporate a “Framework for the Management of Drinking Water Quality” and provide guidance on what constitutes safe drinking water. This risk-based approach takes a holistic view of the watershed and/or aquifer, treatment plant, and distribution system; analyzes for any potential weaknesses or vulnerabilities; and then develops a plan to address these potential weaknesses or vulnerabilities. This approach is comparable to the Hazard Analysis and Critical Control Point (HACCP) framework that is used in the United States for food production and supply. A report by the Awwa Research Foundation (now the Water Research Foundation) evaluated application of the HACCP framework for distribution system protection at two water utilities. However, this regulatory approach does not easily fit within the current SDWA framework of contaminant-by-contaminant regulation (AwwaRF, 2006). More information on the Australian guidelines can be found at their Web site (see “The Internet as a Resource”).

European Union

The European Union (EU) is a voluntary economic alliance consisting of several European countries. The Drinking Water Directives (DWDs) for drinking water quality developed by the EU must be adopted by the individual countries in order to remain an EU member state. Comparable to regulations established by USEPA, the enforceable drinking water standards developed by the EU member states must be at least as strict as the limits established in the DWD. The member states can regulate additional parameters beyond the parameters in the DWD, but cannot adopt stricter standards. The DWD, Council Directive 98/83/EC, addresses the quality of water intended for human consumption and lists 48 parameters that must be monitored and tested regularly. The European Commission started a review of Directive 98/83/EC in 2003 with a large public consultation. Member states report back to the European Commission every three years with their monitoring results. Generally, the WHO guidelines for drinking water are used as the basis for the DWD standards. More information the EU standards can be found at their Web site (see “The Internet as a Resource”).

World Health Organization

The World Health Organization (WHO) is a specialized agency within the United Nations with the primary responsibility of protecting international public health. The WHO produces international guidelines for drinking water quality that are used as the basis for regulation and standard setting by both developing and developed countries. Every country considers a broad range of environmental, social, cultural, and economic factors when determining which guidelines to adopt as their own standards. The 2004 *Guidelines for Drinking Water Quality* introduced the concept of Water Safety Plans, which shifts the regulatory focus from control of the drinking water at the end of the treatment plant or at the tap toward managing drinking water quality from the watershed, through the treatment plant, and through the distribution system. More information on the WHO guidelines can be found at their Web site (see “The Internet as a Resource”).

OUTLOOK FOR THE FUTURE

The SDWA is the starting point for U.S. drinking water regulations. With competing legislative priorities in Congress, it is not likely that the SDWA will be significantly amended anytime soon. The risk management and regulatory development process used by USEPA

will continue to evolve as more research is conducted and more contaminants are evaluated as potential candidates for regulation. As analytical methodologies continue to improve the ability to measure extremely low levels of contaminants, previously undetected contaminants will likely be found in some drinking water supplies. These emerging contaminants may generate public concern because of the uncertainty of their impact on public health at these low levels. Emerging contaminants such as endocrine disruptors, pharmaceuticals, and personal care products will need to be addressed through USEPA's regulatory development processes, using both the SDWA and other environmental statutes, such as the Clean Water Act (CWA) and Food Quality Protection Act (FQPA). States and PWSs will continue to be challenged by more regulations with more inherent complexities that will continue to stress limited resources. The public will continue to be interested in the safety of their drinking water, based on their own growing interest and the stories that will appear in the media.

The U.S. population will continue to grow. Currently, most population growth is projected to be in the southern half of the United States where water quantity and water quality problems will continue to increase. Utilities, regulators, and the public must remain vigilant in protecting existing source waters; finding new sources of water; and raising enough capital to build the appropriate transmission, treatment, and distribution facilities. The future will pose many challenges to keeping water safe and secure.

THE INTERNET AS A RESOURCE

Since the mid-1990s, the Internet has become an increasingly valuable resource for information on drinking water regulations. But one must be careful, because as with many issues, information overload can occur. In 2008, more than 8 million hits resulted when "drinking water regulations" was searched on Google™.

Many government Web sites are now the most direct source for copies of *Federal Register* notices, guidance documents, background documentation, NDWAC reports, and other information. The starting point for any research on U.S. drinking water regulations is the USEPA's Office of Ground Water and Drinking Water Web site (water.epa.gov/drink/index.htm). This Web site is a virtual treasure trove of drinking water regulatory information and has links to electronic copies of *Federal Register* notices dating back to May 1996.

Copies of *Federal Register* notices can also be found on the Government Printing Office's Web site (www.gpoaccess.gov/fr/). Dating back to 2000, the table of contents can be searched, but the publication date of the specific *Federal Register* notice is needed in order to search the table of contents.

Background documentation, such as the economic analysis (EA) and the technology and cost (T&C) documents, can be found through a federal government clearinghouse Web site (www.regulations.gov). For example, searching by the docket number greatly simplifies the search for background documentation on a proposed drinking water regulation. Without the docket number, searching through this Web site can be challenging.

Other useful government Web sites include:

- Office of Management and Budget (OMB); www.whitehouse.gov/omb/inforeg_default
- U.S. Geological Survey (USGS); <http://water.usgs.gov/>
- U.S. Department of Health and Human Services, Centers for Disease Control and Prevention (CDC); www.cdc.gov/healthywater/drinking/index.html
- U.S. Department of Homeland Security (DHS), Office of Infrastructure Protection; www.dhs.gov/xabout/structure/gc_1185203138955.shtm

- U.S. Department of Agriculture (USDA) Rural Development Utilities Programs, Water and Environmental Programs; www.usda.gov/rus/water
- The following drinking water associations can also be a useful source of information:
 - American Water Works Association (AWWA); www.awwa.org
 - Association of State Drinking Water Administrators (ASDWA); www.asdwa.org. Web sites for state drinking water programs can generally be found by searching on the state name followed by “drinking water”.
 - Association of Metropolitan Water Agencies (AMWA); www.amwa.net
 - National Rural Water Association (NRWA); www.nrwa.org
 - National Association of Water Companies (NAWC); www.nawc.com
 - Water Research Foundation; www.waterresearchfoundation.org

Government Web sites (outside of the United States) that are useful sources of information on international drinking water standards include:

- Health Canada; www.hc-sc.gc.ca/ewh-semt/water-eau/drink-potab/index-eng.php
- European Union; http://ec.europa.eu/environment/water/water-drink/index_en.html
- World Health Organization; www.who.int/water_sanitation_health/dwq/en
- Australia; www.nhmrc.gov.au/publications/synopses/eh19syn.htm

DISCLAIMER

This chapter does not necessarily reflect the views and policies of USEPA nor does the mention trade names or products constitute endorsement or recommendation for their use.

ABBREVIATIONS

ADWG	Australian Drinking Water Guidelines

Microbiological and chemical contaminants in drinking water may cause acute or chronic health effects or undesirable aesthetic properties when present at excessive concentrations. Hence, health and aesthetic concerns are the principal motivations for water treatment. This chapter summarizes the approaches used to develop the health and aesthetic basis for drinking water standards and guidance, and the health and aesthetic effects of the major groups of contaminants found in drinking water. Following an introductory discussion of waterborne disease outbreaks, specific pathogenic organisms and indicator organisms are discussed. For chemical contaminants, basic concepts of toxicology and risk assessment for chemical and microbial contaminants are presented, followed by separate sections on inorganic constituents, organic compounds, disinfectants and disinfection by-products (DBPs), and radionuclides. Emphasis is placed on contaminants that occur more frequently and at levels that are of concern for human health as well as emerging contaminants of recent interest. Taste and odor, turbidity, color, mineralization, and hardness are discussed in the final section, which is devoted to aesthetic quality.

Because of space considerations, citations have been limited to those most generally applicable, especially those from U.S. governmental organizations such as the U.S. Environmental Protection Agency (USEPA) and the Centers for Disease Control and Prevention (CDC). A general reference for toxicology is Klaasen (2007). For risk assessment, general references are the USEPA risk assessment documents listed in the guidance section of the USEPA Integrated Risk Information System (IRIS) Website. Useful sources of information on health effects,

occurrence, and environmental fate and transport of specific contaminants include the National Academy of Sciences series on drinking water, the Toxicological Profiles produced by the Agency for Toxic Substances and Disease Registry (ATSDR) of the CDC, the USEPA IRIS database, the World Health Organization (WHO) Guidelines for Water Quality, which will be updated in 2010, and the National Library of Medicine's Toxnet/Hazardous Substances Data Bank (HSDB) and PubMed databases. The Internet websites for these resources are provided at the end of this chapter.

As mentioned in Chap. 1, some states have established standards for some contaminants that are more stringent than the federal standards. More stringent standards may be based on different interpretation of the health effects information, improved capabilities of available analytical methods, or a more favorable cost-benefit analysis, reflecting the local conditions. States may also establish standards or guidance for additional contaminants not regulated on a national basis.

For chemicals, emphasis has been given to potential health effects from long-term exposure to concentrations that may occur in drinking water rather than to the effects of acute poisoning by much higher concentrations. Where the effects are markedly different between routes of exposure, effects from oral exposure rather than inhalation are emphasized. This chapter is intended as an introductory overview of information on health effects and occurrence of drinking water contaminants. The cited references and public health officials should be consulted when evaluating specific situations of contamination. This chapter does not address acute poisoning situations. Effects of acute poisoning are addressed in other handbooks and Internet Websites. If such poisoning has occurred, local poison control authorities should be consulted.

WATERBORNE DISEASE

From 1993 through 2006, the CDC reported 203 waterborne disease outbreaks in the United States and its territories, with a total of 418,894 actual or estimated cases of illness (Table 2-1). The responsible agent was not identified in 50 (25 percent) of these outbreaks, while microbes caused 119 (59 percent) and chemicals caused 34 (17 percent) of the outbreaks. The data include an estimated 403,000 illnesses from the 1993 *Cryptosporidium* disease outbreak in Milwaukee, Wis., but this number has been questioned due to recall bias (Hunter and Syed, 2002). The data also include 26 disease outbreaks (156 cases and 12 deaths) caused by *Legionella* following exposure to water intended for drinking for the period 2001 through 2006. *Legionella* data were not available prior to 2001; thus the outbreak data are underrepresented in this regard. Much of the disease burden involves gastrointestinal (GI) illness, but a variety of other, more serious illnesses also occur (e.g., pneumonia, hepatitis). This reporting period was selected because 1993 was the year when compliance with most provisions of the USEPA Surface Water Treatment Rule was required (USEPA, 1989a). All provisions of the USEPA Total Coliform Rule (TCR) were in effect at the start of 1991 (USEPA, 1989b). The last year for which data are available is 2006.

If outbreaks caused by a source other than a community or a noncommunity water system (e.g., illnesses caused by contaminated bottled water or container, consuming non-potable water, water from private systems, or water from systems serving fewer than 15 residences) are excluded from the data, there were 144 outbreaks affecting 417,468 persons, including 23 outbreaks (16 percent) caused by chemicals affecting 281 persons. Excluding the caseload from the large 1993 Milwaukee *Cryptosporidium* outbreak, the outbreaks due to *Legionella*, as well as the outbreaks in U.S. territories, between 1993 and 2006 the number of disease outbreaks and cases of illness caused by exposure to contaminated water linked to a community or non-community water system in the United States was 122 and 14,324, respectively. This equates to a 14-year

TABLE 2-1 Agents Causing Waterborne Disease Outbreaks in the United States and Territories, 1993–2006^{a,b}

Agent	Number of outbreaks	Footnote	Percent	Number of cases of illness

^aAn outbreak is defined as: (1) two or more persons experience a similar illness after consumption or use of water intended for drinking, and (2) epidemiologic evidence implicates the water as a source of illness. A single case of chemical poisoning constitutes an outbreak if a laboratory study indicates that the water has been contaminated by the chemical.

^bData are from Kramer et al. (1996), Levy et al. (1998), Barwick et al. (2000), Lee et al. (2002), Blackburn et al. (2004), Liang et al. (2006), and Yoder et al. (2008).

^cLegionella data are from 2001–2006. Only includes illness data for water intended for drinking.

^d*Legionella pneumophila* (20), *L. micdadei* (1), *Legionella* spp. (5); *Shigella sonnei* (4) and *Shigella flexneri* (1); *Salmonella* Typhimurium (3), *S. Bareilly* (1).

^eU.S. territories: 1 = one outbreak from the Virgin Islands; 2 = Mariana Islands (Saipan) and Marshall Islands; 3 = Palau.

ⁱOne outbreak each due to: ethylene glycol; bromate and disinfection by-products; ethyl benzene, toluene, and xylene; gasoline by-products; chlorine; unknown chemical.

average of 9 outbreaks and 1023 illnesses per year. Of the 63 (52 percent) outbreaks (6193 cases) that had a community water system as the source, a review of the outbreak details revealed that at least 26 (41 percent), likely more, were caused by events that occurred after delivery of water to the customer. Although 63 percent of the 144 outbreaks involved public water systems (PWSs) using groundwater sources, 91 percent of the PWSs in the United States use groundwater sources (www.epa.gov/safewater/databases/pdfs/data_factoids_2008.pdf). Furthermore, although the USEPA Ground Water Rule (GWR) treatment requirements did not become effective until December 2009 (USEPA, 2006b), many states have had treatment requirements in place for many years for PWS using groundwater sources.

Disease outbreak reporting is voluntary, and cases must be diagnosed and characterized as waterborne. As such, the number of outbreaks and cases are underrepresented in some states, given their respective populations. The summer peak in outbreaks is explained by the many outbreaks that occur at seasonal venues such as summer camps, fairs, and resorts (Table 2-2). Harder to explain is the smaller number of outbreaks that occurred in winter as opposed to the other seasons at year-round venues such as homes, communities, and various facilities.

TABLE 2-2 U.S. Disease Outbreaks by Source Venue and Season, 1993–2006*

Source venue [†]	Total	Season [‡]			
		Winter	Spring	Summer	Fall
Year-round					
Homes	78	11	21	27	19
Facilities	64	10	11	22	21
Total	142	21	32	49	40
Seasonal					
Recreation	43	0	3 (May)	36	4 (3 Sep.)
Winter recreation	4	3	1 (Mar.)	0	0

*Data are from Kramer et al. (1996), Levy et al. (1998), Barwick et al. (2000), Lee et al. (2002), Blackburn et al. (2004), Liang et al. (2006), and Yoder et al. (2008). Outbreaks due to contaminated containers (11), unknown season (2), or multiple seasons (1) not included.

[†]Homes = homes, apartments, condominiums, mobile home parks, communities. Facilities = restaurants (including golf course restaurants), hotels, inns, schools, churches, offices, factories, stores, medical care centers, other. Recreation = camps, fairs/fairgrounds, parks, sport camps/events/venues, resorts/resort areas (except winter resorts).

[‡]Winter = Dec. to Feb.; spring = Mar. to May; summer = Jun. to Aug. fall = Sep. to Nov.

Disease outbreak data do not include sporadic or endemic cases of illness. For several reasons, the number of reported outbreaks and illnesses is a small proportion of the total waterborne disease burden in the United States. The amount of GI illness attributable to public drinking water systems in the United States each year has been estimated to be between 4 and 33 million cases (Colford et al., 2006; Messner et al., 2006). If disease endpoints other than GI illness were included, even higher numbers of cases would result. It should also be noted that a portion of the total population exposed to any disease-causing agent does not become ill. People whose infections are asymptomatic may become “carriers,” capable of spreading disease through the shedding of the infectious agent in their feces and other excretions. This topic is discussed further under Microbial Risk Assessment in the section on Risk Assessment of Drinking Water Contaminants.

PATHOGENIC ORGANISMS

Pathogenic organisms are microorganisms capable of causing disease after getting past host barriers and defenses and multiplying within the host. A number of characteristics and circumstances determine whether or not a microorganism is a pathogen or a harmless or even beneficial member of a host's microbial community (Falkow, 1997). For example, uptake of a bacterial virus or "plasmid" carrying "virulence genes" can convert some types of harmless bacteria into pathogens. Readers who desire information on waterborne pathogens beyond what can be included in this chapter are encouraged to consult the most recent edition of *Waterborne Pathogens* (AWWA, 2006), as well as other recent reviews (e.g., Szewzyk et al., 2000; Leclerc, Schwartzbod, and Dei-Cas, 2002; Cotruvo et al., 2004; Craun et al., 2006). Recent pathogen-specific reviews are cited throughout this section.

The three categories of pathogenic microorganisms that can be transmitted by water are bacteria, viruses, and protozoan parasites (Table 2-1). Disease agents in these categories were responsible for 63 (31 percent), 17 (8 percent), and 35 (17 percent) of the disease outbreaks, respectively (multiple groups were involved in four outbreaks). Due to diagnostic limitations, many of the outbreaks caused by an unknown agent are likely caused by a virus. Although a variety of fungi have been identified in water (Hageskal et al., 2006), there are no documented waterborne disease outbreaks due to fungi in the United States, and there is little if any evidence of potential adverse health effects due to waterborne fungi. Many fungi are pathogenic to humans, but exposure is mostly by airborne inhalation or direct dermal contact. A fourth category, cyanobacteria (blue-green algae), is covered separately. Cyanobacteria are not pathogens. However, excessive growth (blooms) in rivers, lakes, and reservoirs can result in the release of taste- and odor-causing chemicals that can be difficult and expensive to remove during treatment. Some types of cyanobacteria can also produce toxic chemicals, which have harmed wild and domestic animals and, on rare occasions, humans (Carmichael, 2001).

A term increasingly used is *emerging pathogen* or *emerging infectious disease*. The CDC defines emerging diseases as those in which "the incidence in humans has increased in the past two decades or threatens to increase in the near future" (www.cdc.gov/ncidod/EID/about/background.htm). Emerging diseases include those resulting from: (1) a new pathogen created as a result of a change or evolution of an existing organism; (2) a known pathogen spreading to a new geographic area or population; (3) a previously unrecognized pathogen, including those appearing in areas undergoing ecologic transformation; and (4) previously controlled infections reemerging as a result of antimicrobial resistance or breakdowns in public health measures. Some of the pathogens discussed below are considered to be emerging pathogens.

Every biological species except viruses bears a two-word italicized name in Latin. The first word, always capitalized, is the genus (e.g., *Escherichia*). The second name is the species name, not capitalized, and there is usually more than one species for any given genus (e.g., *Escherichia coli* [*E. coli*], *Escherichia hermannii*, etc.). Species are further differentiated as to the types of antigens (protein and carbohydrate molecules) on their surface to which host immune systems respond (serotypes, e.g., *E. coli* O157:H7). For the genus *Salmonella*, what appear to be species names are actually serotypes with the serotype capitalized (e.g., *Salmonella enterica* serotype Typhimurium or simply *Salmonella* Typhimurium). Species can also be differentiated by genetic differences ("genotypes"), their mode of action (e.g., enteroinvasive *E. coli* (EIEC), enterohemorrhagic *E. coli* (EHEC), etc.), or other characteristics.

In nature in general and in source waters and drinking water distribution systems in particular, microbes exist primarily in "biofilms": diverse communities of protozoa,

bacteria (and their secretions), and viruses. Microbial interactions in this environment are constant. For example, viruses (phage) infect bacteria, protozoans feed on bacteria and each other, and bacteria compete with one another. Some bacteria have evolved mechanisms to survive and multiply within protozoa, most notably, *Legionella*, but also other bacterial pathogens (Harb, Gao, and Abu, 2000; Snelling et al., 2006a). Microbial characteristics in this environment, such as survival and resistance to disinfection, can be quite different than when grown in isolation (King et al., 1988; Eboigbodin, Seth, and Biggs, 2008). For example, in the natural environment, the function of antibiotic compounds is not to kill or inhibit the growth of other organisms (with some exceptions) but rather to serve as signaling molecules to communicate and interact with other microbes (Mlot, 2009).

Bacteria

Bacteria are single-celled prokaryotic microorganisms, meaning that their cellular architecture is different from that of the eukaryotic cells of protozoa and animals or of the archaea, which are bacteria-like microorganisms with their own unique architecture. A few types such as *Clostridium* and *Bacillus* can develop into resting endospores that can withstand extreme environmental stresses. Bacteria exist in a variety of shapes, but two common shapes are spheres (cocci) and round-ended rods (bacilli). Typical sizes range from 0.5 to 8 μm , but smaller and larger sizes exist. Some bacteria exist in colonies as clumps, sheets, or chains.

Bacteria reproduce by binary fission. Of the three main groups of pathogens, bacteria are the only group with members capable of growth (reproduction) outside of their host. Many bacteria, including many clinically important pathogens, can be grown in the laboratory. Bacteria occur in feces in high concentrations (e.g., 10^7 to 10^{11} per gram). Some pathogens are aerobes requiring oxygen for growth, while others are anaerobes that are killed in the presence of oxygen (but anaerobic *Clostridia* can form endospores that remain viable in the presence of oxygen). Another group, facultative anaerobes, can thrive in the presence or absence of oxygen. Of the many bacteria in nature, only a few cause disease. Many bacterial infections can be treated with antibiotics. Because of the extensive use of antibiotics in hospitals and farms over many years, a number of bacterial pathogens have developed resistance to many antibiotics. Bacterial pathogens of current interest are described below.

Enteric Bacteria. Until the early 1900s, enteric bacteria were responsible for many waterborne disease epidemics worldwide. Epidemics of typhoid fever (caused by *Salmonella Typhi*), dysentery (*Shigella dysenteriae*), and cholera (*Vibrio cholerae*) were not uncommon and resulted in considerable mortality. Following the advent of clean water technologies (Cutler and Miller, 2005) and improvements in hygiene in the early 1900s, disease outbreaks due to these bacteria no longer occur in the United States, but they continue to occur in countries with inadequate sanitation. Although self-limiting gastrointestinal illness is the primary symptom in most cases of illness caused by enteric bacteria, other types of illnesses occur, and some outbreaks have resulted in hospitalizations and mortality.

Enteric bacteria are members of the family Enterobacteriaceae. Members of this family are foodborne as well as waterborne pathogens that are able to infect exposed persons by the fecal-oral route. For waterborne outbreaks, this usually means drinking water that is contaminated with human or animal feces from which these pathogens are derived. Between 1993 and 2006, species of enteric bacteria in the genera *Escherichia*, *Shigella*,

Salmonella, *Plesiomonas*, and *Yersinia* were identified as causative agents in 26 waterborne disease outbreaks in the United States (Table 2-1). Although all of these pathogens can cause gastroenteritis, infection with enterohemorrhagic *E. coli* O157:H7 can result in bloody diarrhea. In susceptible persons, particularly children and the elderly, this infection can sometimes progress to hemolytic-uremic syndrome whereby kidney failure can result in serious illness or death (Yoon and Hovde, 2008). Cattle and other ruminants are significant sources of *E. coli* O157:H7. A few other *E. coli* strains can also cause hemorrhagic disease, and strains of enterotoxigenic *E. coli* can cause a mild to severe watery diarrheal illness in young children and travelers (Hunter, 2003).

Enteric-like Bacteria. Enteric-like bacteria are found in feces and transmitted by the fecal-oral route of exposure, but they are also found in various aquatic niches. Drinking water-related genera in this group include *Vibrio* and *Aeromonas*. *Vibrio cholerae* can cause gastroenteritis. Two toxin-producing serotypes, *V. cholerae* O1 and O139, can cause cholera, a disease characterized by profuse watery diarrhea leading to dehydration and loss of electrolytes. In the developing world, lack of access to rehydration therapy and medical care are causes of considerable illness and death from cholera. *V. cholerae* caused disease outbreaks in two tropical U.S. territories (Kramer et al., 1996; Blackburn et al., 2004).

Aeromonas hydrophyla and other aeromonads are commonly found in the environment, including distribution system biofilms. Only a few strains of *A. hydrophyla* are human opportunistic pathogens. They can cause gastroenteritis as well as a number of other more serious illnesses that can develop following wound infections. Waterborne transmission is possible but not proven (Borchardt, Stemper, and Standridge, 2003).

Treated water from a properly operated water treatment system (i.e., in compliance with all pathogen-related regulations) should be free of enteric and enteric-like bacteria. These organisms are inactivated by all disinfectants commonly used in water treatment. Disease outbreaks caused by these bacteria have only occurred after consumption of water that was untreated, inadequately treated, or contaminated following treatment, such as by cross-connections or back-siphonage within the distribution system or by use of a contaminated container.

Campylobacter. *Campylobacter* spp. are genetically related to *Helicobacter* spp. (see below) and, like *Helicobacter*, have a helical shape but are otherwise like enteric bacteria in terms of being a leading cause of foodborne and waterborne gastroenteritis (Moore et al., 2005). Between 1993 and 2006, species of *Campylobacter* were involved in 18 outbreaks, most involving the thermophilic species *C. jejuni* (Table 2-1). Other less frequent human infecting species include *C. coli* and *C. upsaliensis*. *Campylobacter* was also the agent responsible for most bacterial outbreaks in Canada (Schuster et al., 2005). Although infection with *Campylobacter* leads mostly to GI illness, in some cases, it can lead to Reiter's syndrome, which is an arthritic disease affecting the joints (~1 percent of cases); Guillain-Barré and Miller Fisher syndromes, which cause acute neuromuscular paralyses (~0.1 percent of cases); and other diseases (Peterson, 1994; Dorrell and Wren, 2007). Men are more susceptible to campylobacteriosis than women (Strachan et al., 2008). Domestic and wild birds are a significant source of *Campylobacter*, but a number of other warm-blooded animals including pets can also be sources. *Campylobacter* can remain viable in environmental waters for extended periods of time in a nonculturable state, and they can also form biofilms and infect free-living protozoa. As with enteric bacteria, *Campylobacter* is amenable to conventional water treatment and disinfection. A related genus, *Arcobacter*, contains several emerging foodborne and waterborne pathogenic species (especially *A. butzleri*) (Ho, Lipman, and Gaastra, 2006; Snelling et al., 2006b; Miller et al., 2007). *Arcobacter* have

been identified in water samples collected during two U.S. waterborne disease outbreaks involving *Campylobacter* and other agents (Figueras, 2008).

Helicobacter. This genus currently contains many named and unnamed gastric, intestinal, and hepatic species. The human-infecting species, *Helicobacter pylori* (*H. pylori*), is found in the stomach where it can cause gastritis. Most infected persons remain asymptomatic, but duodenal or gastric ulcer may develop in about 5 to 10 percent of cases. *H. pylori* also causes mucosa-associated lymphoid tissue (MALT) lymphoma and is a major risk factor for gastric adenocarcinoma (Kusters, van Vliet, and Kuipers, 2006).

In developed countries the mode of transmission of *H. pylori* appears to be mostly by person-to-person from *H. pylori*-containing vomitus, saliva, stools, or medical equipment. Some species, *H. pylori* included, can infect both humans and wild animals. Hence, animals may represent a source of spread among humans (Solnick and Schauer, 2001; On, Hynes, and Wadstron, 2002; Bellack et al., 2006).

The possibility of waterborne transmission of *H. pylori* is an area of active research. Once excreted into the environment, *H. pylori* quickly transits to a nonculturable *coccoid cell* state, which may (Cellini et al., 1994; She et al., 2003) or may not (Eaton et al., 1995; Kusters et al., 1997) be infectious. Some *Helicobacter* species can persist in water in a culturable state for only a few hours, but *H. pylori* can survive for days to weeks (Shahamat et al., 1993; Konishi et al., 2007; Azevedo et al., 2008), a period sufficient for exposure and infection in persons drinking untreated, fecal-contaminated water (Baker and Hegarty, 2001; Rolle-Kampczyk et al., 2004). *H. pylori* has been detected in surface and groundwaters by several investigators but has never been cultured from these sources, perhaps because of limitations of the assays used (She et al., 2003; Watson et al., 2004). *H. pylori* may gain entrance to drinking water distribution systems through either infiltration or treatment deficiencies and has been detected in distribution system biofilms in a nonculturable state (Park, MacKay, and Reid, 2001; Watson et al., 2004; Gao et al., 2008). *H. pylori* can also infect the protozoan *Acanthamoeba* (see below), remaining culturable for up to eight weeks (Winieka-Krusnell et al., 2002).

H. pylori is readily killed by concentrations of disinfectants typically used in drinking water treatment. As a possible corollary to this, infection rates of *H. pylori* in the United States (20 percent of people under age 40 and 50 percent over age 60) are decreasing to the point where some models show the organism gradually disappearing from the population over the next century (Rupnow et al., 2000).

Legionella. *Legionella* bacteria can cause legionellosis, which can be either a self-limiting febrile illness called Pontiac fever or a serious type of pneumonia called Legionnaires' disease with symptoms that are indistinguishable from pneumococcal pneumonia (Fields, Benson, and Besser, 2002). The primary human exposure route is thought to be the inhalation of aerosols of water containing high concentrations of *Legionella* such as during showering. Aerosol inhalation of *Legionella* containing waters from cooling towers and whirlpool spas are other common, nondrinking water-related exposure routes, but disease outbreaks derived from these sources are not included in the data in Table 2-1. Waterborne ingestion of low levels of *Legionella* is common, perhaps universal, but is not associated with disease.

The CDC began reporting disease outbreaks caused by *Legionella* bacteria in 2001. In the six-year reporting period 2001 through 2006, there were 26 outbreaks involving 156 cases and 12 deaths due to *Legionella* from "water intended for drinking" (Table 2-1) (Blackburn et al., 2004; Liang et al., 2006; Yoder et al., 2008). Thus, in the United States, *Legionella* causes more drinking water-related outbreaks (but not more cases), and probably more serious illness and mortality, than any other microorganism. An estimated 8000 to 18,000 persons are hospitalized with legionellosis each year in the United States (Marston et al., 1997).

Mortality rates from Legionnaires' disease used to be significant (15–30 percent) but have been falling since 1980 because of better and faster diagnosis and more widespread use of prophylactic antibiotic therapy (Diederer, 2008). Although a number of different *Legionella* species are frequently found in water distribution systems, about 91 percent of confirmed cases of community-acquired Legionnaire's disease are caused by *L. pneumophila*, and, of this species, 84 percent were *L. pneumophila* serogroup 1 (Yu et al., 2002). Of exposed individuals who become ill, most are elderly, smokers, or have weakened immune systems or underlying illnesses. About 20 other species have been implicated in human disease (Riffard et al., 2004).

Legionella are naturally occurring bacteria (not the result of fecal pollution) widely distributed in fresh water, including groundwater and wet soil (Riffard et al., 2004), mostly as a parasite of protozoa. Growth may occur in the environment in the presence of algae and cyanobacteria (Fliermans, 1996; WHO, 2002). Small numbers of these organisms can survive chlorination and have been found in distribution and plumbing system biofilms (Rogers and Keevil, 1992).

The organism can multiply within many different types of protozoan hosts (e.g., *Acanthamoeba* spp. and *Hartmanella* spp.), but only at temperatures above 20°C (Fliermans, 1996; Snelling et al., 2006a; Ohno et al., 2008). Environments such as hot water systems, showerheads, taps, and respiratory ventilators favor *Legionella* growth (Diederer, 2008). It is believed that the ability to multiply within protozoan hosts enables *L. pneumophila* to evade disinfection and to infect lung macrophages (phagocytic white blood cells) following inhalation.

It has been suggested that control actions should be taken whenever concentrations of *Legionella* exceed 0.1 colony-forming unit (CFU) per mL or when heterotrophic bacteria (see section on Indicators of Water Quality) exceed 10,000 CFU per mL (Health and Safety Commission, 2000; WHO, 2007). Some protozoan hosts can withstand high concentrations of chlorine and high temperatures for brief periods, and *Legionella* embedded within biofilms are also quite resistant to disinfection (Thomas et al., 2004; Loret et al., 2005). Thus, it is difficult to eliminate *Legionella* from plumbing systems. *Legionella* can be controlled in hot water storage tanks by keeping the temperature at 60°C, but high temperatures present a risk for scalding. The installation of thermostatically controlled mixing valves can eliminate the scalding risk (WHO, 2006). High concentrations of chlorine can eliminate *Legionella*, but such doses can corrode pipes. Therefore, most remediation contractors employ superheating to eliminate *Legionella* from building plumbing systems. However, some species can withstand 70°C for up to an hour and remain infective, so recolonization of plumbing systems following heat-shock treatment may occur (Allegra et al., 2008).

Mycobacteria. As with *Legionella*, *Mycobacteria* are free-living bacteria in water and soil (including plant potting soil) that often colonize water distribution systems. As with *Legionella*, *Mycobacteria* have been shown to be able to survive within a number of protozoa (Vaerewijck et al., 2005; Mura et al., 2006; Pagnier et al., 2009). Environmental mycobacteria (EM), including the so-called *Mycobacterium avium* complex (*M. avium* and *M. intracellulare*; MAC), can be waterborne pathogens under certain conditions (Pedley et al., 2004; Vaerewijck et al., 2005). MAC can infect the lungs or GI tract, particularly those of AIDS patients. Symptoms can include fatigue, cough, weight loss, and fever. In AIDS patients, the bacterium can cause debilitating disease and death. Some species of EM, MAC organisms in particular, have been isolated from water taps in medical facilities with the same species isolated from AIDS patients in those facilities; however, the degree of risk for either AIDS patients or healthy persons is unknown. The introduction of antiretroviral therapy for AIDS patients has reduced the amount of disease due to MAC and other mycobacteria (Jones et al., 1999). Many EM other than MAC organisms (e.g., *M. gordonae*, *M. kansasii*, *M. abscessus*, *M. fortuitum*, *M. xenopi*) have been found in water distribution

systems, often more frequently than MAC organisms, and some of these organisms have also been categorized as *opportunistic pathogens* associated with human disease.

Mycobacteria are resistant to various environmental stresses and water treatment disinfectants compared to most other waterborne bacteria and viruses (LeChevallier, 2006; Shin et al., 2008). The ability of *Mycobacteria* to persist in water distribution systems is associated with a complex cell wall, survival or growth at warm water temperatures, association with biofilms, and survival within protozoa. The role of protozoa in the persistence and virulence of EM in distribution systems and the resistance of EM to disinfection requires additional study.

Opportunistic Pathogens. For information on *Acinetobacter*, *Enterobacter*, *Klebsiella*, *Pseudomonas*, and other bacteria groups with species that are potentially pathogenic in persons with weakened immune systems or in other susceptible subpopulations such as burn patients, the reader is referred to AWWA (2006), Leclerc, Schwaartzbod, and Dei-Cas (2002), and Szewzyk et al. (2000). Increasing levels of antibiotic resistance are a growing problem in members of these and other genera (Taubes, 2008).

Viruses

Along with prions (misfolded proteins that can cause disease in some animals including humans) and viroids (small, circular strands of RNA that can infect some plants), viruses are among the smallest, most abundant infectious agents on earth. They range in size from 0.02 to 0.3 μm . They consist of a core of nucleic acid (either DNA or RNA) surrounded by a protein capsid or shell. Some viruses also have an outer host-derived lipid membrane. They depend on host cells for reproduction and have no metabolism of their own. Enteric viruses comprise a number of classes of viruses that infect the intestinal tract of humans and animals and are excreted in their feces (Carter, 2005; Nwachuku and Gerba, 2006). Most pathogenic waterborne viruses can cause acute GI disease, although some cause more severe illnesses. Enteric viruses that infect humans generally do not infect other animals and vice versa, although there are a few exceptions to this rule. Viruses that have caused or have the potential to cause waterborne disease are discussed next.

Norovirus and Other Calicivirus. Of the four groups that comprise the Calicivirus family (Caliciviridae), two can infect humans: noroviruses (NVs) and sapoviruses (SVs). Noroviruses were previously called small round-structured viruses (SRSV), human caliciviruses (HCV), or Norwalk-like viruses. Sapoviruses were previously called Sapporo-like viruses. With the exception of *Legionella pneumophila* and *Giardia lamblia* (see below), NVs have caused more identified waterborne disease outbreaks than any other biological agent. Because caliciviruses cannot be grown in the laboratory and because these viruses are highly infectious, many outbreaks of unknown etiology are likely caused by NVs (Schaub and Oshiro, 2000). In addition, because illness symptoms, acute gastroenteritis, are generally mild compared to those of some other agents, it is likely that many other NV outbreaks are never identified and thousands of additional cases are never reported. Indeed, NVs are estimated to cause 93 percent of the nonbacterial gastroenteritis in the United States (Fankhauser et al., 2002). NVs likely cause more cases of foodborne illness than any other pathogen.

Between 1993 and 2006, there were 15 identified waterborne disease outbreaks (3612 cases) in the United States due to NVs. Of the 12 outbreaks in which a cause was identified, 9 involved the consumption of untreated contaminated water (including two in which a chlorinator was not functioning), two followed a back-siphonage or cross-contamination event (with other possible causes in one), and one involved an improperly cleaned ice-making

machine. Transmission is mainly by the fecal-oral route, with person-to-person spread also playing an important role. Airborne transmission over short distances and spread by contaminated objects (fomites) may also facilitate spread during outbreaks (Parashar et al., 2001). Outbreaks due to the consumption of contaminated foods, particularly molluscan shellfish, are common. Historically, NV disease was often referred to as “winter vomiting disease,” reflecting the seasonal outbreak peak and one of the most common illness symptoms in addition to diarrhea.

Rotavirus. Although no waterborne disease outbreaks due to rotaviruses (RVs) have occurred in the United States in the past 14 years, outbreaks have occurred in earlier years and in other countries as well. RVs are responsible for a significant amount of disease, primarily among infants and young children (Gray et al., 2008). Symptoms in children include vomiting followed by watery diarrhea lasting four to seven days and fever. Most children are infected by age 2 to 3. Adults are susceptible, but in many cases, adults are asymptomatic, though still infectious. The annual pattern of infection in the United States, a winter peak with disease spreading from the west coast in late fall to the east coast in the spring, appears to be due in large part to interstate differences in birth rates (Pitzer et al., 2009). Dehydration can be rapid but can be combated with rehydration therapy. In the developing world, lack of access to rehydration therapy and medical care results in 600,000 to 900,000 deaths each year, which is 6 percent of all mortality of children under age 5 (Bass, Pappano, and Humiston, 2007). Death due to RV in the United States is rare (20–60 per year), but an estimated 477,000 medical care visits and 55,000 to 70,000 hospitalizations each year are a significant burden on health care resources and the economy (Parashar, Alexander, and Glass, 2006).

RVs are primarily transmitted by the fecal-oral route, but there is growing evidence of respiratory transmission as well. RVs have a low infectious dose (Ward et al., 1986) and can persist on surfaces for long periods of time and on hands for an hour or more, likely contributing to RVs apparent hand-to-mouth mode of transmission (Cook et al., 2004). RV is capable of surviving for weeks to months in surface and groundwaters in an infectious state (Caballero et al., 2004; Espinosa et al., 2008). Infection from livestock and pets has been reported but is uncommon (Cook et al., 2004).

Because natural infection confers significant immunity and because two U.S. Food and Drug Administration-licensed RV vaccines are available, the CDC now recommends routine vaccination for infants (Parashar, Alexander, and Glass, 2006; Cortese and Parashar, 2009). The vaccines protect against most, but not all, RV serotypes (Gentsch et al., 2005). Vaccine use has resulted in delayed onset and reduced severity of RV illness among children in the United States (Staat et al., 2008).

Hepatitis A Virus. Hepatitis A virus (HAV) is the sole member of the genus *Hepatovirus* within the small RNA virus family. It is the cause of most cases of infectious hepatitis, an inflammatory disease of the liver (Cuthbert, 2001). In countries with poor sanitation, most people are infected with HAV as children. Disease symptoms in children are either mild or absent and subsequent immunity is lifelong. In the United States and other industrialized countries, most people reach adulthood having never been exposed to HAV. Disease symptoms are generally more severe when the first HAV infection occurs in adulthood rather than childhood (www.who.int/mediacentre/factsheets/fs328/en/index.html). Hepatitis can involve liver inflammation, with symptoms of dark urine and subsequent jaundice (yellowing of skin and eyes due to the inhibition of hemoglobin breakdown) and death in rare cases. Acute disease lasts 2 to 4 weeks and full recovery can take 8 to 10 weeks, with excessive fatigue a common postinfection problem. Relapse occurs in some people. Between 1993 and 2006, two drinking water–related outbreaks occurred in the United States involving the consumption of untreated water from contaminated residential sources.

HAV is spread by the fecal-oral route and is quite stable under a variety of environmental stresses (Nasser, 1994). Travel remains a significant risk factor, as is close contact with an HAV-infected person. Food, especially contaminated shellfish, and waterborne etiologies are involved in about 7.5 percent of all cases. Considerable research is being directed at improved detection methods for this difficult-to-grow virus (Konduru and Kaplan, 2006).

Hepatitis A incidence has declined by 90 percent in the United States (to 1.2 cases per 100,000 persons) between 1995, the first year HAV vaccines were available, and 2006, especially in states where routine vaccination was recommended beginning in 1999 (Wesley, Grytdal, and Gallagher, 2008). However, with underreporting and asymptomatic cases taken into account, there are still an estimated 32,000 new infections each year. In 2006, it was recommended that children ages 12 to 23 months in all states receive an HAV vaccine. This practice should result in the eventual elimination of indigenous transmission in the United States (Fiore, Wasley, and Bell, 2006).

Hepatitis E Virus. A member of the small RNA virus family, Hepatitis E virus (HEV) is the sole member of the genus *Hepevirus* (Panda, Thakral, and Rehman, 2007). Like HAV, HEV is a fecal-oral pathogen. HEV is transmitted mostly by contaminated water in developing countries (Worm, van der Poel, and Brandstatter, 2002). Infection without illness is common. The clinical disease, hepatitis, has symptoms similar to those caused by HAV and other hepatitis viruses, except in pregnant women and their unborn children. In pregnant women, fulminant hepatitis is more common, and death rates can approach 25 percent in the third trimester (Kumar et al., 2004). The most susceptible age groups are young adults. The few cases that occur in the United States and other developed countries are mostly contracted during travel to countries in the developing world where HEV infection is endemic. Sporadic, nontravel-related cases occur mostly in men over age 50 who often have underlying medical conditions (Borgen et al., 2008). Sources of sporadic infections are unknown, but exposures to HEV-containing pigs, pig products, or other domestic or wild animals are possibilities.

Enterovirus. Enteroviruses are a group of more than 60 different types of small RNA viruses that commonly infect humans. They were formerly classified numerically within the groups Polioviruses, Coxsackieviruses, Echoviruses, and Enteroviruses but are now classified as either Polioviruses or Enterovirus groups A, B, C, and D (HEV-A, HEV-B, HEV-C, and HEV-D) but with traditional names kept for previously established serotypes. Echoviruses 22 and 23 have been reclassified as a new genus, *Parechovirus*, as parechoviruses 1 and 2, respectively. Enteroviruses are fecal-oral waterborne pathogens that are associated with a wide range of serious illnesses, including paralysis, aseptic meningitis, myocarditis, encephalitis, and neonatal sepsis. Less serious illnesses include conjunctivitis, mouth and throat sores, sharp abdominal pain, rashes, fever, and respiratory and GI illnesses. Most enterovirus detections occur from June through October. Infections can be acquired through contact with secretions from infected persons, contaminated surfaces, or contaminated water. Transmission to newborns from infected mothers also occurs. Unlike many other viral pathogens, many enteroviruses can be grown in laboratory cultures.

Polioviruses (serotypes 1, 2, and 3) were major worldwide pathogens until the advent of vaccines in 1955 and 1961 and the WHO's effort beginning in 1988 to eradicate these viruses. Acute flaccid paralysis (AFP), which develops in about 1 percent of all infections, mostly in children, is now due to serotypes 1 and 3. Serotype 2 was eradicated, but type 2 vaccine derived strains are now circulating in at least two countries (see below; Shulman et al., 2009; Roberts, 2009a). AFP still occurs in 18 countries, with India, Nigeria, Pakistan, and Afghanistan being the ultimate source of the viruses in the other 14 countries (CDC, 2007; Roberts, 2009b). Outbreaks of AFP due to mutated forms of the live but nonvirulent

oral vaccine derived polio virus (VDPV) also occur in these and other countries. Oral polio vaccines are no longer used in the United States and some other countries. The last cases of naturally acquired polio in the United States occurred in 1979, but four nonparalytic cases of VDPV in unvaccinated children were documented in the United States in 2005 (Bahta et al., 2005). A few enteroviruses other than polioviruses can also cause AFP (Dufresne and Gromeier, 2006; Khetsuriani et al., 2006).

About 15 types of enteroviruses (mostly HEV-B but also HEV-A serotypes) predominate in the United States, with echoviruses 9, 11, 33, and 6 and coxsackievirus B5 accounting for almost half of the 52,812 enteroviruses detected between 1970 and 2005 (Khetsuriani et al., 2006). Illness occurs most often in infants and young children in both epidemic and endemic patterns of infection. About 3.3 percent of the cases, mostly involving infants, are fatal, with fatality rates of 10 to 11 percent for coxsackievirus B4 and parechovirus 1. No disease outbreaks due to drinking water have been recorded in the United States since 1993, but recreational waterborne outbreaks have occurred.

Adenovirus. Adenoviruses (Ads) are among the few types of enteric viruses with a DNA core (Fong and Lipp, 2005). There are 51 numbered serotypes (e.g., Adenovirus 1, or Ad1) that can infect humans. As with many other pathogens, infants are most susceptible among persons with normal immune system function. Exposure is common, perhaps universal (Langley, 2005), and Ads are a common cause of childhood gastroenteritis. Persons with weakened immune systems are most susceptible to infection, with high rates of severe illness and mortality.

Some serotypes are shed in feces but cause respiratory (e.g., Ads 1 through 7) or eye disease (e.g., Ads 3, 7, and 14). These types can also spread via aerosol, direct contact, or sexual routes (Jiang et al., 2006; Langley, 2005). Ads 12, 18, and 31 may cause diarrhea on occasion, but infection usually results in inapparent illness in infants. Other serotypes are associated with GI illness but have not been proven to cause illness. However, there is probably sufficient evidence that Ad 40 and Ad 41 are waterborne pathogens that can cause diarrhea in infants.

Ads can be shed in the feces for months to years following infection. Ads are among the most frequently observed viruses in sewage and environmental waters (Katayama et al., 2008; Rodriguez, Gundy, and Gerba, 2008). Many Ads are difficult if not impossible to grow in laboratory cultures. Hence, much recent research has focused on the development of detection and quantitation assays.

Astrovirus. Astroviruses are members of the small RNA virus family that have a star-like appearance when viewed by electron microscopy (Mendez and Arias, 2007). Astroviruses are divided into two groups, Avastroviruses, which infect birds, and Mamastroviruses, which infect mammals. The human-infecting astroviruses (HAstV) are part of the latter group. HAstVs are a significant cause of mild, self-limiting GI illness throughout the world, especially among infants and young children (Walker and Mitchell, 2003). The elderly and persons with weakened immune systems are also at increased risk of illness. About 2 to 6 percent of diarrheal illness is caused by HAstVs in developed countries. Seasonal peaks occur in the United States, with a winter peak in western states and a late spring or early summer peak in the east. Water and foodborne transmission is likely but not proven. HAstVs are relatively stable in the environment (Abad et al., 2001; Espinosa et al., 2008). Secondary wastewater treatment appears effective in eliminating infectious HAstVs from sewage even without disinfection (El-Senousy et al., 2007).

Other Viruses. New detection methods have led to the discovery of other enteric viruses (Check, 2009). The reader should consult Gerba (2006) and Wilhemi, Roman, and Sanchez-Fauquier (2003) for additional information.

Protozoa

Protozoa, or more precisely protista, are single-celled eukaryotic organisms that vary greatly in size, but most are larger than bacteria. Unlike algae, they cannot perform photosynthesis. They are common in natural waters, moist soils, and as symbionts or parasites of animals and plants (Fayer, 1994; Marshall et al., 1997). Protozoans feed on bacteria, but some pathogenic bacteria such as *Legionella* (see above) have evolved to survive and multiply within these hosts (Snelling et al., 2006a). Protozoa often occur in the environment as resistant spores, cysts, or oocysts. These are dormant stages in the life cycle of the parasite that are resistant to adverse environmental conditions and allow the organism to survive until conditions improve or to facilitate its spread from one host to another. Such cysts and spores are often more resistant to chlorine and other oxidizing disinfectants than viruses and most bacteria with the exception of *Bacillus* and *Clostridium* endospores. Protozoa are found in surface waters and groundwaters directly influenced by surface waters. Worldwide, they have caused hundreds of disease outbreaks (Karanis, Kourenti, and Smith, 2007). A few of the pathogenic protozoa are described next.

Parasitic Protozoa. *Giardia lamblia* (syn. *Giardia intestinalis*, *Giardia duodenalis*) is the most common cause of diarrheal disease worldwide (Adam, 2001) and the second leading cause of drinking water disease outbreaks in the United States after *Legionella*. Between 1993 and 2006, *Giardia* caused or contributed to 25 outbreaks (Table 2-1). *Giardia* has also caused foodborne outbreaks on rare occasions. *Giardia lamblia* can infect many other animals in addition to humans; thus, animal wastes can be a source of human-infecting *Giardia*. The organism forms thick-walled oval cysts (6 to 10 μm wide and 10 to 15 μm long) in the host intestine prior to excretion in feces.

Exposure is by the ingestion of fecal-contaminated water, through direct fecal-oral contact (including touching contaminated objects) or, less commonly, from contaminated food. Summer peaks in disease incidence are due to the fact that *Giardia*, like *Cryptosporidium* (see below), is also a frequent cause of recreational disease outbreaks (Yoder and Beach, 2007). Groups at increased risk for contracting giardiasis include travelers to developing countries, young children, and homosexual males (Wolfe, 1992). Giardiasis is usually a self-limiting disease, but subacute or chronic infection can occur in some people. Most infections are without symptoms. Disease outbreaks occur only when untreated or insufficiently treated water is ingested.

Cryptosporidium includes a diverse group of organisms that, like some other protozoa, forms oocysts (thick-walled zygotes) in the intestines of infected host animals prior to excretion in feces. Oocysts are small in size, 4 to 5 μm in diameter. Oocysts from 13 named species and many more unnamed species are commonly found in the environment and they can infect a wide range of vertebrate hosts (Xiao et al., 2004). Each species has a limited host range but few, if any, are single host-specific. *C. parvum* (previously, bovine genotype, or genotype 2) and *C. hominis* (previously, *C. parvum* genotype 1; Morgan-Ryan et al., 2002) cause most human cases of cryptosporidiosis, and these organisms are second to *Giardia lamblia* in the number of disease outbreaks caused by protozoa. Between 1993 and 2006, 10 outbreaks were caused by these organisms, including the 1993 outbreak in Milwaukee, Wis., that sickened up to 25 percent of the city's population of 1.61 million. This outbreak together with the finding that most existing water treatment processes did not completely remove *Cryptosporidium* oocysts from the treated water (Aboytes et al., 2004) resulted in promulgation of the Enhanced Surface Water Treatment Rules in the United States (ESWTRs, see Chap. 1). The ESWTRs strengthen protection against infection from *Cryptosporidium* and other pathogens while minimizing the health risks from disinfection by-products (DBPs, see below). Humans and farm animals, especially young cattle, are the major sources of these two species. Ingestion of water contaminated with oocysts is

the primary mode of contracting cryptosporidiosis, but person-to-person transmission and contact with fecal-contaminated surfaces are also important causes, especially in child and elderly care centers. A few foodborne outbreaks have also been recorded.

Cryptosporidiosis is a self-limiting diarrheal disease in most people. The disease can be more severe in persons with advanced AIDS and other diseases involving impaired T-cell function (Hunter and Nichols, 2002). The introduction of antiretroviral therapy for AIDS patients has reduced the incidence of severe cryptosporidiosis (Jones et al., 1999).

Method 1623, which is used to enumerate *Cryptosporidium* in water (USEPA, 2001a), cannot differentiate species that can infect humans from those that infect other animals but not humans. Studies of surface waters using methods capable of differentiating species have shown that many oocysts detected in surface waters using Method 1623 are not likely to infect humans (e.g., Xiao et al., 2000; Yang et al., 2008).

The oocysts are not affected by chlorine concentrations used in water treatment, and their high chlorine resistance is the reason why *Cryptosporidium* is the most frequently recognized cause of outbreaks of gastroenteritis in treated recreational waters, such as swimming pools, water parks, and splash fountains (Yoder and Beach, 2007).

Isoospora are a large group of coccidian parasites in the phylum Apicomplexa, which also includes *Cryptosporidium* (Lindsay, Dubey, and Blagburn, 1997). The species that can cause diarrheal disease in humans, *Isoospora belli*, is a common parasite, especially in warm climates. This species produces large oval oocysts 10 to 19 μm wide and 20 to 33 μm long that resemble oocysts of *Toxoplasma* (see below) and, like *Toxoplasma* but unlike *Cryptosporidium*, require 24 hours or more to sporulate and become infectious for humans and other animals following excretion to the environment. Human exposure is by contaminated food or water. The disease is usually self-limiting, but the disease isosporiasis can be chronic and more severe in infants, young children, and especially persons with weakened immune systems such as AIDS patients.

Toxoplasma gondii is a common coccidian parasite of warm-blooded animals (most being *intermediate hosts*) that infects about 16 percent of the U.S. population ages 12 to 49 (Jones, Kruszon-Moran, and Wilson, 2003). Infection occurs by ingesting raw or undercooked meat or contact with soil, sand boxes, cat litter boxes, or water that has been contaminated by feces of domestic or wild cats (Tenter, Heckerth, and Weiss, 2000; Dubey, 2004). Only cats (the *definitive host*) can excrete *T. gondii* oocysts, which are 10 to 12 μm in diameter and require 1 to 21 days in the environment to sporulate and become infectious. Few symptoms occur in most healthy persons, but cysts can remain permanently in nerve, muscle, and other tissues. Fetal exposure from an infected mother can result in abortion or blindness, mental retardation, or epilepsy in the infant or it can remain a subclinical infection. Toxoplasmosis in AIDS patients and persons with weakened immune systems, following reactivation of tissue cysts, is the most frequent cause of severe or fatal encephalitis. The introduction of antiretroviral therapy for AIDS patients has reduced the occurrence of toxoplasmosis of the brain (Jones et al., 1999). Waterborne outbreaks are rare, but three outbreaks outside of the United States have been documented (Villena et al., 2004). Resistant oocysts can survive for months in the environment. Conventional filtration is usually effective in removing oocysts, but oocysts may be difficult to inactivate using disinfection during water treatment (Tenter, Heckerth, and Weiss, 2000; Wainwright et al., 2007).

Entamoeba histolytica is a human-specific pathogen that causes amoebic dysentery following ingestion of cysts from contaminated water or food (Haque et al., 2003). The disease prevalence worldwide is fourth behind AIDS, malaria, and schistosomiasis (Keene, 2006). In the United States, at-risk groups include male homosexuals, travelers and recent immigrants, and institutionalized populations. Infection can result in no symptoms in most cases to mild gastroenteritis and, less frequently, acute bloody diarrhea, fever, sometimes involving liver abscesses (predominantly in males), or a fulminant disease with significant mortality rates (Stanley, 2003; Stauffer and Ravdin, 2003). In 2002, there was an outbreak in the

U.S. territory of Palau involving 59 persons who drank untreated surface water. Waterborne disease outbreaks due to this organism are infrequent in the United States. *E. histolytica* contributed to a 1994 outbreak (424 cases) caused mainly by *Giardia*, which was due to a cross-contamination event at a Tennessee prison. A 2002 disease outbreak occurred at a New York apartment building in which a nonspiciated *Entamoeba* was identified along with *Campylobacter* and *Giardia* (morphologically indistinguishable species *E. dispar* and *E. moshkovskii* are nonpathogenic). This outbreak involved 27 persons who became ill after sewage contaminated a basement well.

Cyclospora cayentanensis has caused 11 or more known foodborne diarrheal disease outbreaks in the United States and Canada and is linked to imported foods such as raspberries and leaf vegetables including basil (Herwaldt, 2007). This organism is also suspected, but not proven, to be a cause of a few waterborne outbreaks, including a U.S. outbreak in 1990 (Huang et al., 1995). The organism is shed in the feces of infected persons as oocysts, which do not sporulate (become infectious) until days or weeks following excretion. The oocysts are 8 to 10 μm in size. The oocysts are usually removed by conventional treatment.

Microsporidia are a large group (~1200 species) of bacteria-sized parasitic organisms related to fungi (Hirt et al., 1999) and with spores possessing a characteristic polar filament or tube. They can infect a large number of animals and are shed in urine, feces, and other secretions (Didier and Weiss, 2006). Fourteen species have been shown to cause disease, sometimes chronic, in humans, with the most significant being *Enterocytozoon bieneusi* (causing diarrhea) and three species of *Encephalitozoon* (*E. intestinalis*, *E. hellem*, and *E. cuniculi*; causing disseminated infections). Prior to the advent of antiretroviral therapies, human-infecting microsporidia most often caused illness in persons with AIDS (Weber et al., 1994). Other at-risk groups include travelers, children, the elderly, and organ transplant patients. Microsporidiosis is likely a zoonotic disease, and waterborne transmission is possible but not proven.

Free-living Protozoa. Free-living protozoa that can also infect suitable hosts and cause illness are called amphizoic pathogens. *Naegleria fowleri* is a thermophilic organism commonly found in moist soils, water, and decaying vegetation that forms a dormant cyst at colder temperatures. Though commonly found in surface waters, *N. fowleri* rarely causes disease, with a 14-year total of 29 cases (2 per year) in the United States. Unfortunately, the disease, primary amoebic meningoencephalitis (PAM), is almost always fatal, with death occurring within 72 hours after symptoms (similar to viral and bacterial meningitis) first appear. Also, unlike encephalitis due to *Acanthamoeba* (see below), many cases of PAM involve young people. Most cases occur following swimming in warm fresh waters, with the transmission route being the nasal passage leading to the brain. In 2002, two young, unrelated individuals contracted fatal PAM in Arizona after being exposed to, but not consuming, untreated well water from the same water system (Marciano-Cabral et al., 2003). In this outbreak, *N. fowleri* was detected in the water storage tank and in refrigerator filter water. The DNA of *N. fowleri* has been detected in 11 (7.7 percent) of 143 wells in Arizona. The average water temperature of the positive wells was 29°C (Blair et al., 2008).

Acanthamoeba spp. is a group of amoeba commonly found in air, soil, and water including swimming pools, spas, and drinking water (Nwachuku and Gerba, 2004). Exposure to these organisms by way of the eyes, nose, lungs, or breaks in the skin is common, but illness is rare. A few species can cause inflammation of the cornea in some people, most often in contact lens wearers exposed to water containing these organisms. These and other species, as well as the related organism *Balamuthia mandrillaris*, can also cause granulomatous amoebic encephalitis (GAE), a fatal disease in persons with weakened immune systems (Martinez and Visvesvara, 1997; Marciano-Cabral and Cabral, 2003). In addition to being pathogenic, *Acanthamoeba* can be hosts for a number of pathogenic bacteria, including important waterborne pathogens such as *Legionella*, *Mycobacteria*, *Helicobacter pylori*,

and enteric and similar bacteria (see above and Snelling et al., 2006a). These bacterial–protozoan interactions enhance the survival capacity (Laskowski-Arce and Orth, 2008) and the antibiotic and disinfectant resistance of the bacteria, as well as the virulence of both entities. Control of these bacteria in drinking water distribution systems requires control of *Acanthamoeba* and other protozoan hosts (e.g., *Hartmannella*). The sizes of the amoeboid and cyst stages (13 to 40 μm) are fairly large, and effective removal by conventional treatment is likely (Marciano-Cabral and Cabral, 2003).

Other Protozoa. Other protozoa that have been identified as the cause of one or two water-borne diarrheal disease outbreaks worldwide include *Balantidium coli* and *Blastocystis hominis* (Karanis, Kourenti, and Smith, 2007). Feces from pigs, humans, and primates are sources of *B. coli* cysts, which are large (50 to 70 μm in size). Removal by conventional treatment is expected. Most human infections occur in warm climates. *B. hominis* have been observed in many types of animals, but its role as a disease agent is still under study. *B. hominis* cysts (*central body forms*) are 6 to 40 μm in size. More information on these parasites, as well as few multicellular parasites of soil and water, can be found in the AWWA Manual 48 (AWWA, 2006).

Cyanobacteria

Cyanobacteria are often referred to as blue-green algae, but they are photosynthetic bacteria and not algae. They can be unicellular or filamentous (colonial) organisms. They are not pathogens, but excessive growth of cyanobacteria in source waters can lead occasionally to the production of chemicals with undesirable tastes or odors (see Aesthetic Quality section) and toxic chemicals (Chorus and Bartram, 1999).

A number of free-floating, toxin-producing strains of cyanobacteria (e.g., *Microcystis*, *Oscillatoria*, *Anabaena*, *Nostoc*) can produce several classes of toxic chemicals, primarily liver toxins and nerve toxins (Haider et al., 2003). The liver toxins (hepatotoxins) include cylindrospermopsin (CYL) and families of microcystin (60 types) and nodularin (6 types). In addition to the liver, CYL can also affect the kidneys, thymus, and heart. The neurotoxins include a family of anatoxin (3) and saxitoxin (20) compounds (Briand et al., 2003) and β -*N*-methylamino-L-alanine (BMAA) (Cox et al., 2005). The function of these toxins in nature is uncertain. They may protect their producers from protozoan predators and/or give a competitive growth advantage over nontoxin-producing cyanobacteria and algae (Wiegand and Pflugmacher, 2005; Welker and von Döhren, 2006), but other functions are possible (Mlot, 2009).

Cyanotoxins have been linked to multiple episodes of illness and death in wild and domestic animals and, on rare occasions, have caused illness and death in humans (Carmichael, 2001). In 1996, intravenous exposure to hepatotoxins at a dialysis center in Brazil caused the death of 76 of 131 people (Carmichael et al., 2001). These and other toxins can also cause respiratory and allergic reactions and gastroenteritis in humans. BMAA is hypothesized to be associated with motor neuron diseases such as Alzheimer's and Parkinson's disease. Some of these toxins also have cancer-promoting effects. Thus, even low concentrations in drinking water are of concern. The WHO has set a guideline of 1 $\mu\text{g/L}$ for microcystin-LR and is proposing the same concentration for CYL in drinking water (Rodriguez et al., 2007). Currently, there is insufficient information to set acceptable levels for any of the other microcystin toxins (e.g., microcystin-LA, -YR, -YM, etc.) or for any of the other hepatotoxins or neurotoxins.

These toxins are produced following algal bloom events in eutrophic lakes and rivers. The toxins are cell-bound and are released upon death or aging of the organisms. As such, algicide treatment of cyanobacterial blooms in lakes and reservoirs or chemical disinfection can

increase waterborne toxin levels. In addition to potential drinking water exposure, human exposure can occur during water recreation or consumption of cyanobacterial health food products. Conventional water treatment has been shown to reduce microcystin concentrations in U.S. waters by 90 to 99.9 percent (Karner et al., 2001; Haddix, Hughley, and LeChevallier, 2007). Chlorine disinfection alone may not be sufficient to reduce high concentrations of anatoxin-a to safe levels, and chloramine disinfection may not be effective against any of the cyanotoxins (Rodriguez et al., 2007).

INDICATORS OF WATER QUALITY

Treated as well as untreated sewage likely contains some level of human pathogens most if not all of the time. However, pathogen occurrence in fecal wastes from individuals, septic tank effluents, or nonhuman animal wastes can be sporadic. In addition, different pathogens can occur at different times and, as already mentioned, many pathogens are difficult or impossible to grow in laboratory cultures. Almost all pathogens can now be detected by molecular tests, but many of these tests are such that the viability or infectivity of the detected pathogen is unknown. In addition, many of these methods are not able to detect low but infectious concentrations. Finally, many pathogen tests are difficult, costly, and time-consuming. For all of these reasons, the testing of water samples for the presence of pathogenic organisms is problematic (Allen, Clancy, and Rice, 2000).

Instead, the sanitary quality of water is determined by testing for one or more *indicator* organisms or groups of organisms. The presence of these organisms indicates that the tested water contains or may contain fecal pollution and hence the possible presence of pathogenic organisms. The detection methods for indicator organisms should be fast, easy to perform, and inexpensive compared to pathogen tests, and this is the case. Indicator organisms should always occur in untreated fecal wastes in concentrations that are higher than those of pathogens, and this is also the case. Ideally, they should mimic pathogens in terms of transport and survival in environmental waters, but this is not always the case. Ideally, they should only be found in fecal wastes, but all indicator organism groups in use today also have nonfecal sources to varying extents. Current indicator organisms and organism groups used as fecal pollution indicators in U.S. drinking water regulations are shown in Table 2-3. The methods used to detect these organisms are culture based and standardized (APHA, AWWA, and WEF, 1998; USEPA, 2001b, 2001c). Although many molecular tests in use cannot distinguish living from dead organisms, other types of molecular tests are under development that may be able to discriminate between live and dead indicator organisms (e.g., Gedalanga and Olson, 2009).

Coliform Bacteria

Total Coliform. Total coliform (TC) bacteria comprise many members of the family Enterobacteraceae (Leclerc et al., 2001). TC bacteria are those that can grow in selective media at 35°C and ferment lactose or possess a β -galactosidase enzyme. As an indicator of fecal contamination, the TC bacteria test has an acknowledged weakness and perhaps an underappreciated strength. On the one hand, the TC group of bacteria are unreliable indicators of fecal contamination because many members are capable of growth and long-term persistence (having a nonfecal origin) in many environments, including water distribution systems. On the other hand, there are more TC bacteria in untreated fecal waste than any of the other fecal indicators or indicator groups, making the TC test the most sensitive (albeit least specific) of all indicator tests (Atherholt et al., 2003). Because of this sensitivity, the

TABLE 2-3 Indicator Organisms Specified in U.S. Regulations

Indicator	Group composition*	U.S. regulatory use [†]
Coliform Bacteria		
Total coliforms	<i>Escherichia coli</i>, <i>Enterobacter</i>, <i>Klebsiella</i>, <i>Citrobacter</i>, <i>Serratia</i>, <i>Leclercia</i>, <i>Yersinia</i>, others[‡]	TCR
Fecal coliforms	<i>Escherichia coli</i>, <i>Enterobacter</i>, and <i>Klebsiella</i>	TCR
<i>Escherichia coli</i>		TCR; LT2ESWTR; GWR
Enterococcus Bacteria		
	<i>Enterococcus faecalis</i>, <i>E. faecium</i>, <i>E. casseliflavus</i>, <i>E. hirae</i>, <i>E. mundtii</i>, <i>E. durans</i>, <i>E. gallinarum</i>, others	GWR
Coliphage (Viruses That Infect Coliform Bacteria)		
Somatic coliphage	Myoviridae (e.g., T2,T4,T6); Podoviridae (e.g., T3,T7); Siphoviridae (e.g., λ , Φ 80, T5); Microviridae (e.g., Φ X174, S13)	GWR
F+ RNA coliphage	Leviviridae: serogroups I (e.g., MS-2, τ 2); II (e.g., GA); III (e.g., Q β , VK); IV (e.g., SP, FI)	GWR

*Major assay constituents in bold type.

[†]TCR = Total Coliform Rule (USEPA, 1989b); LT2ESWTR = Long Term 2 Enhanced Surface Water Treatment Rule (USEPA, 2006a); GWR = Ground Water Rule (USEPA, 2006b).

[‡]Multiple species of each genera listed plus *Hafnia*, *Buttiauxella*, *Kluyvera*, *Pantoea*, *Rahnella*.

TCR (USEPA, 1989b) relies on the TC bacteria test as the initial test to detect the possible presence of fecal contamination in delivered water, as well as to assess water treatment effectiveness and the integrity of the distribution system. Distribution system waters that are free of TC bacteria should have no or minimal levels of pathogens.

Fecal Coliform. Under the TCR, if the TC test result is positive, that sample is then further tested for the presence of either fecal coliform (FC) bacteria or *E. coli*. The FC group of organisms is a subset of the TC group that can grow in selective media at 44.5°C and ferment lactose. The FC group has far fewer nonfecal sources than the TC group but more so than *E. coli*. In most environmental waters, the majority of FC bacteria are *E. coli*. However, other coliform bacteria can, on occasion, comprise a significant proportion of the FC group, with wastewaters from pulp and paper mills the most well-known example. Nonfecal *Klebsiella* can dominate the composition of the FC group in these wastewaters. Because of this lack of specificity and because there are now fast and easy assays available to detect *E. coli*, recommendations have been made to eliminate the FC test from the forthcoming revised TCR (Total Coliform Rule/Distribution System Federal Advisory Committee, 2008).

E. coli. Until recently, *E. coli* was considered unique to fecal wastes with no environmental sources. Nonfecal strains of *E. coli* were first observed in warm water environments and later in temperate waters and sediments as well (Standridge, 2008). Despite this fact, the presence of *E. coli* is still considered to be the most fecal specific of all currently used indicator tests. Most *E. coli* possess a β -glucuronidase as well as a β -galactosidase enzyme and can grow in selective media and ferment lactose at 44.5°C. *E. coli* lack a urease enzyme, allowing this species to be distinguished from closely related enteric organisms in some

tests. The *E. coli* test is the indicator used by small systems in addition to or in place of testing for *Cryptosporidium* in the Long Term 2 Enhanced Surface Water Treatment Rule (USEPA, 2006a). In addition, the GWR allows the use of an *E. coli* test (or an enterococcus or coliphage test depending on state specifications) to examine untreated groundwater following a positive TC test result in the distribution system, per TCR test requirements (USEPA, 2006b).

Enterococcus

Enterococci grow on selective medium at 41°C and possess a β -glucosidase enzyme (some closely related organisms possess this enzyme as well). Fecal wastes contain concentrations of enterococcus bacteria comparable to that of *E. coli*. However, there can be significant nonfecal sources of enterococcus in many types of environmental waters (Leclerc, Devriese, and Mossel, 1996; Muller et al., 2001; Moore, Guzman, and McGee, 2008). The GWR allows the use (depending on state specifications) of an enterococcus test to examine untreated groundwater following a positive TC test result in the distribution system under the TCR (USEPA, 2006b).

Coliphage

Coliphages are viruses that infect *E. coli* and other coliform bacteria (Leclerc et al., 2000). There are two categories of indicator coliphage, or simply phage: (1) somatic phage that infect *E. coli* through their cell wall and (2) male-specific (F+ or F-specific) phages that gain entry through hair-like structures called pili that only male, or F-containing, *E. coli* possess. The test for the two coliphage groups requires two different host bacteria for maximum recoveries (there is a universal host that will detect both coliphage groups, but at lower recovery efficiencies), making the USEPA-approved tests for coliphage slightly more complex and costly compared to the bacterial indicator tests. Coliphage are almost always found in treated as well as untreated sewage, but they are present in the feces of only a few percent of humans at any given time. Thus, coliphage may not be the best indicators for some types of pollution sources. In addition, there are other issues related to the use of coliphage as fecal pollution indicators that warrant caution (Leclerc et al., 2000).

Because coliphage are viruses and more closely mimic HEV pathogens in terms of environmental transport and survival, they are being investigated as a potentially more reliable indicator of fecal pollution in general and of HEV pollution in particular, especially in some groundwaters. The GWR allows the use of coliphage in place of *E. coli* or enterococci (depending on state specifications) to indicate fecal pollution in groundwater (USEPA, 2006b), and the GWR Source Water Monitoring Methods Guidance Manual states that coliphage should be used when the wells that are targeted for assessment monitoring are located in either sand aquifers or tropical settings (USEPA, 2008a). However, a study of hundreds of wells across the United States showed that at sites where more than one sample was collected, if the sample tested positive at some point in time for HEV, it also tested positive for bacterial indicators (Abbaszadegan, LeChevallier, and Gerba, 2003). A study of Canadian groundwater found sampling for bacterial indicators to be the best approach for detecting HEV contamination (Locas et al., 2008). A few studies, however, have found HEV in some groundwater in the absence of fecal indicators (e.g., Borchardt et al., 2003). However, it should be noted that in studies determining the presence of HEV and fecal pollution indicators, sample (or equivalent sample) test volumes for HEV are typically 1 L or more, often 10 to 100 L, while volumes for bacterial indicator organisms are standardized at 100 mL (0.1 L).

Other Fecal Indicator Organisms

No other fecal pollution indicators are currently specified in U.S. drinking water regulations. The use of *Clostridium perfringens* endospores is under investigation as a more suitable indicator than bacteria for predicting the presence of viral and protozoan pathogens and for assessing water treatment efficiency. Due to their extreme longevity in the environment, *C. perfringens* endospores have often been monitored for evidence of human wastes or sewage sludge in ocean and other sediments. Similarly, *Bacillus* spp. endospores have been studied as a possible indicator of water treatment efficiency, with emphasis on their ability to predict the removal of protozoan pathogens. The anaerobic genera *Bacteroides* and *Bifidobacteria*, and the phage that infect these bacteria, are also under investigation as fecal pollution indicators. These bacteria are among the dominant members of the fecal waste microbial community. However, because all but very low oxygen concentrations are toxic to these bacteria and because they are not capable of producing resistant endospores, they survive in the environment for only short periods of time. *Bacteroides* and *Bifidobacteria* are under consideration, along with other bacteria, coliphage, enteric viruses, and some chemicals, as tools for microbial source tracking studies (Scott et al., 2002; USEPA, 2005a).

Heterotrophic Bacteria

Heterotrophic bacteria are members of a large group of bacteria that use organic carbon for energy and growth (Bartram et al., 2003). In the United States, laboratories often measure heterotrophic bacteria using the heterotrophic plate count test (HPC) (APHA, AWWA, and WEF, 1998). Because of its lack of specificity, HPC has not been used to assess the likelihood of waterborne disease; a specific HPC level might contain many, few, or no pathogens. The significance of HPC lies in its indication of poor general biological quality of drinking water. A sudden significant increase in the HPC can suggest a problem with treatment, including poor disinfection practice. Under USEPA regulations, systems that have no detectable disinfectant in the distribution system may claim, for the purposes of the regulation, that disinfectant is present if the HPC does not exceed 500 colonies/mL (see Geldreich et al., 1972).

Microscopic Particulate Analysis

Microscopic particulate analysis (MPA) is a tool for examining groundwater samples to determine if they are under the direct influence of surface water and for evaluating the efficiency of filter treatment processes for systems using surface waters. The method consists of a microscopic examination of the water for the presence of plant debris, pollen, rotifers, crustaceans, amoebas, nematodes, insects/larvae, algae (including diatoms), coccidia (e.g., *Cryptosporidium*), and *Giardia* cysts. Microscopic particulate analysis guidance for groundwater defines five risk categories, based on the concentration of each of these bioindicators. The concentration of this material should be low in true groundwaters. The MPA is described in two USEPA documents: the first for use in groundwaters (USEPA, 1992a) and the second for use by surface water systems to measure the effectiveness of steps taken to optimize filter performance (USEPA, 1996).

Turbidity

Turbidity is a nonspecific measure of the amount of particulate matter in water (e.g., clay, silt, finely divided organic and inorganic matter, microorganisms). Details about the use, measurement, and limitations of turbidity are found in Chap. 3. Adequate turbidity removal involves

partial removal of pathogens in the source water, since most pathogens as well as nonpathogenic bacteria such as iron bacteria, nitrifying bacteria, and sulfur bacteria tend to aggregate with particles, each other, and the chemical coagulants used in the treatment process. High turbidity levels can reduce the efficiency of disinfection by creating a disinfectant demand. The particles may also provide absorption sites for toxic substances in the water, protect pathogens and indicator organisms from disinfection by adsorbing or encasing them, and interfere with the total coliform analysis (USEPA, 1995; LeChevallier, Evans, and Seidler, 1981). Simple analytical methods for turbidity are available (APHA, AWWA, and WEF, 1998). Aesthetic issues related to turbidity are discussed in the section on Aesthetic Quality.

Particle counts in water can also be used as a general indicator of water quality, and this is discussed in Chap. 3.

TOXICOLOGICAL EVALUATION OF DRINKING WATER CONTAMINANTS

Toxicology, the study of the adverse effects of chemicals on living organisms, provides a means of evaluating and understanding the biological effects of drinking water contaminants. Human epidemiology studies usually cannot define cause-and-effect relationships, and sufficient data on duration and magnitude of human exposure do not exist for most contaminants. For these reasons, data from laboratory animal studies are typically used to assess a contaminant's potential risk to humans. In such studies, the doses and the length of exposure to the chemical of concern are known, providing data on the effects and dose-response of the chemical under controlled conditions. The underlying assumption is that effects observed in animals may occur in humans, unless information to the contrary is available.

However, epidemiology, the study of the distribution and determinants of diseases and injuries in human populations, can also provide information about the adverse effects of chemicals on humans. Exposure to substances including arsenic, benzene, vinyl chloride, asbestos, cigarette smoke, and radiation was first linked to the induction of cancer by epidemiologic studies. Although a complete review of toxicological and epidemiological principles is beyond the scope of this chapter, basic concepts needed to understand the information follow.

Chemicals can cause clearly deleterious effects as well as biological changes (e.g., changes in certain enzyme levels) that may or may not be considered adverse. Some adverse health effects in organisms occur immediately (within 24–48 hours after exposure), but others are delayed (e.g., 5–40 years or more for cancer latency in humans). Adverse effects may be reversible or irreversible, depending upon their nature, severity, and the organ affected. Often more is known about the immediate effects of single or short-term high doses than the delayed effects of long-term, low-dose exposure. Unless otherwise noted, the emphasis in this chapter is on the latter, since long-term, low-dose effects are more relevant to most drinking water contamination issues.

Dose-Response in Toxicology

The underlying principle of toxicology is that any chemical may have harmful effects and that the response of a living organism to a chemical depends upon the dose. Dose is typically expressed as weight of chemical administered per body weight per day, such as milligrams per kilogram per day (mg/kg/day). As dose is increased, effects are usually expected to occur in a greater percentage of the exposed group of people or experimental animals. This is termed the *dose-response relationship*.

The concept of dose-response is important because simply identifying the toxicological effects of a chemical (known as *hazard identification*) does not provide the complete information needed to assess human health risk. Before an evaluation (*risk characterization*) can be made regarding the public health significance of exposure to a substance, the dose-response relationship and extent of human exposure must also be known.

Usually, a clear dose-response relationship exists, with effects increasing over a certain dose range below which there is a threshold dose at which no effects are seen (Fig. 2-1).

FIGURE 2-1 Typical dose-response curve for a chemical with a threshold for response.

For some effects, particularly cancers which occur through a genotoxic mode of action, it is assumed that exposure to any dose results in some level of risk; thus, there is no threshold below which no risk exists. Nonmonotonic (U-shaped or inverted U-shaped) dose-response relationships can also occur. For these, lower doses can produce greater effects than higher doses over a portion of the dose range, particularly for some endocrine and neurotoxic effects. Vitamins can also exhibit this type of dose-response relationship, as toxicity can result both from deficiency at low doses and from excessive exposure at high doses. Development of approaches to address these types of dose-response relationships is a current issue for risk assessment of environmental contaminants (Myers, Zoeller, and vom Saal, 2009).

The response of a person or an animal to a chemical depends on both toxicodynamic and toxicokinetic factors. Toxicodynamics is concerned with the biochemical and physiological effects of chemicals and the mechanisms of action by which these effects occur. Toxicokinetics relates to the fate of a substance in the body, including absorption, distribution, metabolism, and excretion. In other words, toxicodynamics refers to what a chemical does to the body, while toxicokinetics refers to what the body does to the chemical. Both toxicokinetic and toxicodynamic parameters may vary between species as well as among members of the same species, including experimental animal groups and human populations. Thus, humans may be more or less sensitive to a chemical than experimental animals, and some exposed people may be more sensitive than others.

Specific subgroups within the human population may be more sensitive to the toxicity of chemicals due to differences in toxicodynamics and/or toxicokinetics. These subpopulations include fetuses, children, the elderly, and individuals with certain genetic variants, diseases, or medical conditions. Effects occurring during fetal development or infancy (e.g., inhibition of thyroid function) may cause permanent damage, while the same effect in older individuals may have less serious consequences that are reversible when exposure ceases. Additionally, fetuses and children may be more sensitive because of physiological or biochemical differences from adults. Toxicokinetic differences may also increase the sensitivity of these subgroups. For example, GI absorption of lead and mercury salts is as much as 10 to 20 times greater in infants, and up to several-fold greater in pregnant women, than in other adults (CDC, 1991; ATSDR, 1999). The ability to metabolize or excrete certain toxic chemicals can be diminished in the elderly, increasing their sensitivity to these chemicals.

Types of Toxicological Effects

A variety of adverse health effects are possible. The general types of effects, listed below, are those that are most relevant to exposure to contaminants found in drinking water.

1. *Systemic toxicity*. Causing a deleterious response in a biological system, disrupting function, or producing death. These effects may result from acute (short-term), subchronic (intermediate-term), or chronic (long-term) exposure. The term *systemic toxicity* is often used to refer to noncancer effects in the context of toxicity and risk assessment of environmental contaminants. Examples of systemic toxicity include weight loss, anemia, damage to the liver or kidney, and decreased thyroid hormone production. It is assumed that there is a threshold dose for most systemic effects below which no effects are expected to occur.
2. *Carcinogenicity (oncogenicity)*. Causing or inducing uncontrolled growth of aberrant cells into neoplastic tumors. Chemicals may cause tumor formation by initiating the series of changes in DNA necessary for carcinogenesis, and/or by promoting the growth of initiated cells. These chemicals are referred to as *initiators* and *promoters*, respectively. Chemicals that cause benign tumors, in addition to those that cause malignant tumors, are usually assumed to pose a cancer risk to humans. In assessing the risks of exposure to chemicals that cause cancer, it is usually assumed that no threshold exists. This means that there is some risk of cancer from exposure to any amount of the chemical.
3. *Mutagenicity*. Causing heritable alteration of the genetic material (DNA) within living cells. A mutation is typically defined as a change in the genetic code of a specific gene that results in a change in a cellular or biochemical characteristic. Many carcinogens are also mutagens, and vice versa. Mutagenicity is a subset of the effects included in genotoxicity.
4. *Genotoxicity (clastogenicity)*. Causing alterations or damage to the genetic material (DNA) in living cells, such as deletions of portions of or entire chromosomes, but also including other phenomena, such as creation of micronuclei, sister chromatid exchanges, and unscheduled DNA synthesis (due to repair processes). Some changes may be lethal to the cell. Genotoxicity encompasses mutagenicity as well as other types of damage to DNA. Many carcinogens are also genotoxic.
5. *Teratogenicity*. Causing nonhereditary congenital malformations (birth defects) in offspring as a result of exposure during gestation.
6. *Developmental toxicity*. Adverse effects resulting from exposure to a chemical during development, which includes exposure to either parent prior to conception, exposure during gestation, or exposure after birth until puberty. Developmental effects may become evident at any time of life. For example, some effects resulting from prenatal exposures are not seen until puberty or middle age. Teratogenic effects are a subset of the effects in this category.
7. *Reproductive toxicity*. Adverse effects on the male or female reproductive system resulting from exposure to a chemical. Examples include effects on sexual development, mating behavior, fertility, pregnancy, and lactation.

Toxicology Studies for Evaluation of Drinking Water Contaminants

As stated above, the focus of this section is on effects of chronic (lifetime, which is about two years in rodents) or subchronic (up to 10 percent of the lifespan, 2 to 13 weeks in rodents) exposures, rather than acute effects resulting from brief exposures to high doses.

For assessment of developmental effects, studies involving exposure during gestation are relevant. Chemicals may be administered to animals in drinking water or the diet, by gavage (administered through a tube into the stomach as a bolus dose dissolved in oil or water), dermally, by inhalation, or by intraperitoneal (abdominal), intravenous, or intramuscular injection. For assessment of drinking water contaminants, oral studies, particularly those in which exposure is through drinking water or the diet, are preferred, because these dosing methods best simulate human exposures through drinking water. Studies in which chemicals are administered by injection are not used as the basis for quantitative risk assessment of drinking water contaminants, as this route is not relevant to environmental exposure.

Noncancer Effects. For noncarcinogenic endpoints, studies examine mortality, body weight, and pathological changes in organs and blood, including absolute organ weights and the ratio of organ weights to body weight, microscopic appearance, and enzyme activities. Among the organs frequently affected are the liver and kidney because of their roles in metabolism and excretion of toxic chemicals. Neurologic function, effects on the immune system, behavioral changes, changes in hormone levels, and other specific endpoints may also be assessed if relevant. In recent years, increased emphasis has been given to studies of teratogenicity and developmental and reproductive toxicity (such as changes in fertility, birth weight, and survival), as the period of development is now known to be the most sensitive life stage for many chemicals.

Carcinogenic Effects. Assessment of a chemical's carcinogenic potential is primarily based on the results of two types of studies: chronic (lifetime) animal studies and tests of mutagenicity and genotoxicity. Many chronic studies have been conducted by the National Cancer Institute (NCI) or National Toxicology Program (NTP), and reports of these studies are available on the NTP Website. In a chronic rodent study, rats, mice, or hamsters are exposed to the test chemical for two years. Doses are determined by subchronic range-finding studies conducted prior to the chronic study. Doses ideally include the maximum tolerated dose (MTD), often defined as the dose reducing body weight by about 10 percent, and one half and one quarter of the MTD. A control (unexposed) group is also included. As mentioned above, oral studies are preferred for assessment of drinking water contaminants. However, if no appropriate oral data are available, inhalation data may be used.

After the end of the exposure period, animals are killed and necropsied. A wide variety of organs or tissues are examined for tumors both visually and microscopically. The data on tumor incidence in each of the tissues evaluated are analyzed to determine whether there is a statistically significant increase in the incidence of malignant tumors or total tumors (malignant and benign) in the experimental groups in any of the tissues compared to background incidence in the control group. There has been some disagreement about the human relevance of the results of cancer studies in rodents, particularly liver cancers in certain mouse strains following very high doses of the test chemical. However, default assumptions used in cancer risk assessment are that, in the absence of specific data to the contrary, carcinogenicity observed in animals indicates the potential for carcinogenic effects in humans, and that a carcinogenic chemical may cause tumors in different organs in animals and humans.

The doses used in animal studies are much higher than the doses to which humans are exposed in the environment for several reasons. High doses are used in order to increase the number of transformed cells within the target tissues. In addition, with the numbers of animals used in these studies (typically 50 per sex per dose group), an increased tumor incidence of at least several percent must occur in order to detect a statistically significant difference between treated and control groups. High doses must be given to produce increased tumor frequencies of this magnitude. In contrast, the cancer risk levels of interest in humans exposed to low doses of environmental contaminants are much lower, down to the 1 in one million range.

Genotoxicity and Mutagenicity. The Ames test is one of many *in vitro* screening systems for mutagenicity and other types of genotoxic effects. Such effects are considered to be an indicator of carcinogenic potential. Strains of the bacterium *Salmonella* Typhimurium that can detect different types of mutations, such as frame shift mutations and base pair substitution mutations, have been developed. These strains require the amino acid histidine to grow. Through mutation of the relevant gene, they can become histidine independent and thus able to grow in the absence of histidine. Mutagenic potency is determined by comparing the number of bacteria that become histidine independent when exposed to the test chemical to the number that become histidine independent spontaneously under control (unexposed) conditions. Usually, a chemical is tested with and without the addition of rodent liver metabolic enzymes and necessary cofactors in order to detect chemicals that are not themselves mutagenic but are metabolized, or activated, in the body to mutagenic metabolites.

To characterize mutagenicity, a battery of *in vivo* (whole animal) and *in vitro* (in cell cultures, bacteria, etc.) assays using other microorganisms (e.g., yeast and fungi), fruit flies (*Drosophila*), and mammalian cells are often used. Because many known carcinogens test positive in these assays, they are useful as screening tools. Endpoints evaluated include mutagenicity, DNA strand breaks, chromosomal aberrations, and ability of a chemical to react with the DNA (adduct formation), as well as assays of other phenomena whose meaning are not fully understood but appear to be correlated with carcinogenic potential (e.g., sister chromatid exchange and micronuclei formation). Some assays appear to be more sensitive to certain types of carcinogens.

The animal tests currently used for the assessment of noncancer and cancer effects of chemicals of environmental concern are expensive and time consuming, so that the number of chemicals that can be tested each year is limited by practical considerations. Additionally, reducing the use of animals in toxicity studies addresses concerns related to animal rights and animal welfare. A recent report by the National Research Council (NRC) of the National Academy of Sciences (NRC, 2007), commissioned by USEPA, envisaged a shift from the current whole animal-based testing systems to testing founded primarily on *in vitro* methods that evaluate changes in biological processes using cells, cell lines, or cellular components. However, many questions and issues must be addressed for this vision to become a reality, and it is unclear whether the *in vitro* methods advocated by this report will ever be capable of detecting all or most toxic effects of concern.

RISK ASSESSMENT OF DRINKING WATER CONTAMINANTS

The human health basis (maximum contaminant level goals, MCLGs) for the drinking water standards (maximum contaminant levels [MCLs]), as well as the drinking water guidance (Health Advisories), developed by USEPA and other agencies are derived through risk assessment approaches. Recent general references for risk assessment of environmental contaminants are Nielsen, Ostergaard, and Larsen (2008) and, specifically for risk assessment of drinking water contaminants, Howd and Fan (2008). As discussed in Chap. 1, MCLGs are nonenforceable, health-based goals that are to “be set at a level at which no known or anticipated adverse effect on human health occurs and that allows for an adequate margin of safety.” MCLGs are considered along with other factors to develop the MCL, which is an enforceable regulatory standard.

Guidance documents providing details on risk assessment approaches are linked from the USEPA IRIS Website. The overall framework for the risk assessment approach used by USEPA and other agencies was developed by the NRC (1983). The four steps of this approach are:

1. *Hazard identification*—qualitative determination of the adverse effects that a constituent may cause
2. *Dose-response assessment*—quantitative determination of the effects that a constituent may cause at different doses
3. *Exposure assessment*—determination of the route and amount of human exposure
4. *Risk characterization*—description of risk assessment results, underlying assumptions, and uncertainties

Many uncertainties are involved in the extrapolation of data from experimental animals to potential effects in humans and from the high doses typically used in the animal studies to the much lower exposures usually occurring from drinking water contaminants. Because of these uncertainties, it is necessary to use assumptions in the risk assessment process. As the risk assessment process is intended to be protective of public health, the assumptions used in the presence of uncertainty are meant to be reasonable but conservative. If data become available to address a source of uncertainty, the risk assessment can be revised to replace the assumption with information based on the data.

A chemical's classification as a carcinogen or a noncarcinogen is important, since a different general risk assessment approach is used for noncarcinogens than for most carcinogens. Contaminants are classified as to their weight of evidence for carcinogenicity according to categorization schemes. USEPA adopted new Guidelines for Cancer Risk Assessment in 2005 to replace the previous 1986 guidelines. However, assessments under the 1986 guidelines are still in place for many chemicals that have not been reassessed under the new USEPA (2005b) guidelines.

Chemicals treated as carcinogens are those classified as “carcinogenic to humans” or “likely to be carcinogenic to humans” under the 2005 guidelines, as “known human carcinogens” (Group A) or “probable human carcinogens” (Group B1 and Group B2) under the 1986 guidelines, and as Group 1 or Group 2A by the International Agency for Research on Cancer (IARC). Chemicals treated as noncarcinogens are those classified as having “inadequate evidence” or as “not likely to be carcinogenic” (USEPA, 2005b), as “not classifiable” (Group D) or “not carcinogenic to humans” (Group E) (USEPA, 1986a), or as Group 3 or Group 4 by IARC. Specific approaches are used to address chemicals classified as having “suggestive evidence” (USEPA, 2005b), “possible human carcinogens” (Group C) (1986a), or Group 2B by IARC.

Noncarcinogen Risk Assessment

Point of Departure. For most noncarcinogenic effects, it is assumed that there is a threshold dose below which no adverse effects occur. A Reference Dose (RfD) at which no adverse effects are expected from lifetime exposure is developed from appropriate animal or, less commonly, human data. The RfD is derived by applying appropriate uncertainty factors to a dose (in mg/kg/day) chosen from the dose range used in the study or modeled from the study data. This dose, called the point of departure, can be the highest dose at which no effects have been observed (no observed adverse effect level, or NOAEL), the lowest dose at which adverse effects have been observed (lowest observed adverse effect level, or LOAEL), or a benchmark dose derived by modeling the dose-response data to predict a dose at which minimal effects (e.g., 5 percent or 10 percent change in the parameter of interest) will occur. When data from several appropriate studies are available, the highest NOAEL that is below the lowest LOAEL from the various studies is chosen as the point of departure for RfD development.

Uncertainty Factors. The uncertainty factors (formerly called “safety factors”) used in RfD development account for factors such as: differences in sensitivity between humans and experimental animals, variability in sensitivity within the human population, less than lifetime

duration of a study, need to extrapolate from an LOAEL to an NOAEL, or gaps in the toxicology database for the chemical. Uncertainty factors of 10 each are often used, but factors of 3 or other values can be chosen if warranted by the data. USEPA recommends that the total uncertainty factor (the product of the individual uncertainty factors) not exceed 3000.

$$\text{RfD}(\text{mg/kg/day}) = \frac{\text{NOAEL, LOAEL, or benchmark dose ((ng/kg/day))}}{\text{product of appropriate uncertainty factors}} \quad (2-1)$$

Exposure Assumptions. From the RfD, a drinking water equivalent level (DWEL) is calculated. The DWEL represents a concentration at which adverse health effects are not anticipated to occur from a lifetime of exposure, assuming 100 percent of exposure to the contaminant comes from drinking water.

$$\text{DWEL (mg/L)} = \frac{\text{RfD (mg/kg/day)} \times \text{body weight (kg)}}{\text{ingestion rate (L/day)}} \quad (2-2)$$

Exposure assumptions for adults (body weight of 70 kg, and a drinking water ingestion rate of 2 L/day) are often used to develop health-based drinking water concentrations protective for lifetime exposure, such as MCLGs and Lifetime Health Advisories. If the assessment is based on effects relevant to infants (e.g., methemoglobinemia from exposure to nitrate), then assumptions appropriate for infants, such as a body weight of 10 kg and a consumption rate of 1 L/day are assumed. Assumptions for infants or children are also used by USEPA to develop Health Advisories for short-term (1 day, 10 days) or longer-term (7 years) exposure durations.

Relative Source Contribution. In developing MCLGs or Health Advisories for noncarcinogenic contaminants, contributions from nondrinking water sources of exposure, including air and food, are also taken into account so that total exposure from all sources does not exceed the RfD. In order to do this, a relative source contribution (RSC) factor of between 20 and 80 percent is applied to the DWEL (USEPA, 2000a). When the necessary data on air and food exposures are not available to develop a contaminant-specific RSC, as is the case for most contaminants, a conservative default value for the RSC of 20 percent is used. If sufficient data are available on non-water sources of exposure, a contaminant-specific RSC is derived. If drinking water contributes between 20 and 80 percent of total exposure at the DWEL, the exposure contributions from food and air are subtracted from the exposure at the DWEL to calculate the MCLG or Health Advisory. If drinking water contributes 80 percent or more to total exposure, a “ceiling” RSC value of 80 percent is used to protect individuals whose non-water exposures may be higher than that indicated by available data. If drinking water contributes less than 20 percent of total exposure, a “floor” RSC value of 20 percent is generally used. In these cases where drinking water contributes a relatively small portion of total exposure, efforts are best directed toward reducing the exposures from other sources, as further reductions of the drinking water standard or guidance based on an RSC of less than 20 percent will not result in a significant decrease in total exposure to the contaminant. Once the RSC has been determined, the MCLG or Health Advisory is calculated as follows:

$$\text{MCLG or Health Advisory (mg/L)} = \text{DWEL (mg/L)} \times \text{RSC (\%)} \quad (2-3)$$

Carcinogen Risk Assessment

Nonthreshold versus Threshold Assumption. In assessing the risks of exposure to chemicals that cause cancer, it is usually assumed that some risk of cancer results from exposure to any amount of the chemical. The default assumption recommended in the USEPA

Guidelines for Carcinogen Risk Assessment (USEPA, 2005b) is that there is no threshold for carcinogenicity unless a threshold mode of action has been clearly demonstrated.

For a few chemicals, it has been shown that cancer occurs secondary to systemic effects. In these cases, it is assumed that a threshold for carcinogenicity exists and an RfD approach similar to that described above for noncarcinogens is appropriate. Examples of this approach are chloroform, for which tumors in rodents appear to occur only after cell damage and regenerative growth, and antithyroid agents that cause sustained elevations in levels of thyroid-stimulating hormone (TSH), resulting in continued stimulation of the thyroid and the development of thyroid tumors.

Because of the lack of evidence for a threshold for most carcinogens, USEPA sets MCLGs for most carcinogenic contaminants at “zero” as an aspirational goal, as a matter of regulatory policy (USEPA, 1987a, 1991a). This expresses the ideal that drinking water should not contain carcinogens. In this context, zero is not a number (as in 0 mg/L) but is a concept (as in “none”).

Estimation of Cancer Risk. Under the current USEPA (2005b) risk assessment guidelines, cancer risk is usually estimated quantitatively by linear extrapolation from a benchmark dose for tumor data from animal studies. In some cases, such as benzene, risk estimates come from human epidemiological data. The carcinogenic potential of a chemical is expressed quantitatively as a slope factor or potency factor, in which cancer risk per lifetime daily dose is given in units of per milligrams per kilogram per day [mg/kg/day]⁻¹. The slope factor used for risk assessment is the 95th percentile upper confidence limit on the modeled slope factor. Because of the conservative assumptions and approaches used in cancer risk assessment, the risk estimates are considered to be upper bounds on the actual risk, and the actual risk is likely to be lower and could be as low as zero. The slope factor or potency factor is related to the dose (in mg/kg/day) and the lifetime cancer risk, which is unitless, as follows:

$$\text{Risk (unitless)} = \text{dose (mg/kg/day)} \times \text{slope factor (mg/kg/day)}^{-1} \quad (2-4)$$

Health-based Drinking Water Concentration. The drinking water concentration at a given cancer risk level (10^{-4} , 10^{-5} , 10^{-6}) can be calculated from the following equation, using assumptions of 70 kg for adult body weight and 2 L/day for ingestion rate:

$$\text{Drinking water conc. (mg/L)} = \frac{\text{risk level (10}^{-x}\text{)} \times \text{bodyweight (kg)}}{\text{slope factor (mg/kg/day)}^{-1} \times \text{ingestion rate (L/Day)}} \quad (2-5)$$

The actual regulatory standard, or MCL, is based on practical considerations, such as analytical limitations and treatment costs, with the goal that the lifetime cancer risk should remain below 1 in 10,000.

Risk Assessment of Suggestive or Possible Human Carcinogens

For certain contaminants, some evidence for carcinogenicity exists, but the weight of evidence is not sufficient for classification as “likely to be carcinogenic to humans” (USEPA, 2005b) or “probable human carcinogen” (Group B2) (USEPA, 1986a). These contaminants are classified as “suggestive carcinogens” (USEPA, 2005b) or “possible human carcinogens” (Group C) (USEPA, 1986a). The risk assessment approach used for such chemicals is a science policy decision. The USEPA drinking water MCLGs and Health Advisories for contaminants in these categories are based on the RfD for systemic effects, with the

incorporation of an additional uncertainty factor to account for the evidence of possible carcinogenicity. The uncertainty factor is usually 10, but other values from 1 to 10 may be used as appropriate. The same equation used to develop MCLGs for noncarcinogens (above) is used. Less commonly, if there are insufficient data to develop an RfD, the MCLG is based on the cancer slope factor and a lifetime risk level of 10^{-5} (1 in 100,000). Within USEPA, other programs may use other approaches to address chemicals in this category. For example, in the Superfund program for cleanup of contaminated sites, health-based criteria for these chemicals are based on a lifetime cancer risk level of 10^{-6} (1 in 1,000,000).

Additional Considerations in MCL Development

As discussed in more detail in Chap. 1, regulatory standards for drinking water contaminants (MCLs) consider other factors in addition to health effects alone. Factors considered may include analytical limitations, availability of treatment technology, costs, and others. For example, the public health benefit of reducing infectious disease from the use of chemical disinfectants is balanced against the cancer risks of the disinfection by-products formed during the disinfection process. For carcinogens, the MCLG is set at zero as a matter of policy, and the MCL is determined by considering the factors mentioned above. For some noncarcinogens, the MCL is also set above the MCLG due to practical considerations.

Sources of Information for Health-based Drinking Water Values

As discussed in Chap. 1, a useful resource for information on health-based assessments of drinking water contaminants is the USEPA Drinking Water Standards and Health Advisories tables (USEPA, 2006c; USEPA, 2009a), which are periodically updated. In addition to the regulatory MCLs, MCLGs, and the various short-term and long-term Health Advisories for children and adults, the tables summarize the RfDs and DWELs for contaminants with risk assessments based on noncarcinogenic end points. As the RfD is intended to provide a wide margin of safety, small exceedances of an MCL usually do not represent immediate concern (but see sections on nitrates and lead for examples of exceptions to this generalization). The tables also provide the carcinogenicity classification and the concentrations of compounds corresponding to a 10^{-4} (1 in 10,000) incremental lifetime cancer risk as estimated by USEPA. These tables also provide secondary MCLs (SMCLs) based on aesthetic effects, as well as useful definitions of terms used in drinking water risk assessment and regulation.

Information on health effects and occurrence of unregulated drinking water contaminants that have been considered for regulation by USEPA can be found on the USEPA Office of Water Contaminant Candidate List (CCL) website. Additional information on health effects may be found in the general references mentioned at the beginning of this chapter and in the sections on individual contaminants. Within this chapter, for consistency, MCLGs and Health Advisories developed by the USEPA Office of Water are generally provided. However, it should be noted that the risk assessment basis for some older MCLs may not agree with the more current information provided in IRIS.

Additionally, as noted above, some states have established standards that are more stringent than the federal standards for some contaminants. States have also established standards or guidance for contaminants that have not been addressed by USEPA.

Microbial Risk Assessment

Epidemiological studies attempt to directly measure the amount of infection or illness due to the consumption of drinking water in sample populations (Colford et al., 2006; Messner et al., 2006). Determining the level of such illness through these studies is difficult, expensive, and

time consuming. In addition, these studies have low sensitivity (i.e., the ability to measure small increases in health risk). Microbial risk assessment (MRA) is a useful alternative or complement to epidemiology studies when attempting to assess the extent of infection (e.g., Eisenberg et al., 2006). In contrast to epidemiological studies, MRA studies are inexpensive and can be conducted comparatively quickly. MRA may be the sole means to obtain health-risk information when epidemiologically derived data are limited or absent.

Drinking water MRA has been an area of research for over 25 years. It is a formal process that translates the occurrence of pathogens in drinking water and the volume of water consumed into a probability of infection or illness (Haas, Rose, and Gerba, 1999). There are typically four steps involved in MRA: (1) an important subset of pathogens is identified; (2) human exposure, from ingestion or inhalation, is characterized; (3) pathogen dose-response information is obtained from existing data from clinical trials or disease surveillance studies; and (4) a range of possible risk estimates is mathematically determined. Depending on data availability and the type of information needed, different statistical approaches employing different types of MRA models are used.

The many uses of MRAs include providing information for setting regulatory standards, analyzing and improving water treatment, characterizing the mode of disease transmission during an outbreak, and identifying additional information needs. As one example, MRA is the basis of some U.S. drinking water treatment regulations whereby treatment requirements (e.g., specified levels of disinfection and filtration) are specified. These treatments achieve specified levels of removal or inactivation (e.g., 99.9 percent, 99.99 percent) of target organisms or organism groups in source waters such that the resulting level of “acceptable risk” from consuming the treated water is not more than 1 infection in 10,000 exposed persons per year (e.g., USEPA, 1989a, 2006a). The term *acceptable risk* is controversial, and alternative risk endpoints, such as *disability adjusted life years* (the number of days lost due to sickness or death), have been used by other organizations (LeChevallier and Buckley, 2007).

Microorganisms have attributes that make MRA more complicated than chemical risk assessment (ILSI, 1996). For example, although pathogen infectivity information can sometimes be obtained from disease outbreak data, the most reliable dose-response information is obtained from feeding studies whereby small numbers of healthy adults each ingest a different amount of a single pathogen. The number of infections or illnesses that result from each dose determines the infective potential for that pathogen (e.g., the dose that is infectious for 50 percent of the exposed population, namely the ID_{50}). However, for ethical and economic reasons, information from human feeding studies is available for only a few strains of pathogens. Furthermore, the general population includes children, the elderly, pregnant women, and persons with weakened immune systems, and these “sensitive subpopulations” likely have susceptibilities to pathogens that are different from adults with normal immune system function.

There are thousands of species and strains of pathogens. Different species and different strains of the same species (see section on Pathogenic Organisms) can vary greatly in both dose-response (see above) as well as the severity of symptoms following infection. For example, for three different strains of *Cryptosporidium parvum*, the ID_{50} is 2066, 132, and 12 oocysts (Messner, Chappell, and Okhuysen, 2001). Because of this, MRA is usually based on analysis of only a few pathogens (or a combination of characteristics of related pathogens, such as enteric viruses). Such pathogens have a low infectious dose, the potential to cause serious disease symptoms, occur most frequently in source water, and/or have properties that make them difficult to treat.

Additional issues include the fact that the types of pathogens present and the concentration and distribution of each at a source water location can vary greatly over seasons as well as much shorter periods of time and within short distances within the water column (e.g., Wilkes et al., 2009). There are also a host of methodological problems involved in

detecting pathogens, determining their infective potential, and determining their respective concentrations in source waters and in treated waters where they are either absent or present at low levels (see Indicators of Water Quality section; Regli et al., 1991; Emelko, Schmidt, and Roberson, 2008). MRA is a field of study in the early stages of development. Given all of the pathogen-specific issues that underlie MRA-derived information, the best use of MRA data at the present time is perhaps to focus on the uncertainty or limits of the information obtained.

INORGANIC CONSTITUENTS

Inorganic constituents can be present in natural waters, in contaminated source waters, or in some cases may result from contact of water with piping or plumbing materials. Lead, copper, zinc, and asbestos are constituents that can originate from distribution and plumbing systems.

Inorganic chemicals found in drinking water represent a variety of health concerns. Some are known or suspected carcinogens, such as arsenic and lead. Numerous inorganic chemicals are essential to human nutrition at low doses, yet demonstrate adverse health effects at higher doses. These include chromium, copper, manganese, molybdenum, nickel, selenium, zinc, and sodium and are reviewed by the Institute of Medicine Food and Nutrition Board (2006). Several inorganic chemicals, including sodium, barium, and lead, have been associated with increased blood pressure. Numerous reports have also shown an inverse relationship between water hardness and hypertensive heart disease, and this topic is under continuing investigation.

Health aspects of inorganic constituents of interest in drinking water are summarized in this section. Inorganic disinfectants and DBPs are discussed in a later section.

Aluminum

Aluminum occurs naturally in nearly all foods, and the average dietary intake is about 20 mg/day. Aluminum salts are widely used in antiperspirants, soaps, cosmetics, and food additives. Additionally, cans for carbonated beverages are made of aluminum. Aluminum occurs in both raw and treated drinking waters, but it is estimated that drinking water typically represents only a small fraction of total aluminum intake (Reiber and Kukull, 1996).

Aluminum shows low acute toxicity but is a neurotoxicant when administered under certain conditions, as reviewed by California EPA (2001) and ATSDR (2008a). Chronic high-level exposure data are limited but indicate that aluminum affects phosphorus absorption, resulting in weakness, bone pain, and anorexia. Carcinogenicity, mutagenicity, and teratogenicity tests have all been negative. Associations between aluminum and two neurological disorders, Alzheimer's disease and dementia associated with kidney dialysis, have been studied. The available data suggest that aluminum is not likely the causative agent in the development of Alzheimer's disease. However, aluminum may play a role by acting as a cofactor in the chain of pathological events resulting in Alzheimer's disease (ATSDR, 2008a). Dialysis dementia has been reasonably documented to be caused by aluminum (Ganrot, 1986; Shovlin et al., 1993). Kidney dialysis machines now use water with a very low concentration of aluminum to prevent this exposure in the patients.

Aluminum was included on the original list of 83 contaminants to be regulated under the 1986 SDWA amendments. USEPA removed aluminum from the list because it was concluded that there was no evidence that aluminum ingested in drinking water poses a health risk (USEPA, 1988a). The USEPA secondary maximum contaminant level (SMCL)

for aluminum of 50 to 200 $\mu\text{g/L}$ is based on prevention of discoloration of water and is intended to encourage removal of coagulated material before treated water enters the distribution system.

Arsenic

Arsenic concentrations in U.S. drinking waters are typically low. However, an estimated 5000 community systems (out of 70,000) using groundwater and 370 systems (out of 6000) using surface water had concentrations above 5 $\mu\text{g/L}$ (Reid, 1994). Elevated arsenic concentrations occur primarily in the Western states, but are also found in the Midwest and the geological Piedmont Region of the East Coast. Weathering of rocks containing arsenic and the smelting of nonferrous metal ores, especially copper, account for most of the arsenic in water supplies. Until the 1950s, arsenical compounds were also major agricultural insecticides. Arsenic exists in drinking water primarily in the inorganic state, and arsenite (III) and arsenate (V) are the most prevalent toxic forms found in drinking water (NRC, 1999a; USEPA, 2000b).

Arsenic may be a trace dietary requirement in certain farm animals, but not in humans, and is present in many foods such as meat, fish, poultry, grain, and cereals (NRC, 1999a). Market basket surveys suggest that the daily adult intake of all forms of arsenic is about 50 μg , of which 1 to 20 μg is inorganic (ATSDR, 2007). In fish and shellfish, it is present in organic arsenical forms, which are thought to be much less toxic than inorganic arsenic. In grains such as rice, arsenic is present primarily in the inorganic form.

The toxicity of arsenic has been thoroughly reviewed (NRC, 1999a, 2001; ATSDR, 2007; USEPA, 2000b). The toxic endpoints of concern for arsenic in drinking water relate to chronic effects of arsenic; levels found in drinking water are below those resulting in acute effects. Acute effects resulting from accidental or intentional exposure to large doses of arsenic involve the skin, nervous system, GI system, blood, and kidneys. The lethal dose for poisoning incidents has been reported to be 1 to 4 mg/kg (USEPA, 2000b).

Effects of chronic exposure of humans to lower levels of arsenic include both systemic (noncancer) toxicity and cancer. Much of the data on these effects comes from studies of populations with elevated levels of arsenic in their drinking water in Taiwan, Bangladesh, Mongolia, South America, and the western United States. Systemic (noncancer) effects of arsenic include dermatological toxicity, peripheral vascular disease, and increased risk of cardiovascular disease, diabetes, and gastroenterological disease. The most prominent systemic effects of long-term arsenic exposure involve the skin and include hyperpigmentation and development of keratoses. Blackfoot disease, a severe peripheral vascular insufficiency that can cause gangrene of the extremities, has been reported in Taiwanese individuals exposed to arsenic.

Arsenic is one of a relatively small number of chemicals that has been classified by USEPA as a Known Human Carcinogen (Group A), based on human epidemiological data. Unlike most other carcinogens of environmental concern, arsenic does not induce cancer in the traditional animal testing models, perhaps due to differences in metabolism between the test animals and humans. However, gestational exposure of rodents to arsenic was shown to increase tumor incidence in adulthood (Liu and Waalkes, 2008). Exposure to arsenic through drinking water has long been linked to an increased risk of skin cancer in humans. More recently, an elevated risk of internal cancers has been demonstrated in populations from Taiwan, Japan, Argentina, and Chile. The organs in which cancer rates were reported to be elevated include bladder, lung, liver, and kidney (reviewed in NRC, 1999a, 2001; ATSDR, 2007). Ingestion of arsenical medicines and other arsenic exposures have also been associated with several internal cancers, but several small studies of communities in the United States with relatively high arsenic levels in drinking water have failed to

demonstrate any health effects. The interactive effect of smoking and the relative absence of tobacco use in those communities may have played a role in the apparent lack of effect. The NRC (2001) concluded that it would be difficult to detect increases in cancer risk from arsenic in the U.S. population, even at the highest of the possible estimated risk levels, since the arsenic concentrations present in U.S. drinking water are not expected to cause a cancer incidence that is statistically significantly elevated over the relatively high background rates of the cancers of concern.

The mechanism of action by which arsenic causes cancer has not been definitively elucidated. Arsenic appears to impact a number of cellular processes involved with DNA repair and chromosome replication, leading to the hypothesis that it causes cancer by indirect mechanisms, rather than by directly interacting with DNA. However, it has been shown (Mass et al., 2001) that methylated trivalent forms of arsenic, which can be formed through metabolic processes from inorganic arsenic, can act directly to damage DNA *in vitro*. Several studies have suggested that the primary carcinogenic mechanism involves the metabolites, mono- and dimethylarsenous acid.

In 2001, USEPA (2001d) decreased the MCL for arsenic to 10 µg/L, based on cancer risks, replacing the existing MCL of 50 µg/L based on a 1942 U.S. Public Health Service standard. As part of the MCL development process, cancer risk estimates for arsenic in drinking water were developed by the NRC (1999a, 2001) from bladder and lung cancer data from Taiwanese epidemiology studies. The lifetime cancer risk at the MCL of 10 µg/L is estimated to be 3 to 4 per 1000, which is high relative to the risks of most other regulated drinking water contaminants.

Asbestos

Asbestos is the name for a group of naturally occurring, hydrated silicate minerals with fibrous appearance. Included in this group are the minerals chrysotile, crocidolite, anthophyllite, and some of the tremolite-actinolite and cummingtonite-grunerite series. All except chrysotile fibers are known as amphibole. Most commercially mined asbestos is chrysotile. Asbestos occurs in water exposed to natural deposits of these minerals, asbestos mining discharges, and asbestos-cement pipe (USEPA, 1985a).

The physical dimensions of asbestos fibers, rather than the type of fiber, are more important in determining the health effects, with the shorter, thinner fibers more highly associated with cancers by inhalation. Human occupational and laboratory animal inhalation exposures are associated with a specific type of cancer, mesothelioma, in lung, pleura, and peritoneum (USEPA, 1985a). An NTP study also observed benign GI neoplasms in rats exposed in the diet to intermediate-range fibers (65 percent of the fibers larger than 10 µm, 14 percent larger than 100 µm) for their lifetime (USEPA, 1985a). Human epidemiologic studies of asbestos in drinking water have had inconsistent results, but there are suggestions of elevated risk for gastric, kidney, and pancreatic cancers (Cantor, 1997).

The USEPA MCL and MCLG for asbestos fibers >10 µm is 7×10^6 fibers/L. This is based on the estimate that drinking water exposure to 7×10^6 fibers (of size >10 µm/L) will not result in an increased lifetime cancer risk of more than 1×10^{-6} (1 in 1,000,000). This estimate is based on the results of the NTP oral rat study (USEPA, 1991a).

Boron

Boron may be present in water from natural or anthropogenic sources. It is found in rock formations, especially in the western United States, and in seawater at about 4.5 mg/L. It is used industrially, in pesticides, and in detergents and soaps and is released from coal-burning power plants (USEPA, 2008b).

Boron is detected at some concentration in almost all surface and groundwaters tested, with higher concentrations generally found in groundwater. In a study of 228 groundwater and 113 surface water samples, it was detected in groundwater above 0.7 mg/L in 8.8 percent and above 1.4 mg/L in 3.1 percent of samples but was not detected above 0.7 mg/L in any surface water sample. Boron is often present at milligram per liter concentrations in the finished drinking water produced by desalination of seawater (NRC, 2008).

Acute exposure to high levels of boron causes GI effects and skin redness. It is considered a possible trace mineral nutrient for humans (IOM, 2006). The primary effects of concern from long-term exposure to low levels of boron are testicular toxicity and developmental effects. Testicular effects including atrophy, inhibition of sperm formation, decreased fertility, and sterility have been seen in several animal species. In developmental studies with rats, mice, and rabbits, oral exposure to boric acid resulted in decreased pregnancy rates, increased prenatal mortality, decreased fetal weights, and increased malformations in fetuses and pups. Boron is not considered mutagenic and is not considered to be carcinogenic by USEPA (USEPA, 2008b).

USEPA (2008b) recently decided not to develop an MCL for boron as part of its CCL process. The USEPA RfD for boron is 0.2 mg/kg/day based on developmental effects in rats. USEPA Drinking Water Health Advisories for boron have recently been updated (USEPA, 2008c). The Ten-day Health Advisory of 3 mg/kg/day for children is based on testicular toxicity in a subchronic dietary study in rats. The Longer-term Health Advisory of 2 mg/L for children is based on testicular toxicity in a chronic rat study. The Longer-term Health Advisory for adults and the Lifetime Health Advisory of 5 mg/L are based on developmental effects in the fetus and exposure assumptions for pregnant women (USEPA, 2008c).

Cadmium

Cadmium enters the environment from a variety of industrial applications and may enter consumers' tap water by corrosion of galvanized pipe and solder used in hot water heaters. Various foods and tobacco smoke also contribute to cadmium exposure.

Cadmium can cause kidney dysfunction, hypertension, anemia, and altered liver function (USEPA, 1985a). Chronic occupational exposure has resulted in renal dysfunction and neuropsychological impairments. The concentration of cadmium in the kidney increases over time, and renal toxicity is related to the concentration in the kidney. Cadmium has been shown to induce testicular and prostate tumors in laboratory animals injected subcutaneously (ATSDR, 1993). It is considered to be a probable human carcinogen (Group B1) by the inhalation route based on limited evidence in workers but is not classifiable as to carcinogenicity by the oral route. It is regulated based on its renal toxicity in humans, based on the highest cadmium concentration in the kidney, 200 mg/kg, which is not associated with significant proteinuria (USEPA, 1985a). A toxicokinetic model was used to determine the NOAEL of 0.005 mg/kg/day, which is the chronic dose from drinking water that would result in a concentration of 200 mg/kg in the kidney. An uncertainty factor of 10, appropriate for a NOAEL from human data, and an RSC factor of 25 percent were applied to develop the MCLG and an MCL of 5 µg/L (USEPA, 1985a, 1991a).

Chromium

Chromium may occur in drinking water in its hexavalent or trivalent states. The process of water disinfection can affect its oxidation state, increasing the proportion in the hexavalent state (Lai and McNeill, 2006). Chromium can occur naturally in water or result from sources such as wastes from chromate production or electroplating operations, mining, and garbage and fossil fuel combustion (USEPA, 1985a).

The toxic potency of chromium is dependent on its oxidation state, with Cr(VI) being much more potent than Cr(III). The stomach has a substantial capacity to reduce Cr(VI) to Cr(III), but kinetic factors which compete with the reduction capacity make it likely that absorption of unreduced Cr(VI) occurs after ingestion of even relatively small doses of Cr(VI) (O'Flaherty et al., 2001; NJDEP, 2009). Cr(VI) compounds rapidly enter cells, while Cr(III) compounds enter much more slowly. Once it is taken into cells, Cr(VI) is rapidly reduced to Cr(III), with Cr(V) and Cr(IV) as intermediates. Within the cell, Cr(III) may react with peptides, proteins, and DNA, resulting in DNA-protein crosslinks, DNA strand breaks, and alterations in cellular signaling pathways, which may contribute to toxicity and carcinogenicity of chromium compounds (ATSDR, 2008b).

Cr(III) is an essential nutrient for normal glucose, protein, and fat metabolism; has low toxicity; and is poorly absorbed. Currently, the biological target for the essential effects of Cr(III) is unknown. The Institute of Medicine Food and Nutrition Board (2001) of the NAS determined an adequate intake (e.g., a level typically consumed by healthy individuals) of 20 to 45 μg Cr(III)/day for adolescents and adults.

Cr(VI) is a known human carcinogen (Group A) by the inhalation route of exposure, as epidemiology studies have shown it to cause lung tumors in exposed workers. Until recently, inadequate data were available to assess its oral carcinogenicity. The MCL and MCLG of 100 $\mu\text{g}/\text{L}$ for total chromium are based on an NOAEL of 2.4 mg/kg/day in a one-year rat drinking water study of hexavalent chromium, an uncertainty factor of 500, and the assumption that humans are exposed to 0.1 mg/day in the diet. However, a recent NTP (2008a) drinking water study has shown clear evidence of oral carcinogenicity based on gastrointestinal tumors in mice and oral tumors in rats. If the MCLG and MCL are reevaluated based on a slope factor developed from these data (California EPA, 2009; NJDEP, 2009), a much lower drinking water standard will likely result.

Copper

Copper is found commonly in drinking water (USEPA, 1985a). The principal sources in water supplies are from the addition of copper salts to control algae in lakes and reservoirs. Additionally, low levels (generally, below 20 $\mu\text{g}/\text{L}$) can derive from rock weathering, and some can come from industrial sources. In treated drinking waters, sources of copper are from water corrosion of brass and copper pipes and fixtures.

Copper is a nutritional requirement, and deficiency leads to anemia, skeletal defects, nervous system degeneration, and reproductive abnormalities. The daily requirements are estimated as 0.9 mg/day for adults, 0.34 mg/day for 1- to 3-year-olds, and 0.2 mg/day for infants (Institute of Medicine Food and Nutrition Board, 2001).

Copper in excess of nutritional requirements is excreted. However, at high doses, copper can cause acute effects such as GI disturbances, damage to the liver and kidneys, and anemia. The lowest dose at which adult GI tract irritation was seen was 5.3 mg/day (USEPA, 1991b). A study of 4- to 6-month-old infants found that growth and the incidence of diarrhea were not affected by ingesting 2 mg/L in milk formula (Olivares et al., 1998). The Institute of Medicine tolerable intake level for 1- to 3-year-olds was set at 1 mg/day. Those with Wilson's disease, an inherited condition in about 1 in 40,000 individuals that results in copper accumulation in the body, are more sensitive to the effects of copper in water and food and may require medical intervention. Exposure of mice via subcutaneous injection yielded tumors; however, oral exposure in several studies did not. Mutagenicity tests have been negative.

Copper is regulated under special provisions of the Lead and Copper Rule (USEPA, 1991b). Under the rule, if more than 10 percent of the samples from residential taps most at risk for copper contamination exceed the action level of 1.3 mg/L, then water purveyors

must take action to minimize corrosion. An SMCL of 1.0 mg/L, based on taste, applies to water entering the distribution system from the water treatment plant. Residents in homes that use copper pipe are often advised to drink water only from the cold tap and to flush standing water from the pipes each morning before drinking it or using it to make beverages; these measures usually also decrease the concentration of lead in the drinking water.

Fluoride

Fluoride occurs naturally in some soils and rocks and in many water supplies. Drinking water is the source of greatest exposure in most individuals; other exposure sources include food, dental products, and pesticides. To protect against the development of dental caries, fluoride is widely added at 0.7 to 1.2 mg/L to public water supplies in the United States that do not contain it naturally at the desired level. In 2000, it was estimated that approximately 162 million people in the United States used artificially fluoridated water (NRC, 2006a). Acute effects of overdosing in the range of 20 to 200 mg/L, which can occur due to equipment failure in fluoridating systems, can cause nausea, diarrhea, abdominal pain, headache, and dizziness (CDC, Division of Oral Health, 1992).

The USEPA SMCL of 2 mg/L is intended as a guideline for areas that have high levels of naturally occurring fluoride. The SMCL is based on protection from dental fluorosis (tooth discoloration and/or pitting) caused by excess fluoride exposures during the formative period prior to eruption of teeth in children. This effect is considered by USEPA to be a cosmetic effect rather than an adverse health effect. Chronic high-level exposure to fluoride can increase the risk of fractures and lead to skeletal fluorosis. In this condition, fluoride accumulates in the bone over many years, causing stiffness and pain in the joints and eventually changes in bone structure, calcification of ligaments, and pain. Evidence of a relationship between fluoride exposure and an increased incidence of bone cancer (osteosarcoma) in young males is mixed but cannot yet be ruled out.

The MCL and MCLG for fluoride are 4 mg/L, based on prevention of bone disease. In 1992, it was estimated that 1.4 million people in the United States used drinking water with natural fluoride concentrations of 2.0 to 3.9 mg/L, and just over 200,000 people used drinking water with concentrations equal to or exceeding 4 mg/L (NRC, 2006a). A recent NRC (2006a) report concluded that the MCL and MCLG of 4 mg/L should be decreased to protect children from developing severe enamel fluorosis and to reduce the risk of bone fracture and possibly skeletal fluorosis, particularly in subpopulations that accumulate fluoride in their bones.

Hardness

Hardness is due to calcium and magnesium present in water and is expressed as an equivalent concentration as calcium carbonate (CaCO_3). Other divalent and trivalent ions can contribute to hardness but are almost always less than 1 mg/L and do not make a significant contribution. Although no distinctly defined levels exist, waters with less than 75 mg/L CaCO_3 are generally considered soft, those with between 75 and 150 mg/L CaCO_3 are said to be moderately hard, those with 150 to 300 mg/L CaCO_3 are hard, and waters with more than 300 mg/L CaCO_3 are classified as very hard.

An inverse relationship has been observed between the incidence of cardiovascular disease and the amount of hardness in the water (Catling et al., 2008). Hypotheses outlined below suggest a protective effect from either the major or minor constituents of hard water or, conversely, a harmful effect from corrosion by-products found at higher concentrations in soft water.

Many investigators attribute a protective effect for cardiovascular disease to the presence of calcium and magnesium (reviewed by Marx and Neutra, 1997; McCarron, 1998; Monarca et al., 2006). A moderate increase in calcium in the diet has been observed to decrease levels of circulating cholesterol; this is speculated to be a factor in relating water hardness and cardiovascular disease. Magnesium is theorized to protect against lipid deposits in arteries, to reduce cardiac irritability and damage, and may also have anticoagulant properties that could protect against cardiovascular diseases by inhibiting blood clot formation.

A few other studies suggest that minor constituents often associated with hard water may exert a beneficial effect on the cardiovascular system. Candidate trace elements include vanadium, lithium, manganese, and chromium. On the other hand, other investigators suggest that certain trace metals found in higher concentrations in soft water due to corrosion, such as cadmium, lead, copper, and zinc, may be involved in the causation of cardiovascular disease.

For each of these hypotheses, it is uncertain whether drinking water provides enough of these elements to have any significant impact on the pathogenesis of cardiovascular disease. For example, hard water generally supplies less than 10 percent of the total dietary intake of calcium and magnesium, and water provides even smaller proportions of the total intake of the various suspect trace metals. Given the level of uncertainty on this subject, USEPA currently has no policy with respect to the hardness or softness of public water supplies. However, USEPA strongly supports corrosion control measures, some of which increase hardness, to reduce exposure to lead.

Iron

Iron is commonly found in the soluble reduced form (FeII) in groundwater and at the bottom of reservoirs where reducing conditions exist. Iron can also enter drinking water from corrosion of iron or steel pipes and storage tanks.

Because there is a nutritional requirement of 10 to 12 mg per day of iron for healthy adult men and 10 to 15 mg per day for women (NRC, 1989), it is unlikely that health problems will arise even from the maximum concentrations found in drinking water. However, in individuals genetically susceptible to hemochromatosis, excess iron can accumulate in the body, resulting in liver, pancreatic, and heart dysfunction and failure after long-term high exposures (Motulsky, 1988). About 1 person in 200 is potentially at risk for this condition, though the actual incidence is much lower (Walker et al., 1998).

The SMCL for iron of 0.3 mg/L is based on discoloration of laundry and a metallic taste that becomes noticeable in the range of 0.1 to 1.0 mg/L (see Aesthetic Quality later in this chapter).

Lead

Lead occurs in drinking water primarily from corrosion of lead pipe and of solder and faucets constructed with leaded brass, especially in areas with soft or acidic water. However, the primary source of exposure for children, who are more sensitive than adults to lead toxicity, is lead-based paint in older homes. Because of concerns about the health effects of lead, it is no longer used in gasoline, residential paint, or solder for food cans and water pipes.

Lead accumulates in bone over the lifetime; most lead in the body is stored in bone. The main target for lead toxicity is the nervous system, both in adults and children. Infants and young children absorb ingested lead more readily than older children and young adults (National Academy of Sciences Safe Drinking Water Committee, 1982). Of great public health concern, low levels of exposure during prenatal development, in infancy, or in early childhood causes neurodevelopmental effects, such as delays in mental and physical development and

decreases in intelligence, which may be permanent. Higher blood lead levels are associated with many other effects, including interference with heme synthesis necessary for formation of red blood cells, anemia, kidney damage, miscarriage, impaired sperm production, interference with vitamin D metabolism, and elevations in blood pressure in adults (USEPA, 1988a). In its IRIS database of risk assessment information, USEPA has classified lead as a probable human carcinogen because some lead compounds cause renal tumors in rats.

Exposure to lead is measured by the blood lead level. The CDC action level for blood lead in children is 10 $\mu\text{g}/\text{dL}$, but no threshold blood lead level for neurodevelopmental effects in children, such as slight IQ decrements, has been determined. At this low blood level, the lead from plumbing becomes more significant as a potential source, particularly when other sources are reduced or eliminated.

USEPA has established an action level instead of an MCL for lead (USEPA, 1991b). It requires that water purveyors sample residential taps that have been determined to be the most likely to have a lead corrosion problem. If more than 10 percent of the residential taps sampled are above the action level of 15 $\mu\text{g}/\text{L}$, treatment measures are required to reduce corrosive properties of the water and, thus, the lead levels. The MCLG for lead is set at zero because no threshold is known for neurodevelopmental effects, to affirm the overall USEPA goal of reducing total lead exposures, and because lead is classified as a probable human carcinogen.

Manganese

Manganese is found in the soluble reduced form (MnII) in groundwater and at the bottom of reservoirs where reducing conditions exist. Man-made sources include discarded batteries, steel alloy production, and agricultural products. Manganese is removed from water primarily due to aesthetic reasons (taste and staining), with a SMCL of 0.05 mg/L .

Manganese is an essential nutrient, fulfilling a catalytic role in various cellular enzymes, but deficiencies are rare because it is found in many foods. The greatest source of exposure is the diet (0.7 to 10.9 mg/day) (USEPA, 2004), while the median drinking water concentration is 10 $\mu\text{g}/\text{L}$. The adequate daily intake for infants up to 6 months old is thought to be 3 $\mu\text{g}/\text{day}$, based on levels in breast milk, with higher requirements for older individuals, up to 2.3 mg/day in adult males (Institute of Medicine, 2001).

Occupational inhalation exposure can lead to manganism, an irreversible, slow-onset neurotoxic disease with symptoms similar to Parkinson's disease. Manganese is generally considered to be nontoxic orally, and human epidemiology studies of its neurotoxic potential through oral exposure are inconclusive. Rodents are not considered to be a good model for manganese toxicity in humans due to differences in accumulation in the brain and higher dietary requirements. Manganese is not considered to be carcinogenic. The USEPA Lifetime Health Advisory (2004) of 0.3 mg/L is based on the estimation of a safe level from the reported upper limit of dietary exposures in adults. It includes a modifying factor of 3 to account for possible higher bioavailability from water than from food. A recent publication (Ljung and Vahter, 2007) has raised questions as to whether the WHO guideline for manganese in drinking water of 0.4 mg/L is protective in children, based on data on greater absorption, slower excretion, and greater susceptibility to neurotoxicity in infants and children than in adults.

Mercury

Mercury occurs primarily as an inorganic salt in water and in the organic form, methylmercury, in sediments and fish (USEPA, 1985a). Mercury enters the environment from the burning of fossil fuels, incineration of products containing mercury, past uses in

pesticides, and leaching of organic mercury from antifungal outdoor paints, as well as natural sources.

Inorganic mercury is poorly absorbed in the adult GI tract, does not readily penetrate cells, and is not as toxic as methylmercury. Calomel, mercurous chloride, was used in the past as a laxative. However, the absorption of inorganic mercury can be much higher in infants and young children than in older individuals. The most sensitive toxic endpoint for inorganic mercury in adult laboratory animals is the induction of an autoimmune disease of the kidney (ATSDR, 1999).

Inorganic mercury released into the environment enters water bodies where it is transformed by bacteria in sediments to methylmercury, which bioaccumulates through the food chain. Organic forms such as methylmercury are readily absorbed in the GI tract and can easily enter the central nervous system (CNS). Methylmercury is neurotoxic, and exposure can result in mental and motor dysfunctions or death. It can cross the placental barrier and reach the fetus, which is sensitive to its neurodevelopmental toxicity. Thus, pregnant women are the subpopulation of greatest concern for exposure to methylmercury. Fish contaminated with methylmercury caused the well-known mercury poisonings in Japan's Minamata Bay, characterized by deaths, CNS disorders, and mental retardation. Lower levels of exposure, such as those resulting from consuming large amounts of fish containing mercury, result in neurodevelopmental effects in children and neurological effects in adults. However, drinking water is not a significant source of methylmercury exposure. Metallic (elemental) mercury is also neurotoxic when inhaled but is not found at significant levels in water.

USEPA has classified inorganic mercury as a possible human carcinogen (Group C) based on a chronic oral study in rats (NTP, 1993) that showed some evidence of carcinogenicity in male rats and equivocal evidence in female rats and male mice. *In vitro* mutagenicity and genotoxicity studies of inorganic and organic mercury gave mixed results (ATSDR, 1999). The MCLG and MCL of 2 µg/L are based on kidney effects of the inorganic mercury, which is the form of mercury found in water (USEPA, 1991a).

Nitrate and Nitrite

Nitrate is one of the major anions in natural waters, and concentrations can be greatly elevated due to leaching of nitrogen from farm fertilizer, feedlots, and septic tanks. The mean concentration of nitrate nitrogen (NO_3^- as N) in a typical surface water supply is around 0.2 to 2 mg/L, and individual wells can have significantly higher concentrations. Adult dietary nitrate intake is approximately 20 mg/day, mostly from vegetables such as lettuce, celery, beets, and spinach (National Academy of Sciences Committee on Nitrite and Alternative Curing Agents in Food, 1981).

Nitrite does not occur typically in natural waters at significant levels, except under reducing conditions or by oxidation of ammonia. Sodium nitrite was widely used for cured meats, pickling, and beer, but such usage has been sharply curtailed. Rarely, water supplies in buildings have been contaminated with nitrite by faulty cross-connections or procedures during boiler cleaning with nitrous acid.

Nitrite, or nitrate converted to nitrite in the body, can undergo two chemical reactions that can cause adverse health effects: induction of methemoglobinemia, especially in infants under six months of age, and the potential formation of carcinogenic nitrosamides and nitrosamines (National Academy of Sciences Safe Drinking Water Committee, 1977; USEPA, 1989c).

Methemoglobin, normally present at 1 to 3 percent in the blood, is the oxidized form of hemoglobin and cannot act as an oxygen carrier. Certain substances, such as the nitrite ion, oxidize hemoglobin to methemoglobin (National Academy of Sciences Safe Drinking Water Committee, 1977). In adults, only a small percentage of ingested nitrate is reduced to nitrite by bacteria in the mouth. However, in infants, the relatively alkaline conditions in the

stomach allow bacteria there to reduce up to 100 percent of the nitrate to nitrite, particularly when a concurrent GI infection is present. Furthermore, infants do not have the same capability as adults to convert methemoglobin back to hemoglobin. When the concentration of methemoglobin in the blood reaches 5 to 10 percent, symptoms can include lethargy, shortness of breath, and a bluish skin color (blue-baby syndrome). Anoxia and death can occur at high exposures to nitrites or nitrates.

Carcinogenic nitrosamines and nitrosamides are formed when nitrite reacts in the stomach with secondary amines, such as the amino acids from dietary protein (IARC, 1978). This process is inhibited by antioxidants in the diet, such as vitamin C. A recent series of epidemiological case-control studies conducted in Iowa by the National Cancer Institute and others (reviewed by Ward et al., 2005, 2007, 2008) suggest a relationship between nitrate and cancer in various tissues in the subset of people consuming more red meat and less vitamin C than the average.

The data on the role of nitrates in developmental effects, such as birth defects, are regarded as being inconclusive (Ward et al., 2005).

The MCLGs and MCLs are 10 mg/L for nitrate measured as nitrogen (equivalent to 45 mg/L nitrate) and 1 mg/L for nitrite measured as nitrogen (USEPA, 1991a). In addition, the MCL for total nitrate-N and nitrite-N is 10 mg/L. While most MCLGs are based on exposure assumptions for adults (70 kg body weight and 2 L/day water consumption), the MCLGs for nitrate and nitrite are based on exposure assumptions for an infant (10 kg body weight and 1 L/day water consumption), as they are most sensitive to the effects of these compounds.

Perchlorate

Perchlorate is a chemical with diverse uses in flares, fireworks, rocket fuel, and explosives and it occurs naturally in fertilizers from certain regions, such as Chile. It also has been used clinically to treat hyperthyroidism because it blocks the uptake of iodine into the thyroid gland, resulting in reduced production of the iodine-containing hormones, thyroxine (T4) and triiodothyronine (T3). In a normal, healthy individual, reduced levels of thyroid hormones are prevented to a large extent by a negative feedback loop involving stimulation of the thyroid by the pituitary hormone, thyroid stimulating hormone (TSH). Thyroid hormones are critical in fetal and infant brain development, and deficiency during these periods can cause irreversible developmental effects. Thus, the primary concern about environmental exposures to perchlorate is its potential to interfere with thyroid function in fetuses and infants.

The NRC (2005) recommended an RfD based on the small but detailed study by Greer et al. (2002), which measured the inhibition of iodine uptake by the thyroid and the levels of thyroid hormones in adult volunteers dosed with perchlorate. In this study, a dosage of 7 $\mu\text{g}/\text{kg}/\text{day}$ did not affect thyroidal iodine uptake. Reduced iodine uptake is not considered to be an adverse effect and is a full biological step away from a reduction in thyroxine or a homeostatic increase in TSH. Neither of these effects occurred even at the highest dose of perchlorate in the study, 500 $\mu\text{g}/\text{kg}/\text{day}$.

Based on this study, the NRC established an RfD of 0.0007 mg/kg/day, which was adopted by the USEPA IRIS database in 2006. This RfD incorporates an uncertainty factor of 10 to protect sensitive subpopulations. Additional uncertainty factors were not considered necessary since the observed effect was not in and of itself considered adverse. The protectiveness of this RfD is supported by other data indicating the absence of a thyroid hormone effect on newborns and pregnant women in locations with perchlorate in the drinking water.

The DWEL for a 70-kg adult based on this RfD is 24.5 $\mu\text{g}/\text{L}$ of perchlorate. The recent publication of U.S. Food and Drug Administration data on exposure to perchlorate in foods

(Murray et al., 2008) indicates that an RSC of 0.6 is appropriate, instead of the default RSC of 0.2, suggesting a health-based drinking water level protective for adults of 15 $\mu\text{g/L}$.

Recent physiologically based pharmacokinetic modeling (USEPA, 2008d) indicates that infants who are bottle-fed (mostly with formula reconstituted from powder) receive a dose (mg/kg/day) approximately six times higher than the adult dose at the same drinking water concentration. These findings suggest that the drinking water concentration of 15 $\mu\text{g/L}$ based on adult exposure is not sufficiently protective of infants. USEPA (2008e) has recently developed an Interim Health Advisory of 15 $\mu\text{g/L}$ for perchlorate. Perchlorate is one of four contaminants listed on the USEPA CCL3 which the USEPA Science Advisory Board recommended as a priority for consideration for regulation based on available data on toxicity, occurrence, and treatability (USEPA, 2009b). At the time of this writing, USEPA is reevaluating an earlier proposal not to establish an MCL for perchlorate and has requested comments on this issue (USEPA, 2009c).

The USEPA Office of Water perchlorate Website should be consulted for further updates. <http://www.epa.gov/safewater/contaminants/unregulated/perchlorate.html>. California, Massachusetts, and New Jersey have proposed or adopted a perchlorate drinking water standard (Zewdie et al., 2009).

Selenium

Selenium is an essential dietary element with most human intake coming from food. The NRC (1989) has recommended that the daily diet include between 55 and 75 μg selenium, with the higher end of this range recommended for adult males and pregnant or nursing females. Selenium is a key component of glutathione peroxidase, a vital thyroid enzyme (Corvilain, Contempre, and Longombe, 1993). In humans exposed to high dietary levels, dermatitis, hair loss, abnormal nail formation and loss, diarrhea, liver degeneration, fatigue, peripheral nervous system abnormalities, and a garlic odor have been observed (reviewed by Poirier, 1994 and by Patterson and Levander, 1997). The USEPA IRIS RfD of 0.005 mg/kg/day is based on the NOAEL for selenium toxicity in an area of China with high levels in the environment, and includes an uncertainty factor of 3 to account for sensitive individuals.

Selenium reacts *in vivo* with other elements to protect against heavy metal toxicity. Naturally occurring selenium compounds have not been shown to be carcinogenic in animals, and selenium may inhibit tumor formation (USEPA, 1985a; Patterson and Levander, 1997), although the data on this effect are controversial (Clark and Alberts, 1995; Navarro et al., 2007). Selenium has not been found to be teratogenic in mammals (Poirer, 1994).

An MCLG and an MCL of 50 $\mu\text{g/L}$ (USEPA, 1991a) have been established based on the RfD described above.

Sodium

Sodium is a naturally occurring constituent of drinking water. A survey of 2100 finished waters conducted between 1963 and 1966 by the U.S. Public Health Service found concentrations ranging from 0.4 to 1900 mg/L, with 42 percent of samples above 20 mg/L and 4 percent above 250 mg/L (White et al., 1967). Sodium levels at the tap can be increased by water softeners, which can add approximately 1 mg sodium for every 2 mg hardness removed.

There is strong evidence for an at-risk population that is predisposed to high blood pressure (hypertension) from dietary sodium (Institute of Medicine Panel on Dietary Reference Intakes for Electrolytes and Water, 2004). Older persons, African-Americans, and those

with hypertension, diabetes, or kidney disease are more likely than others to be members of this at-risk population. Hypertension is of concern because it increases the risk of coronary heart disease, stroke, and certain other diseases (Institute of Medicine Panel on Dietary Reference Intakes for Electrolytes and Water, 2004).

Renin, angiotensin, and aldosterone are hormones that form a system that regulates cardiac output and blood pressure in response to changes in physiological factors, including sodium levels. This system can become less responsive with advancing age, resulting in increased sensitivity of blood pressure to sodium intake (Institute of Medicine Panel on Dietary Reference Intakes for Electrolytes and Water, 2004). The Institute of Medicine report concluded that “overall, the available evidence on the effects of sodium reduction on blood pressure in children is limited and inconsistent.”

Food is the major source of sodium. The suggested adult maximum daily intake is 2300 mg (American Heart Association, 2008), and the Institute of Medicine (2004) suggested that 1200 mg/day is an adult minimum requirement. Typical adult intake is 2000 to 10,000 mg/day (Institute of Medicine, 2004), with an average intake of 3000 to 5000 mg/day (USDA, 2009); physically active persons may require higher levels. Drinking water at a typical concentration of 20 mg/L contributes about 1 percent of the minimum requirement, assuming consumption of 2 L/day. The USEPA guidance level for sodium of 30 to 60 mg/L is based on taste (see Taste and Odor in section on Aesthetic Quality), and consuming 2 L per day of water with sodium at the high end of this range would contribute approximately 5-10 percent of the minimum requirement.

Sulfate

Sulfate is a naturally occurring anion. High concentrations of sulfate in drinking water may cause transitory diarrhea (USEPA, 1990a). Most adults experience a laxative effect when sulfate concentrations are above 1000 mg/L, whereas medical case reports indicate that bottle-fed infants develop diarrhea at levels above 600 mg/L. Acute diarrhea can cause dehydration, particularly in infants and young children who may already have a microbial diarrheal condition. Adults living in areas having high sulfate concentrations in their drinking water easily adjust, with no ill effects. The SMCL for sulfate is 250 mg/L based on taste (see section on Aesthetic Quality). The U.S. Army standard for soldiers drinking 5 L/day of water is 300 mg/L.

ORGANIC CONSTITUENTS

Organic compounds in water derive from three major sources: (1) the breakdown of naturally occurring organic materials, (2) man-made chemicals from domestic and commercial activities, and (3) treatment additives and chemicals formed during reactions that occur during water treatment and transmission. Naturally occurring materials are the greatest source of organic compounds in water (see Chap. 3). They are composed of humic materials from plants and algae, microorganisms and their metabolites, and high-molecular-weight aliphatic and aromatic hydrocarbons. These natural organics are typically not of health concern, although some are nuisance constituents such as odiferous metabolites (see section on Aesthetic Quality). A few of the high-molecular-weight natural aliphatic and aromatic hydrocarbons may have adverse health effects. In addition, humics serve as precursors (reactants) in the formation of trihalomethanes (THMs), haloacetic acids (HAAs), and other organohalogen DBPs during disinfection (see Chap. 19).

Man-made organic chemicals from domestic and commercial activities enter water supplies through wastewater discharges, agricultural and urban runoff, leachate from

contaminated soils, and air deposition to surface waters or to soils followed by migration to groundwater. Many of the organic drinking water contaminants with potential for adverse health effects are part of this group. They include pesticides (such as atrazine and aldicarb), solvents and metal degreasers (such as trichlorobenzene, tetrachloroethylene, trichloroethylene, and trichloroethane), and emerging contaminants such as pharmaceuticals and perfluorinated chemicals.

Organic contaminants formed during water disinfection include by-products such as THMs (e.g., chloroform) and HAAs (e.g., di- and trichloroacetic acids). Other compounds such as acrylamide are components of high molecular weight polymers used as flocculants and filter aids used in water treatment and epichlorohydrin, a component of one group of cationic polymers used as a coagulant. During finished water transmission, undesirable components of pipes, coating, linings, and joint adhesives, such as PAHs, epichlorohydrin, and solvents, can leach into water. Health effects of some organic chemicals that are of concern as drinking water contaminants are summarized below.

Volatile Organic Chemicals

The term *volatile organic chemical* (VOC) refers to the characteristic evaporative properties (or the vapor pressure) of these compounds. In general, VOCs are at least slightly water soluble, and three broad groups of VOCs have been found in drinking water. One group includes compounds found in petroleum products, including aromatics such as benzene, toluene, ethylbenzene, and xylenes, as well as gasoline additives such as methyl-*tert*-butyl-ether. Typical sources are leaking fuel oil and gasoline tanks. Another group is the halogenated VOCs, used as solvents and degreasers in industrial and commercial facilities including dry cleaners and automobile repair garages. Their former use as septic tank cleaners also accounts for many instances of private well contamination. Some halogenated VOCs (e.g., ethylene dibromide, dichloropropanes, and 1,2,3-trichloropropane) have also been used as pesticide fumigants. The third group includes some of the chlorinated organic DBPs, particularly the THMs. Some THMs have also entered groundwater through industrial contamination.

As VOCs easily volatilize from hot water used in the home, inhalation is an important route of exposure to these chemicals from drinking water, in addition to ingestion. The air in bathrooms can represent a major source of exposure because of volatilization from shower and bath water (McKone, 1987; Jo, Weisel, and Liroy, 1990; Maxwell, Burmaster, and Ozonoff, 1991). In addition, dermal absorption (through the skin) can occur from bath water because the VOCs are lipophilic. The exposures to VOCs in drinking water from the combined dermal and inhalation routes can equal the exposure received through ingestion (McKone, 1987).

Their lipophilic characteristic also enable VOCs to enter the brain from the blood. At high exposure concentrations, VOCs can cause reversible effects, including dizziness, nausea, and cardiac depression. Chronic inhalation of high levels of many VOCs causes CNS toxicity and may also produce irritation of the eyes, nose, and throat, but these effects are not relevant to drinking water contamination. Many VOCs cause toxicity to the liver and/or the kidney after chronic exposure, and some VOCs have been found to cause cancer in humans and/or laboratory animals.

Benzene and Other Aromatic Gasoline Components (Ethylbenzene, Toluene, and Xylene). The group of aromatic hydrocarbons that are found in petroleum products—benzene, toluene, ethylbenzene, and xylene, are known as the BTEX compounds. Drinking water can be contaminated with these chemicals from leaking underground storage tanks and other sources of petroleum contamination. Benzene, which is toxic to the bone marrow and causes leukemia, is by far the most toxic of this group of structurally related compounds.

Benzene is produced by petroleum refining, coal tar distillation, coal processing, and coal coking. It is also widely used as a chemical intermediate. Gasoline in the United States has contained anywhere from 0.5 to 5 percent benzene by volume. By 2011, USEPA will require that gasoline made or imported to the United States have an average annual benzene content of no higher than 0.62 percent (USEPA, 2008f).

Chronic exposure to sufficient levels of benzene, such as have occurred in occupational settings, causes toxicity to the hematopoietic (blood-forming) system. The target organ is the bone marrow, and effects include decreased numbers of red blood cells, platelets, or white blood cells (anemia, thrombocytopenia, or leukopenia) and leukemia. It is considered to be a human carcinogen. The mechanism of toxicity has not been totally elucidated, but toxicity is known to result from metabolites of benzene, rather than from the parent compound. By extrapolation from occupational studies, a drinking water concentration of 0.6 to 2.2 $\mu\text{g}/\text{L}$ benzene has been calculated to result in an excess lifetime cancer risk of 1 in 1,000,000 (USEPA 1998a, 1999). The federal MCL of 5 $\mu\text{g}/\text{L}$ for benzene is based on carcinogenic potential. Many states have promulgated stricter standards.

Ethylbenzene, toluene, and xylene are components of gasoline and fuel oil that are less toxic than benzene. Ethylbenzene is also used as a solvent and in the production of styrene. In a two-year inhalation study (NTP, 1999), kidney tumors in male and female rats, testicular tumors in male rats, lung tumors in male mice, and liver tumors in female mice occurred at an increased incidence. The relevance of these findings to human carcinogenic potential has not yet been evaluated by USEPA, and it is treated as a noncarcinogen and classified as Group D by the USEPA IRIS risk assessment database and in the development of the MCLG (USEPA, 1987a). The MCL and MCLG of 0.7 mg/L and the IRIS RfD of 0.1 $\text{mg}/\text{kg}/\text{day}$ are based on the NOAEL for liver and kidney effects in a one-year gavage study in rats.

Toluene is part of the aromatic fraction in gasoline and is used as a starting material in the production of benzene and other chemicals and as a solvent for paints, coatings, gums, glues, and resins. CNS toxicity is the primary effect of concern from acute or chronic inhalation exposure (ATSDR, 2000a). It is not considered to be a carcinogen. The RfD in the USEPA IRIS database of 0.08 $\text{mg}/\text{kg}/\text{day}$ and the MCL and MCLG of 1 mg/L are based on increased kidney weight in a subchronic rat gavage study.

Xylenes occur as three isomers, ortho-, meta-, and para-, that are treated as one in the USEPA health effects evaluation. Xylenes are part of the aromatic fraction that has been used in gasoline and are used as solvents and in the synthesis of many organic chemicals, pharmaceuticals, and vitamins. Like other chemicals in this group, high levels of exposure cause CNS toxicity. In a two-year gavage study (NTP, 1986), neither cancer nor other specific organ toxicity was observed in rats or mice. The MCL and MCLG of 10 mg/L for xylene, as well as the IRIS RfD, are based on the NOAEL for body weight loss in this study.

Chlorinated Volatile Organic Chemicals. Chlorinated solvents are among the most commonly encountered organic drinking water contaminants. Information on important members of this group of chemicals is summarized below.

Carbon Tetrachloride. Carbon tetrachloride has been used as a dry cleaning agent, solvent, reagent in chemical synthesis, fire extinguisher fluid, and grain fumigant, but its primary use was in chlorofluorocarbon (CFC) production. Annual production has declined since its use in consumer products was banned in the 1970s. Its production and import are currently being phased out as an ozone-depleting substance under the Clean Air Act and the Montreal Protocol.

The liver and kidney are the organs that are most sensitive to the effects of carbon tetrachloride from both acute and long-term exposure. Hepatic effects include fatty infiltration, release of liver enzymes, inhibition of enzyme activity, and, ultimately, necrosis.

Mutagenicity and genotoxicity tests using bacteria, mammalian cells, and short-term *in vivo* rat assays were mostly negative. Chronic exposures produced liver cancers in mice, rats, and hamsters, and it is classified as a probable human carcinogen (Group B2) by USEPA. No teratogenic effects have been demonstrated (ATSDR, 1994). The federal MCL for carbon tetrachloride of 5 µg/L is based on carcinogenic potential.

Dichlorobenzenes (ortho-, meta-, para-, or o-, m-, p-). o-Dichlorobenzene is used primarily in the production of organic chemicals, pharmaceuticals, pesticides, and dyes and as a deodorant in industrial wastewater treatment, and m-dichlorobenzene is used to make herbicides. Large amounts of p-dichlorobenzene are used as an insecticidal fumigant, laundry deodorant, and for mildew control. Dichlorobenzenes have been found in the milk of nursing mothers in several states (USEPA, 1985a).

The primary toxic effects of o- and p-dichlorobenzenes are on the blood, lung, kidney, and liver. Since similar data are not available for the meta-isomer, assessments for this isomer are based on data for o-dichlorobenzene. There is no evidence of carcinogenicity for o-dichlorobenzene, and USEPA treats it as a noncarcinogen (Group D). The RfD is based on the NOAEL for liver necrosis in rats in a subchronic gavage study (NTP, 1985). The MCL and MCLG for o-dichlorobenzene are 0.6 mg/L, based on an RfD of 0.9 mg/kg/day. The Lifetime Health Advisory for m-dichlorobenzene is also 0.6 mg/L based on the same RfD.

In a chronic gavage study of p-dichlorobenzene (NTP, 1987a), treatment-related increases were observed in the incidence of renal tubular cell adenocarcinomas in male rats and hepatocellular adenomas in male and female mice. Rare hepatoblastomas also occurred in male mice. Based on these data, p-dichlorobenzene is classified as a possible human carcinogen (Group C). The MCL and MCLG are 0.075 mg/L, based on the NOAEL for kidney lesions in rats (USEPA, 1987a, 1987b).

1,2-Dichloroethane (Ethylene Dichloride). 1,2-Dichloroethane is or has been used in the manufacture of vinyl chloride, as a lead scavenger in gasoline, as an insecticidal fumigant, as a constituent of paint varnish and finish removers, as a metal degreaser, in soap and scouring compounds, in wetting agents, and in ore flotation. It is environmentally persistent and is slightly water-soluble.

In humans, high doses of 1,2-dichloroethane cause toxicity to the CNS, circulatory system, kidney, and possibly the liver. Chronic doses in laboratory animals lead to hepatic and renal changes. 1,2-Dichloroethane is metabolized to reactive intermediates that are mutagenic and genotoxic in many microbial and mammalian test systems (ATSDR, 2001). In a chronic gavage study, it increased the incidence of tumors of the forestomach, circulatory system, and mammary glands in rats and of the uterus, mammary glands, and lung in mice (NTP, 1978). It is classified as a probable human carcinogen (Group B2). The MCLG is zero and the MCL is 5 µg/L.

1,1-Dichloroethylene (Vinylidene Chloride). 1,1-Dichloroethylene is used primarily as an intermediate in the synthesis of copolymers for food packaging films, adhesives, and coatings. It is formed by the hydrolysis of 1,1,1-trichloroethane.

Acute oral or inhalation exposures to 1,1-dichloroethylene cause toxicity to the liver, kidneys, and lung (USEPA, 2002a). Liver is the primary site of toxicity after chronic exposures, and kidney toxicity occurs in male mice. The organ damage is believed to result from metabolism of the parent compound to cytotoxic metabolites. Most genotoxicity assays in mammalian systems were negative. In the presence of mammalian enzymes that metabolize foreign chemicals, 1,1-dichloroethylene was mutagenic in bacterial and mammalian cell assays (USEPA, 2002a). Carcinogenicity test results have been equivocal. One inhalation study with mice and rats appeared to produce malignant kidney tumors in rats and malignant mammary tumors and leukemia in mice. The results of many other inhalation and feeding studies were negative, with the possible exception of mammary tumors. However, the design of many of these studies was not optimal for detecting carcinogenic effects (USEPA, 2002a). 1,1-Dichloroethylene is classified as a suggestive carcinogen by USEPA

(2002a). The MCLG and MCL are 7 µg/L based on liver effects in rats in a chronic drinking water study.

1,2-Dichloroethylenes. 1,2-Dichloroethylenes exist as cis- and trans-isomers. Both isomers are used, alone or in combination, as solvents and chemical intermediates. They are moderately water soluble.

The 1,2-dichloroethylenes are not highly toxic. Little toxicity was seen in a subchronic dietary study of the trans-isomer at doses up to 8000 mg/kg/day in mice and 3000 mg/kg/day in rats (NTP, 2002). No genotoxic or mutagenic effects were observed for trans-1,2-dichloroethylene, though cis-1,2-dichloroethylene was positive in some assays. They are not considered to be carcinogenic and are classified as Group D by USEPA. The MCLGs for both isomers are based on liver effects in animal studies. The MCLG and MCL for cis-1,2-dichloroethylene are 70 µg/L and for trans-1,2-dichloroethylene are 100 µg/L.

Methylene Chloride (Dichloromethane). Methylene chloride has been widely used in the manufacture of paint removers, urethane foam, pesticides and other chemical products, degreasers, cleaners, pressurized spray products, and fire extinguishers.

Increased levels of carbon monoxide bound to hemoglobin (carboxyhemoglobin) have been observed in people acutely poisoned by methylene chloride through inhalation or oral exposures (ATSDR, 2000b). Rats maintained on drinking water containing 130 mg/L methylene chloride for 91 days showed no adverse effects. Methylene chloride was mutagenic in bacterial assays but was negative in most mammalian cell assays. Chronic exposure through inhalation caused increased mammary gland tumors in rats and increased lung and liver tumors in mice. A chronic drinking water study showed increased liver tumors in female mice (ATSDR, 2000b). Methylene chloride is classified as a probable human carcinogen (Group B2). The MCL of 5 µg/L is based on carcinogenicity.

Tetrachloroethylene (Perchloroethylene). Tetrachloroethylene is used as a solvent in textile processing, metal degreasing, and dry cleaning and as a precursor in the manufacture of fluorocarbons. It was also used as a septic tank cleaner. USEPA (2010) recently estimated that over 600,000 people (>0.3 percent) served by public water supplies receive water with tetrachloroethylene at or above the MCL of 5 µg/L, and over 12,000,000 people (>5 percent) served by public water supplies receive water with concentrations at or above the Estimated Quantitation Level of 0.5 µg/L. Contamination in private wells has been as high as several milligrams per liter.

A recent draft review of the toxicity of tetrachloroethylene (USEPA, 2008g) concluded that inhalation causes CNS effects in both humans and animals, with effects on both vision and cognition. The doses at which these effects were seen are likely above those relevant to exposures from drinking water. The liver and kidney are affected by both oral and inhalation exposures. USEPA (2008g) concluded that tetrachloroethylene is “likely to be carcinogenic to humans” by both inhalation and oral exposure. This conclusion was based on findings of carcinogenicity in 10 of 10 chronic rodent studies and consistent association with excess cancer risks in human epidemiologic studies, although a causal mechanism has yet to be definitively established. The MCLG for tetrachloroethylene is zero, based on carcinogenicity, and the MCL is 5 µg/L.

1,1,1-Trichloroethane (Methyl Chloroform). Because 1,1,1-trichloroethane is less toxic than many other chlorinated solvents, it was previously commonly used in many household products and industrial applications. However, 1,1,1-trichloroethane is an ozone-depleting substance, and its production is currently being phased out under the Clean Air Act and the Montreal Protocol (ATSDR, 2006).

As with most VOCs, exposure to high levels of 1,1,1-trichloroethane orally or by inhalation causes CNS toxicity such as behavioral effects, unconsciousness, and death due to respiratory depression. Some recent animal studies suggest that long-term inhalation can cause permanent brain damage (ATSDR, 2006; USEPA, 2007a).

The USEPA MCLG and MCL of 200 µg/L are based on minimal liver effects in mice exposed by inhalation for 14 weeks (USEPA, 1984), as no appropriate oral study was

available when these values were developed. It is considered a noncarcinogen (Group D). More recently, the NTP conducted a subchronic study in which 1,1,1-trichloroethane was administered to mice and rats in microcapsules in the feed (NTP, 2000). This dosing regimen was designed to simulate drinking water exposure. The most sensitive endpoint was decreased body weight in mice compared to vehicle controls. Evaluation of the results of this study will likely lead to a recommendation of a health-based drinking water concentration much higher than the current MCLG of 200 µg/L.

Trichloroethylene (Trichloroethene). Trichloroethylene (TCE) is used primarily in metal degreasing. Its past use in dry cleaning was largely discontinued in the 1950s when it was replaced by tetrachloroethylene. Other uses include adhesives, paint strippers, paints, and varnishes. Other uses in the production of foods, pesticides, drugs, and cosmetics have been discontinued.

TCE is the most frequently reported organic contaminant in groundwater and is a common contaminant at hazardous waste sites (ATSDR, 1997). USEPA (2010) recently estimated that over 400,000 (~0.2 percent) of people served by public water supplies receive water with tetrachloroethylene at or above the MCL of 5 µg/L, and about 12,000,000 (>5 percent) of people served by public water supplies receive water with concentrations at or above the Estimated Quantitation Level of 0.5 µg/L. Trichloroethylene has been found at concentrations up to several milligrams per liter in private wells.

TCE causes toxicity to the central nervous system, the kidney, the liver, the immune system, the male reproductive system, and the developing fetus (USEPA, 2009). It is metabolized through two separate pathways: oxidation by cytochrome P-450 to metabolites thought responsible for liver toxicity, and conjugation with glutathione by glutathione S-transferase leading to formation of reactive metabolites thought responsible for kidney toxicity.

USEPA (2009d) conducted a meta-analysis of 14 high-quality human epidemiology studies, and classified TCE as “Carcinogenic to Humans” by all routes of exposure based on convincing evidence of a causal association between TCE exposure and kidney cancer. USEPA (2009d) also concluded that there is compelling evidence that TCE causes lymphoma in humans, and more limited evidence for lymphoma and biliary tract cancer. In chronic animal studies, TCE caused kidney tumors in rats, but not mice or hamsters, and liver tumors in mice. The data for several other types of tumors were weaker. The reactive metabolites formed through the glutathione conjugation pathway are clearly mutagenic, leading USEPA (2009d) to conclude that the kidney tumors, thought to result from these metabolites, occur through a mutagenic mode of action. IARC classified TCE as a probable human carcinogen based on occupational and environmental epidemiology (IARC, 1996). The MCLG is zero, based on carcinogenicity, and the MCL is 5 µg/L.

Vinyl Chloride (Monochloroethene). Vinyl chloride is used in the production of polyvinyl chloride (PVC) resins, which are widely used in construction, including drinking water pipes, as well as in many consumer and industrial products and in the building and construction industries. Its use in propellants and aerosols was banned in 1974.

The association between occupational exposure to vinyl chloride and the development of liver angiosarcomas is one of the best-characterized cases of chemical-induced carcinogenicity in humans. Liver angiosarcomas are an extremely rare tumor, with only 20 to 30 cases per year reported in the United States, and many of the reported cases are associated with vinyl chloride exposure. Exposure has also been associated with increased death due to primary liver cancer and may be associated with other types of cancer (USEPA, 2000c). Angiosarcoma and liver cancer are also found in rats, mice, and hamsters administered vinyl chloride via the oral and inhalation routes. The genotoxic mode of action of vinyl chloride is well characterized, involving a reactive metabolite that forms DNA adducts that lead to

tumor formation. Vinyl chloride is classified as a known human carcinogen by the oral and inhalation route. The MCLG is zero, based on carcinogenicity, and the MCL is 2 µg/L.

Methyl-Tert-Butyl-Ether and Other Gasoline Oxygenates. Methyl-*tert*-butyl-ether (MTBE) is an oxygenate that has been widely used both as a gasoline octane enhancer and for meeting USEPA Clean Air Act oxyfuel requirements. Premium gasoline has contained 5 to 8 percent MTBE to boost octane. Under the Clean Air Act, gasoline containing 15 percent MTBE was used in the Wintertime Oxygenated Fuels Program to reduce carbon monoxide formation in nonattainment areas, and gasoline containing 11 percent MTBE was used in the Federal Reformulated Gasoline Program to reduce formation of ozone precursors in nonattainment areas. In 1995, MTBE was the third most-produced organic chemical in the United States, behind ethylene and propylene, with 17.6 billion pounds produced (NJDEP, 2001).

MTBE is one of the most commonly detected groundwater contaminants and its use in gasoline is now being phased out in many states because of its potential to contaminate water supplies. For example, it has been detected in about 20 percent of public water supplies and private wells tested in New Jersey (NJDEP, 2001). MTBE is more resistant to degradation and moves through the soil to groundwater much faster than the other common groundwater contaminants from gasoline, such as benzene, toluene, ethylbenzene, and xylene (BTEX compounds). Sources of MTBE in groundwater and surface water include leaking underground storage tanks and pipelines, accidental spills, stormwater runoff, the use of gasoline engines in boats, and air deposition (NJDEP, 2001).

Individuals inhaling vapors from gasoline containing MTBE at the gasoline pump and in automobiles have reported symptoms such as headaches, nausea, and respiratory and eye irritation. In water, MTBE has a noticeable odor at 20 to 40 µg/L (USEPA, 1997a). It was not highly toxic to rats exposed by gavage for several months (Robinson, Bruner, and Olson, 1990). Although MTBE is not mutagenic or genotoxic, exposure to high levels by inhalation (8000 ppm) or by gavage (1000 mg/kg) was associated with the development of lymphoma and leukemia, as well as liver, renal, and testicular cancers in rodents (Burleigh-Flayer, Chun, and Kintigh, 1992; Belpoggi, Soffritti, and Maltoni, 1995). The relevance of these cancers to human health is not clear. A chronic study intended to evaluate carcinogenicity through the drinking water route is currently underway (Bermudez, Parkinson, and Dodd, 2009).

USEPA has not developed an MCL for MTBE, although it has been considered as a candidate for regulation in the CCLs developed in 1998, 2005, and 2008. MTBE is one of four contaminants listed on the USEPA CCL3, which the USEPA Science Advisory Board recommended as a priority for consideration for regulation based on available data on toxicity, occurrence, and treatability (USEPA, 2009b). Because of its widespread occurrence in drinking water and groundwater, at least 42 states have developed a standard or guidance for drinking water and/or groundwater (Delta Environmental Consultants, 2005a). USEPA has developed an advisory of 20 to 40 µg/L based on taste and odor, which is intended to provide a health-protective margin of exposure for both cancer and noncancer health effects (USEPA, 1997a).

In addition to MTBE, a number of other ethers and alcohols have been used as gasoline oxygenates. These include di-isopropyl ether (DIPE), ethyl *tert*-butyl ether (ETBE), *tert*-amyl methyl ether (TAME), *tert*-butyl alcohol (TBA), and ethanol. USEPA has not developed MCLs for these oxygenates, and discussion of their health effects is beyond the scope of this chapter. Many states have developed standards or guidance values for drinking water and/or groundwater for one or more of these contaminants (Delta Environmental Consultants, 2005b).

Pesticides

Pesticides include a wide range of compounds such as insecticides, herbicides, nematocides, rodenticides, and fungicides. These categories are divided into chemical families.

Chemicals within the same family typically result in related types of health effects, as discussed below.

Pesticides display a range of solubility in water, and many bind tightly to organic material in soil particles, slowing entry into surface or groundwater. Many of these compounds are chlorinated, increasing their persistence for agricultural uses as well as in the general environment. Fumigant pesticides are relatively water soluble, resulting in contamination of drinking water sources. In contrast, the lipophilic organochlorine pesticides, such as lindane, chlordane, and DDT (and its degradates/metabolites, DDD and DDE), are rarely seen above trace levels in public water systems, especially since their uses were cancelled. However, they are often found in river sediments, and they bioaccumulate in lipids (fat) through the food chain.

For the great majority of people, food represents a greater source of exposure to pesticides than drinking water (MacIntosh et al., 1996). Pesticides can reach drinking water concentrations of major health concern after accidental spills or in wells located close to application or mixing sites. Occurrence of pesticides in water sources varies with land use (e.g., low in areas with undeveloped land), season, and periods of high runoff. The U.S. Geological Survey (USGS) has conducted several surveys of water quality that have included pesticides. The National Ambient Water Quality Assessment (NAWQA) survey, conducted in 1992 through 2001, detected pesticides in 55 to 60 percent of shallow wells (mostly non-potable) and almost 100 percent of streams in agricultural and urban areas (Gilliom et al., 2006). Most detections were in the low part per trillion (0.001 $\mu\text{g/L}$) range. Two triazine and three acetanilide herbicides (see below) were associated with agricultural land use, while another triazine, two substituted-urea herbicides, 2,4-D (high-use lawn herbicide), and organophosphate and carbamate insecticides were found in urban settings. Health-based levels were exceeded for one or more pesticide in 1 percent of shallow wells in agricultural areas and 5 percent in urban areas and in 7 to 10 percent of streams. The NAWQA Source Water Quality Assessment, which sampled during 2002–2005, detected a variety of pesticides in streams and finished water. Maximum concentrations of two triazines, one acetanilide, and one substituted-urea herbicide were close to or exceeded levels of health concern in some samples (Kingsbury, Delzer, and Hopple, 2008). Data from the USEPA Unregulated Contaminant Monitoring Rule indicate that pesticides were detected at a point of entry in less than 1 percent of public drinking water systems and were detected above an MCL or Health Advisory at a point of entry in less than 0.1 percent of public water systems. Most detections above a Health Advisory were of the herbicide dacthal or its metabolites (USEPA, 2001e, 2008g).

Cancellation or severe restriction of use during the 1970s and 1980s has reduced the levels of some pesticides in the environment (USGS, 2006). These pesticides include the herbicide 2,4,5-TP (Silvex); certain fumigant nematicides (e.g., dibromochloropropane (DBCP), 1,2-dichloropropane, 1,2,3-trichloropropane, and ethylene dibromide [EDB]); and most organochlorine insecticides (chlordane, DDT, dieldrin, endrin, heptachlor, lindane, and toxaphene). Nevertheless, in monitoring done under the Unregulated Contaminant Monitoring Rule, some were found at or above levels of potential health concern.

The health effects associated with pesticides vary among the specific chemicals. Effects can be crudely differentiated into acute effects that occur from short-term exposure to high levels and chronic effects from long-term, low-level exposure. The former can include liver and kidney damage; major interference with nervous, immune, and reproductive system functions; and birth defects. Less severe effects on the nervous system are frequently expressed as “nonspecific” symptoms such as dizziness, nausea, and fatigue. Effects that may occur from long-term, low-level exposures include increased risk of birth defects and cancer risk. Uncertainties exist regarding the effects of exposure to mixtures of pesticides. Most pesticide degradates and metabolites are less toxic than their parent pesticide, but some have similar or greater toxicities.

For most pesticides, estimates of the risks of cancer and birth defects are based on studies in laboratory animals. However, epidemiologic studies have found increased incidence

of soft-tissue sarcoma and lymphoid cancers among farmers (reviewed by Dich et al., 1997). These effects may be related to the past presence of dioxin and other organochlorine chemicals in some pesticides as by-products of manufacturing (Kogevinas et al., 1997). Some studies have linked DDT and its metabolites to breast cancer, but the data are mostly negative (reviewed by Calle et al., 2002). Childhood cancers have also been linked to general pesticide exposure, particularly parental exposure during pregnancy and nursing (Infante-Rivard and Weichenthal, 2007), but these studies are not considered conclusive. The National Cancer Institute's Agricultural Health Study (2008) (recently updated by Blair and Beane Freeman (2009)) of agricultural pesticide applicators provides more recent evidence of a link between cancer and high-intensity exposure to certain pesticides. Prostate cancer was associated specifically with organochlorine pesticides, and an increased incidence among those with family histories of prostate cancer was also associated with exposure to a wider variety of pesticides, particularly certain organophosphate insecticides (Alavanja et al., 2003).

Epidemiological studies of reproductive and developmental effects of pesticides in current use, including organophosphates, carbamates, pyrethroids, ethylenebisdithiocarbamates, and chlorophenoxy herbicides, were reviewed by Bjørling-Poulsen et al. (2008). Many of these studies suggest that maternal exposure to pesticides is linked to adverse reproductive outcome, but exposures to mixtures of pesticides and the potential for recall bias preclude making definitive linkages between specific chemicals and effects.

Some pesticides affect endocrine systems, such as the effect of the fungicide vinclozolin on the sex steroid system and the effect of the triazine and acetanilide herbicides on the thyroid (Kavlock, 2001). Considerable research is being conducted on the relationship between these endocrine effects and cancer and reproductive toxicity. There is strong evidence that environmental exposures to pesticides can cause endocrine effects in nontarget wildlife species.

Families of pesticides typically share common toxicological mechanisms. USEPA documents, which address cumulative risk assessment from pesticides in general and specifically for organophosphates, N-methyl carbamates, triazines, and chloroacetanilides, are found at <http://www.epa.gov/oppsrrd1/cumulative/>.

Herbicides

Herbicides are not highly acutely toxic to mammals including humans, but some may be weakly carcinogenic. Determination of the carcinogenic potential of chlorinated aromatic herbicides was complicated by contamination due to the coproduction of carcinogenic polychlorinated aromatics during earlier manufacturing. Most notably, 2,4,5-trichlorophenoxyacetic acid (a component of Agent Orange, used as a Vietnam War defoliant) was contaminated with dioxin (2,3,7,8-TCDD). 2,4,5-T was the first of the herbicides to be discontinued. Dacthal was also previously similarly contaminated but is still in use since these contaminants are not present during current production (see below). These contaminant by-products are not mobile in soils and are generally not found in drinking water.

Triazine Herbicides (*Atrazine, Metribuzin, Prometon, Simazine*). USEPA (2006d) concluded that "certain triazine pesticides have been identified by a common mechanism group, including atrazine, simazine, propazine, and their chlorinated degradates desethyl-s-atrazine (DEA), desisopropyl-s-atrazine (DIA), and diaminochlorotriazine (DACT). These triazine pesticides share a common mechanism of toxicity. In laboratory studies in rats, at experimental dose levels higher than those encountered in the environment, the triazines have the ability to potentially cause neuroendocrine developmental and reproductive effects that may be relevant to humans. Specifically, these pesticides may disrupt part of the central nervous system (the hypothalamic-pituitary-gonadal (HPG) axis). This endocrine disruptive effect causes increased mammary tumors in Sprague-Dawley rats but may not

be relevant to the potential risk of human breast cancer. Tumors were not found in mice treated with these chemicals.

Other effects have also been observed for specific triazine herbicides, as noted below.

1. *Atrazine*. Specific organ toxicity or teratogenicity was not observed in a variety of rodent studies, but cardiac pathologies were seen in dogs (ATSDR, 2003). Atrazine appears to be weakly to moderately mutagenic and genotoxic (ATSDR, 2003), and there is some evidence linking it with lymphomas among those with occupational exposures (Rusiecki et al., 2004), but there is little data on carcinogenicity at environmentally relevant doses. There is also some epidemiological evidence linking atrazine at environmentally relevant levels to reduced fetal growth and certain birth defects (Villaneueva et al., 2005; Mattix et al., 2007; Ochoa-Acuna et al., 2009; Waller et al., 2010). The NOAEL from a rat two-generation reproduction study is the basis for the USEPA DWEL of 200 $\mu\text{g/L}$.
2. *Metribuzin*. Effects seen after long-term exposure include thyroid enlargement in rats, kidney and liver enlargement in mice, but no apparent occurred toxicity in dogs (USEPA, 2008i). No teratogenicity was observed. There is little evidence for mutagenicity or carcinogenicity. The Lifetime Health Advisory is 70 $\mu\text{g/L}$.
3. *Prometon*. This chemical appears to have relatively low toxicity, but due to “low confidence” in the published studies, USEPA is conducting further investigations (USEPA, 2008i). There was little evidence of organ toxicity or teratogenicity and no data on mutagenicity and carcinogenicity. The Lifetime Health Advisory level is 100 $\mu\text{g/L}$.
4. *Simazine*. In a two-year rat feeding study, decreases in weight gain and hematologic parameters were observed (USEPA, 2008i). A recent one-year dog feeding study also identified a hematological effect. No adverse effects on female reproductive capacity were observed after a two-generation rat feeding study, and no developmental effects, aside from delayed bone formation, have been seen. Mutagenicity and genotoxicity tests yielded mixed results. The MCL is 4 $\mu\text{g/L}$.

Acetanilides (Alachlor and Metolachlor)

1. *Alachlor*. Chronic effects noted in laboratory feeding studies include hepatotoxicity and hemolytic anemia in dogs and hepatotoxicity, nephritis, retinal degeneration, and degenerative changes in a variety of other organs in rats (USEPA, 2008i). Few developmental or teratogenic effects have been observed. Chronic feeding studies using mice have demonstrated that alachlor causes lung tumors, and studies in rats have demonstrated stomach, thyroid, and nasal tumors (Heydens, Lamb, and Wilson, 2001). Stomach tumors appear to arise from nonthreshold effects on the gastric mucosa. Thyroid tumors were probably mediated by a thyroidal-pituitary homeostatic feedback threshold mechanism. Nasal tumors appear to be related to a metabolite produced at high levels in the rat but not in mice or primates. The Agricultural Health Study reported an increased incidence of lymphohematopoietic cancers, such as leukemias and multiple myelomas, among agricultural pesticide users (Lee et al., 2004). Alachlor and its metabolites are moderately genotoxic and weakly mutagenic. The USEPA (2006c) determined the drinking water concentration resulting in a 1 in 10,000 lifetime cancer risk as 40 $\mu\text{g/L}$ and established the MCL at 2 $\mu\text{g/L}$.
2. *Metolachlor*. Long-term exposure to high doses in rats caused liver and kidney enlargement and atrophy of seminal vesicle and testes in males. Reproductive and teratogenic effects were not seen. Evidence of increased liver tumors was seen in female rats, but male rats and mice showed no increase in tumors and mutagenicity tests were negative (USEPA, 2008h). An MCL has not been set, and the Lifetime Health Advisory is 700 $\mu\text{g/L}$.

Chlorophenoxyacetic Acids 2,4-D (2,4-Dichlorophenoxyacetic Acid). In a 90-day feeding study, 2,4-D caused hematologic (reduced hemoglobin and red blood cells), hepatic, and renal toxicity in rats, although mice were less sensitive (USEPA, 2008h). There was no reproductive or teratogenic toxicity. Tests in most microbial systems showed no mutagenic activity, and *in vivo* animal assays have also been largely negative. Teratogenicity data are largely negative, and no dose-dependent tumor formation has been reported. There has been considerable epidemiologic analysis, and the results have been mixed though mostly negative (Garabrant and Philbert, 2002). Despite its very widespread use of 2,4-D, co-exposures to other agricultural chemicals prevent making definitive associations with any effects. The MCL is 70 µg/L. Metabolites of 2,4-D in drinking water may also be of concern, but this has not yet been addressed in regulation.

Other Herbicides

1. **Dacthal (DCPA).** Chronic feeding studies in rats have resulted in lung, liver, kidney, and thyroid pathology as well as alterations in thyroid hormone levels (USEPA, 2008j). There were no adverse reproductive or teratological effects. The thyroid tumors may be caused by a mechanism for which a threshold exists involving stimulation of the thyroid through the thyroid-pituitary feedback system. The liver cancer data are difficult to interpret due in part to contamination of the test compound by dioxin and hexachlorobenzene, but the lung and kidney tumors are not explained by the contaminants. Little information is available on toxicity of dacthal's metabolites, but they appear to be much less toxic than the parent compound. Dacthal was classified as a possible human carcinogen by USEPA, and the Lifetime Health Advisory is 70 µg/L.
2. **Diuron.** Diuron has low acute toxicity but causes red blood cell damage (hemolytic anemia) and compensatory regeneration and developmental effects on bone growth at high doses. It has low mutagenic and genotoxic potential but caused bladder tumors in rats and mammary carcinomas in female mice given high doses in chronic studies (USEPA, 2003a). It is classified as likely to be carcinogenic to humans by USEPA, and the drinking water concentration at the 1 in 10,000 lifetime is given as 200 µg/L. Its major aquatic metabolite resembles a related herbicide that is also considered a likely carcinogen.
3. **Glyphosate.** Glyphosate is widely used to control weeds, grasses, and other plants. It appears to be a relatively low-toxicity herbicide in terms of human health but can affect liver, kidney, and reproductive health with long-term exposure at high levels. The MCLG and MCL have been set by USEPA at 700 µg/L.

Insecticides

Insecticide chemical families of concern, based on toxicity and presence in source water, include organophosphates (e.g., chlorpyrifos and diazinon), which are related to chemical warfare nerve agents, and carbamates (e.g., carbaryl, carbofuran, and oxamyl). These chemicals inhibit the neuromuscular junction enzyme, acetylcholinesterase, in insects. While use of these insecticides has been increasingly restricted, many are still used. Because of biochemical similarities between insect and vertebrate nervous systems, these classes of insecticides have a high potential to cause acute and medium-term health effects in sensitive individuals. In humans and other animals, acetylcholinesterase inhibition causes a buildup of acetylcholine, affecting both the skeletal muscles and the nerves and smooth muscles of the autonomic nervous system. Effects include weakness, sweating, increased intestinal motility (diarrhea-like symptom), salivation, tears, and constriction of the pupils. The effects end within hours after termination of exposure. Exposure to these insecticides can be monitored by measuring inhibition of a related cholinesterase in blood. In general, the levels found in public drinking

water probably do not constitute an acute threat to health. However, recent human and laboratory animal studies indicate that carbamate and organophosphate insecticides, especially chlorpyrifos, may also cause neurodevelopmental effects (Eskenazi et al., 2007).

Carbamates (Aldicarb, Aldicarb Sulfoxide, and Aldicarb Sulfone). Aldicarb is the most acutely neurotoxic of any of the widely used pesticides, and its use has been cancelled. Aldicarb has not been shown to be a mutagen or a carcinogen in animal studies, but its use was associated with increased colon cancer in the Agricultural Health Study (Lee et al., 2007). The MCLs for aldicarb and its metabolites aldicarb sulfoxide and aldicarb sulfone are 3, 4, and 2 $\mu\text{g/L}$, respectively. Because these related compounds share a common mechanism of action, their toxicity in a mixture is considered to be additive.

In addition to neurotoxic effects, laboratory animals exposed to carbofuran exhibited testicular degeneration. Based on limited evidence, it does not appear to be carcinogenic. The MCL is 40 $\mu\text{g/L}$.

Oxamyl is mildly neurotoxic. No histopathological changes were noted in organs of exposed animals, and no reproductive or developmental effects have been seen (USEPA, 1992b). It is classified as a noncarcinogen. The MCL is 200 $\mu\text{g/L}$.

Organophosphates (Diazinon and Chlorpyrifos). The metabolite diazoxon accounts for the major effects of diazinon, including neurotoxicity. Diazinon is moderately mutagenic but is not carcinogenic. No MCL has been set by USEPA, and the Lifetime Health Advisory is 1 $\mu\text{g/L}$.

In addition to inhibition of acetylcholinesterase, chlorpyrifos causes neurotoxicity through other mechanisms. It was associated with prostate, lung, and rectal cancer in the Agricultural Health Study (Alavanja et al., 2003; Lee et al., 2007). Limited data from studies of carcinogenicity in laboratory animals are negative, though mutagenicity and genotoxicity tests show mixed results. No MCL has been set by USEPA, and the Lifetime Health Advisory is 2 $\mu\text{g/L}$.

Organochlorines. A variety of organochlorines were previously used as pesticides because of their neurotoxic effects. Their mode of action appears to involve effects on the neurotransmitter gamma-amino butyric acid and effects on the sodium channel in nerves of the insect nervous system. However, their use has been restricted and/or cancelled due to their environmental persistence. Other concerns with these compounds included development of resistance by insects (e.g., DDT and malarial mosquitoes), toxicity to wildlife (e.g., DDT and malformed bird eggs), and human carcinogenic potential. Several are potent carcinogens. For example, the drinking water concentration resulting in a 1 in 10,000 lifetime cancer risk for aldrin and dieldrin is estimated as only 0.2 $\mu\text{g/L}$ (USEPA, 2008i).

Soil Fumigants/Nematicides. A variety of chlorinated short alkanes, 1,2-dibromo-3-chloropropane (DBCP), 1,2-dichloropropane, 1,3-dichloropropene, 1,2,3-trichloropropane, and ethylene dibromide (EDB), have been used as fumigant nematicides. Use of several of these has been phased out, as noted above. These chemicals have also been used for other purposes; for example, 1,2,3-trichloropropane was used as an industrial solvent and degreasing agent and is still used as an intermediate in the production of other chemicals. DBCP caused reproductive toxicity in occupationally exposed men, including decreased or absent sperm production, testicular atrophy, hormonal changes, and decreased proportion of male offspring (ATSDR, 1992). Both DBCP and EDB caused male reproductive toxicity in animal studies (USEPA, 2008i). In general, they are classified as likely carcinogens, causing tumors in multiple organs in animal studies through a mutagenic mode of action (NTP, 2005a; USEPA, 2006c). In particular, 1,2,3-trichloropropane has been shown to be especially potent in laboratory animals, with the drinking water concentration resulting in

a 1 in 10,000 lifetime cancer risk of less than 1 µg/L. The MCLs for these chemicals are 5 µg/L for 1,2-dichloropropane, 0.2 µg/L for DBCP, and 0.05 µg/L for EDB (USEPA, 2006c). There is no MCL for 1,3-dichloropropene or 1,2,3-trichloropropane. 1,2,3-Trichloropropane is considered to be an emerging contaminant based on occurrence and potential health effects. Several states are in the process of developing a drinking water standard for it, and it is currently being considered by USEPA for MCL development through the CCL process.

Fungicides

Although no fungicides regarded as significant health threats are found at notable levels in water, ethylene thiourea (ETU), which is a water-soluble breakdown product of the ethylene bisdithiocarbamate (EBDC) chemical family (e.g., maneb, mancozeb, and zineb) is important. Uses of many of the EBDC fungicides were restricted in the late 1980s due to concerns about residues on food crops and risks from occupational exposure, but their use is still widespread.

ETU caused thyroid toxicity in adult rodents, resulting in reduced levels of thyroid hormone. Developmental toxicity including retarded CNS development may be related to thyroid toxicity (USEPA, 2008i). Liver and thyroid tumors were increased in mice and rats exposed to ETU, but the results of mutagenicity and genotoxicity testing were mixed (reviewed by Dearfield, 1994). Thyroid tumors occurred in the context of thyroid hyperplasia resulting from the increased level of thyroid stimulating hormone production by the pituitary in response to the low level of thyroid hormone. There is no MCL and MCLG for ETU. It is listed as a probable human carcinogen by the USEPA Office of Water, and the drinking water concentration at the 1 in 10,000 cancer risk level is given as 20 µg/L.

Additional and Emerging Drinking Water Contaminants

Endocrine Disruptors. A recent area of concern is the occurrence in water of low levels of a wide variety of environmental contaminants that can affect the endocrine system (Snyder et al., 2008; Diamante-Kandarakis et al., 2009). In particular, environmental contaminants that affect the function of thyroid and steroid hormones are known to interfere with development and reproduction in wildlife, and such effects may also be occurring in humans (Colburn, vom Saal, and Soto, 1993; Porterfield, 1994; Toppari et al., 1996). Excreted steroids of both endogenous and pharmaceutical origin, various pesticides, organochlorines (e.g., dioxin, certain PCB congeners, DDT and metabolites), chemicals found in plastics such as phthalates and bisphenol A, and detergent compounds are among the chemicals of concern, in large part because of their documented effects in laboratory animals and on wildlife. These chemicals can enter waterways through known point sources such as wastewater treatment plants and agricultural runoff, as well as nonpoint sources such as atmospheric deposition and stormwater discharge. An AwwaRF (2003) project demonstrated that most surface waters and many groundwater sources exhibited measurable estrogenic activity, although most finished drinking waters did not exhibit activity.

Pharmaceuticals and Personal Care Products. A related area of concern is the plethora of chemicals found at trace concentrations in surface waters, stemming from pharmaceutical, food, and household products (USGS, 2002; Focazio et al., 2008). These chemicals enter waterways primarily through incomplete removal in wastewater treatment plants. Medications enter wastewater both by excretion from the body and by disposal of unused medications by flushing down the toilet. Available occurrence studies and risk assessments indicate that medicines occur in finished drinking water at levels well

below therapeutic doses (Focazio et al., 2008; Schulman et al., 2002; Schwab et al., 2005; Webb et al., 2003).

Mixtures of Organic Chemicals. Groundwater studies have also found trace levels of a variety of organic chemicals at low levels, some of which may be only tentatively identified (NJDEP, 2003). The potential for human health effects from exposure to low levels of diverse chemical mixtures has yet to be determined (Trubo, 2005). A potential approach to address such mixtures of contaminants that lack specific health effects information is to institute treatment technologies, such as activated carbon, which will remove organic chemicals in general.

Perfluorinated Chemicals. The organic chemicals classified as persistent, bioaccumulative, and toxic (PBT) by USEPA are well known for their toxicity to humans and wildlife, persistence in the environment, and bioaccumulation through the food chain. These chemicals, which include dioxins and furans, polychlorinated biphenyls, and pesticides such as chlordane, DDT and related compounds, and aldrin/dieldrin, as well as some of more recent concern such as the flame retardant polybrominated diphenyl ethers (PBDEs), are not primarily significant as drinking water contaminants. This is because these chemicals tend to have high octanol/water partition coefficients, and thus a high affinity for sediments and a low solubility in water. The primary source of human exposure to these compounds is through the diet, from lipids in fish, meat, and dairy products, and they tend to concentrate in fat in the body.

Recently, another group of persistent and toxic chemicals that are of concern in drinking water has emerged. These are perfluorochemicals (PFCs) such as perfluorooctanoic acid (PFOA, C8), perfluorooctane sulfonate (PFOS), perfluorobutanoic acid (PFBA), perfluoropentanoic acid (PFPeA), perfluorohexane sulfonate (PFHxS), perfluorohexanoic acid (PFHxA), and other related chemicals. In contrast to the PBT chemicals mentioned above, PFCs are highly water soluble. They are used in the production of water- and stain-resistant products including cookware and clothing, as well as in fire-fighting foams. They also arise from their breakdown in the environment and in the body of related chemicals, fluorotelomer alcohols, which are used in consumer products such as grease-proof food wrappers and stain-resistant carpet treatments. They do not degrade in the environment and have been found at low concentrations in drinking water not known to be impacted by discharge from a facilities that manufacture or use them (Mak et al., 2009; Post et al., 2009). The use of PFOS has been phased out, and the use of PFOA is currently being phased out by the manufacturers, and efforts are ongoing to replace them with less toxic shorter chain compounds in the future.

The environmental occurrence and toxicology of several PFCs was reviewed by Lau et al. (2007). The discussion below focuses on PFOA, the PFC that has received the greatest attention as a drinking water contaminant. PFOA is found in the serum of almost all individuals, at a mean concentration in the United States of about 4 $\mu\text{g/L}$, with a human serum half-life of several years (Lau et al., 2007). In communities with water supplies contaminated with PFOA, the median serum concentration contributed from drinking water is about 100 times the concentration in the drinking water source (Emmett et al., 2006; Post et al., 2009). Thus, low levels in drinking water may add substantially to the general population's exposure from the diet, consumer products, and other sources. For example, a drinking water concentration of 0.02 $\mu\text{g/L}$ would be expected to increase serum concentrations by about 2 $\mu\text{g/L}$, an increase of 50 percent over the background serum concentration of about 4 $\mu\text{g/L}$.

In animal studies, PFOA causes developmental effects and adverse effects on the liver, immune system, and lipid metabolism (Lau et al., 2007). Increased tumor incidence was seen in chronic rat studies, and it has been classified as a likely human carcinogen by the USEPA Science Advisory Board (USEPA, 2006e). Recent studies in communities whose drinking water was contaminated by industrial discharge have found associations between

serum levels of PFOA and elevated cholesterol and uric acid, changes in immune function, and possibly other biological parameters (Fletcher, Steenland, and Savitz, 2009; Steenland, Fletcher, and Savitz, 2008, 2009; C8 Health Project, 2009).

PFOA is one of four contaminants listed on the USEPA CCL3, which the USEPA Science Advisory Board recommended as a priority for consideration for regulation based on available data on toxicity, occurrence, and treatability (USEPA, 2009b).

Nanoparticles. A final category of emerging contaminants is nanoparticles or nanomaterials, which are defined as particles or materials with at least one dimension smaller than 100 nm. The toxicological effects of nanoparticles are believed to depend on their physicochemical parameters such as particle size and size distribution, agglomeration state, shape, crystal structure, chemical composition, surface area, surface chemistry, surface charge, and porosity, rather than solely on their chemical composition (Oberdörster et al., 2005). Nanoparticles are currently used in many consumer products, including clothing, laundry detergents, and washing machines and in drug delivery systems for pharmaceuticals. Their possible use in groundwater remediation and drinking water treatment is being investigated. These and other applications could potentially lead to their presence in drinking water. Future research will provide information on the occurrence and potential for human health risks from nanoparticles in drinking water; currently, little is known about these questions (Boxall, Tiede, and Chaudry, 2007).

Chemicals in Treatment Additives, Linings, and Coatings

In the United States, NSF International (www.nsf.org) develops standards for all types of materials and equipment used in drinking water treatment, distribution systems, and storage facilities. These standards are based on prevention of leaching at unsafe levels of these chemicals into drinking water. Chemicals evaluated by NSF International include solvents, monomers, and heavy metals. A few examples of additives, linings, and coatings are given here.

Acrylamide. The most important source of drinking water contamination by acrylamide is the use of polyacrylamide flocculants containing residual levels of acrylamide monomer. They are also used as grouting agents in the construction of drinking water reservoirs and wells (WHO, 2003). It has recently been discovered that high levels of acrylamide are formed during the frying or baking of a variety of foods, particularly those containing carbohydrates, such as cereals, french fried potatoes, potato chips, breads, pastries, and coffee (WHO, 2005).

Acrylamide's principal toxic effect is peripheral neuropathy (damage to the nerves in the arms or legs). Neurotoxicity is seen in animal studies and in humans exposed via the dermal, oral, or inhalation routes. Acrylamide is metabolized to a reactive compound that binds to DNA and hemoglobin. DNA adducts in many organs, and hemoglobin adducts are detected in animals given acrylamide or its metabolite. Acrylamide in drinking water was carcinogenic to rats in two studies, causing tumors of the thyroid, scrotum, adrenal and mammary glands, central nervous system, oral cavity, uterus, clitoris, and pituitary (WHO, 2005). In reproduction studies, male rodents showed reduced fertility, dominant lethal effects, and adverse effects on sperm count and morphology.

Acrylamide is regulated by a treatment technique in lieu of an MCL. When polyacrylamide is used in drinking water systems, the combination of polymer dose and monomer level may not exceed 0.05 percent monomer dosed at 1 mg/L polymer (USEPA, 1991a). In its recent review of its drinking water standards, USEPA (2010) concluded that improvements in manufacturing capabilities have reduced the residual monomer content in acrylamide-based polymeric coagulants aids, and these changes would support a decrease in the treatment technique for acrylamide.

Epichlorohydrin. Epichlorohydrin (ECH) is a halogenated alkyl epoxide. It is used as a raw material in the manufacture of a variety of plastics, including cationic polymers used as coagulants in potable water treatment and as a solvent for lacquers sometimes used to coat the interiors of water tanks and pipes.

Epichlorohydrin is mutagenic in bacterial and mammalian cells and is carcinogenic, causing forestomach tumors when given orally and nasal tumors by inhalation (IARC, 1999). Epichlorohydrin is regulated by a treatment technique in lieu of an MCL. When epichlorohydrin is used in drinking water systems, the combination of dose and monomer level may not exceed 0.01 percent monomer dosed at 20 mg/L polymer (USEPA, 1991a). In its recent review of its drinking water standards, USEPA (2010) concluded that improvements in manufacturing capabilities have reduced the residual monomer content in epichlorohydrin-based polymeric coagulants aids, and these changes would support a decrease in the treatment technique for epichlorohydrin.

Polynuclear Aromatic Hydrocarbons. Polynuclear (or polycyclic) aromatic hydrocarbons (PAHs) are a diverse class of compounds consisting of substituted and unsubstituted polycyclic and heterocyclic aromatic rings. They are formed in the pyrolysis of naturally occurring hydrocarbons and found as constituents of coal, coal tar, petroleum, fuel combustion products, and cigarette smoke (National Academy of Sciences Safe Drinking Water Committee, 1982). Polynuclear aromatic hydrocarbons can enter drinking water by leaching from tar or asphalt linings of distribution pipelines, but their solubility is limited.

PAHs vary in their toxicity, and some are carcinogenic while others are not. Benzo(a)pyrene is the most thoroughly studied PAH. It causes cancer in animals exposed orally or by inhalation. Benzo(a)pyrene is genotoxic and is metabolized to a reactive compound that forms adducts with DNA (California EPA, 1997; National Academy of Sciences Safe Drinking Water Committee, 1982). The MCL for benzo(a)pyrene is 0.2 µg/L.

DISINFECTANTS AND DISINFECTION BY-PRODUCTS

General Background

The disinfection of drinking water, although reducing the risk of waterborne disease, creates other potential risks through the formation of compounds known as disinfection by-products (DBPs) during the disinfection process. The occurrence, genotoxicity, and carcinogenicity of these compounds were recently comprehensively reviewed by Richardson et al. (2007). Organic DBPs are formed through the reaction of disinfectants with organic matter in source waters; their presence was first recognized in the 1970s when trihalomethanes (THMs) were detected in chlorinated drinking water. At this time, more than 600 DBPs have been identified, including haloacetic acids (HAAs), haloacetonitriles, halo ketones, haloaldehydes, chloropicrin, cyanogen chloride, MX and related compounds, chlorophenols, nitrosamines, and others. These compounds are usually present in drinking water at relatively low concentrations, ranging from nanograms per liter to approximately 100 µg/L. For many of these compounds, occurrence data and health effects information are limited or unavailable. In addition to the identified DBPs, a large portion of the total organic halide formed during chlorination and the assimilable organic carbon formed during ozonation remains uncharacterized. The formation and control of DBPs is covered in Chap. 19.

It is important to recognize that, as with all substances, the human health risk from DBPs in drinking water is a function of both their concentration and their toxic potency. Thus, highly toxic DBPs, such as MX, iodo-trihalomethanes, and others, which are present at very

low concentrations, may pose an equal or greater risk than less toxic DBPs present at much higher concentrations. Additionally, the identified and uncharacterized DBPs in the complex mixtures present in drinking water may interact toxicologically in ways that have not yet been characterized. A final consideration relevant to assessing the risks of DBPs in drinking water relates to exposure pathways. Volatile DBPs enter household air, especially with hot water use in showers, and inhalation and dermal exposures can be more significant than ingestion.

Health Basis for DBP Regulation

Under the Stage 1 Disinfectants/Disinfection By-Products Rule finalized by USEPA in 1998 (USEPA, 1998b), public water systems are required to meet limits for 11 DBPs: total trihalomethanes (TTHMs; chloroform, bromodichloromethane, dibromochloromethane, and bromoform), the sum concentration for five HAAs (mono-, di-, and trichloroacetic acids and mono- and dibromoacetic acids), bromate, chlorite and three disinfectants: chlorine, chlorine dioxide, and chloramines. The rule establishes maximum residual disinfectant level goals (MRDLGs) and maximum residual disinfectant levels (MRDLs) for disinfectants. The MRDLGs are nonenforceable goals, analogous to MCLGs and based on potential health effects, without consideration of disinfectant benefits of the chemical. The MRDLs are enforceable standards, analogous to MCLs, which are set as close to the MRDLGs as feasible and which recognize the benefits of adding a disinfectant to water. MCLGs and MCLs are established for DBPs. A RSC factor of 0.8 (80 percent), instead of the default value of 20 percent, was used in setting MRDLGs and MCLGs for noncarcinogenic disinfectants and DBPs, as sufficient data were available to show that food and ambient air are not significant sources of exposure (USEPA, 1994a). As a treatment control technology, USEPA has a coagulation requirement to control DBPs by removing total organic carbon (TOC) as a collective surrogate for DBP precursors—see Chap. 19. In 2006, the Stage 2 D/DBP Rule, which contains additional implementation requirements to ensure that the regulatory limits are not exceeded at specific locations within a drinking water distribution system, was finalized (USEPA, 2006f).

Approaches for Evaluation of Health Effects of DBPs

The primary toxic endpoints of concern from chronic exposure to low levels of DBPs in drinking water are cancer and reproductive/developmental effects. However, chronic carcinogenicity bioassays and/or developmental and reproductive studies in experimental animals have been conducted for only a relatively small number of DBPs. Discussion of the health effects of some of these disinfectants and DBPs follows. Many emerging DBPs have been tested only *in vitro* for genotoxicity and/or cytotoxicity, while for others, no toxicity data exist. These data are summarized in Table 2-4 (from Richardson et al., 2007). Some overall generalizations can be made about the biological activity of DBPs. For analogous DBPs, genotoxicity and cytotoxic potency are generally greatest in iodinated compounds, followed by brominated compounds, with chlorinated compounds the least potent. Similarly, DBPs containing nitrogen are generally more active than their analogues that do not contain nitrogen (Richardson et al., 2007).

As long-term animal testing is not feasible for the vast number of DBPs and mixtures of DBPs that may be present in drinking water, several different approaches have been proposed or applied for evaluation of the health risks of DBPs in drinking water. For example, DBPs were prioritized for further toxicology studies based on mechanism-based structure-activity relationships and genotoxicity data (Woo et al., 2002). An occurrence survey was conducted for the 50 DBPs that received the highest priority ranking in this study, including iodinated THMs, other mono- and di-halomethanes, a haloacid, haloacetoneitriles, haloacetates, halo ketones, halonitromethanes, haloamides, MX and other halogenated furanones, and carbonyls (Krasner et al., 2006). An approach using exposure assessment modeling, physiologically

based pharmacokinetic modeling, and cumulative relative potency factors has been proposed to assess the risks of multiroute exposures to mixtures of DBPs (Teuschler et al., 2004). Another approach involves studying the toxicity of the four regulated THMs individually, in binary combinations, and as the mixture of all four compounds (Simmons et al., 2004).

Additionally, the toxicity of undefined complex mixtures containing both known and uncharacterized DBPs may be assessed through studies of concentrates of finished drinking water. For example, the Four-Lab Study was a multicomponent study of the mixture of DBPs present in surface water treated either by chlorination or ozonation followed by posttreatment chlorination (Simmons et al., 2008). The finished water was concentrated approximately 130-fold by reverse osmosis. This concentrate was tested for mutagenicity in *Salmonella* (Claxton et al., 2008), cytotoxicity and effects on gene expression in cultured rat hepatocytes (Crosby et al., 2008), and developmental effects in rats given the concentrates as their drinking water on days 6 through 16 of gestation (Narotsky et al., 2008). In these studies, mutagenicity was similar to that seen in previous studies of drinking water concentrates; differences in gene expression were seen in concentrates of chlorinated and ozonated waters and no adverse developmental effects were seen in the offspring of rats dosed during pregnancy.

In addition to toxicology studies on the effects of disinfectants and DBPs in experimental animals, epidemiology studies have evaluated the association of exposure to chlorinated surface water with several adverse outcomes: cancer, cardiovascular disease, and adverse

reproductive outcomes, including birth defects. A number of studies have found small increases in bladder, colon, and rectal cancers, linked with duration of exposure and volume of water consumed or with noningestion exposures to water such as showering and swimming. However, other studies have observed no association (Richardson et al., 2007). A pooled analysis of several recent well-designed case-control studies has also observed a small, but statistically significant, dose-related, elevated risk of bladder cancer after adjustment for confounding factors (Villanueva et al., 2004). Increased incidence of spontaneous abortions, decreased birth weight, prematurity, intrauterine growth retardation, and oral cleft and neural tube defects have also been reported with exposure to DBPs, while other studies were negative for these effects (Rice et al., 2008). Thus, there is still considerable debate in the scientific community on the significance of these findings.

Discussion of the health effects of some important disinfectants and DBPs follows. Because of space limitations, it is not possible to include discussions of all categories of DBPs that have been detected in finished drinking water.

Disinfectants and Inorganic DBPs

Chlorine. The forms of chlorine used in water treatment and its chemistry are covered in Chap. 17.

No evidence of reproductive or developmental effects have been reported for chlorine in drinking water, and no systemic effects were observed in rodents following oral exposure to chlorine as hypochlorite over a two-year period (USEPA, 1994b, 1997b). Chlorine in water was not carcinogenic in chronic rodent studies. Chlorinated water has been shown to be mutagenic to bacterial and mammalian cells, but assessment of the mutagenic potential of chlorine is confounded by the reactive nature of chlorine and by the formation of mutagenic reaction products during *in vitro* testing. The MRDLG and an enforceable MRDL of 4.0 mg/L for residual free chlorine in water are based on the NOAEL in a chronic rat drinking water study.

Chloramines. The chemistry of chloramination and discussion of its use are covered in Chap. 17. Inorganic chloramines can occur as mono-, di-, and trichloramine. The form that dominates depends on dosing of chlorine and ammonia and on pH—see Chap. 17—but it is common to find monochloramine as the dominant species for water plants practicing chloramination. It is desirable to minimize the formation of di- and trichloramines, since they produce an undesirable odor.

Human health effects of monochloramine in drinking water have been observed only in hemodialysis patients. Chloramines in dialysis water cause oxidation of hemoglobin to methemoglobin and denaturation of hemoglobin. For this reason, it is a good practice for water treatment utilities to notify dialysis centers when using chloramination. Monochloramine in drinking water at concentrations up to 24 mg/L (short term) and 5 mg/L (for 12 weeks) caused no effects in healthy volunteers (USEPA, 1994c, 1997b). Two lifetime rodent studies showed minimal toxicity, such as decreased body and organ weights, along with some liver effects (weight changes, hypertrophy, and changes in chromatid patterns). These effects appear to be related to decreased water consumption, due to the unpalatability of higher concentrations of chloramines to the test animals, and thus may not be indicative of toxicity of the chloramines being tested (USEPA, 1994c, 1997b). The MRDLG and MRDL are 4.0 mg/L, measured as chlorine residual in water based on the NOAEL in a chronic drinking water study in rats (USEPA, 1997b, 1998b).

Chlorine Dioxide, Chlorite, and Chlorate. Chlorine dioxide (ClO_2) is fairly unstable and dissociates rapidly into chlorite and chloride in water (USEPA, 1994d). The primary concerns with using chlorine dioxide as a disinfectant are the toxic effects attributed to

residual chlorite and chlorate. Because chlorine dioxide converts to chlorite *in vivo*, health effects attributed to chlorine dioxide are assumed to be the same as for chlorite. The health effects of chlorine dioxide, chlorite, and chlorate have each been evaluated separately in humans and in laboratory animals.

Chlorine dioxide. The major toxic effects seen in animals exposed to chlorine dioxide and its by-products, chlorite and chlorate, in drinking water are oxidative damage to red blood cells, decreased thyroxine levels, and delayed neurodevelopment from exposures both after birth and in a two-generation study (USEPA, 1994d). Studies evaluating developmental or reproductive effects have found decreases in the number of implants and live fetuses per dam in female rats given chlorine dioxide in drinking water before mating and during pregnancy. Mutagenicity tests in mice and bacterial systems were negative (USEPA, 1994d, 1997b). No studies on the carcinogenic properties of orally ingested ClO_2 are available, but exposure to concentrates of water treated with ClO_2 did not increase the incidence of lung tumors in mice, nor was any initiating activity observed in mouse skin or rat liver bioassays (USEPA, 1994d). Chlorine dioxide is considered a noncarcinogen (Group D). The MRDLG and an MRDL of 0.8 mg/L are based on decreased thyroxine and behavioral effects in rat pups exposed during gestation and lactation (USEPA, 1994d, 1998b).

Chlorite. Chlorite ion is relatively stable and degrades slowly to chloride (USEPA, 1994d). Rats exposed in drinking water had decreased red blood cells and hemoglobin, and these effects are thought to be due to oxidative stress from glutathione depletion. In several studies, chlorite was associated with a decrease in the growth rate of rat pups between birth and weaning. Behavioral effects indicating delayed neurodevelopment are seen in rat pups exposed perinatally to chlorite (USEPA, 1994d, 1998c, 1998d). Mutagenicity testing of chlorite in mouse assays was negative. As with chlorine dioxide, no clear tumorigenic activity has been observed in animals given oral doses of chlorite, and it is considered to be a noncarcinogen (Group D) (USEPA, 1994d). The MCLG of 0.8 mg/L is based on behavioral effects in rat pups exposed prenatally and after birth. The MCL is 1.0 mg/L (USEPA, 1998d).

Chlorate. Chlorate occurs as a stable by-product in drinking water disinfected with chlorine dioxide. Incidents of chlorate poisoning were reported during its previous use as an herbicide. Effects in people, who consumed large amounts included methemoglobinemia, hemolysis, and renal failure, with the lowest fatal dose reported as 15 g (USEPA, 1994d). Data were considered inadequate to develop an MCLG for chlorate in the USEPA Stage 1 D/DBP Rule (USEPA, 1998b). More recently, a chronic drinking water study and mutagenicity testing were conducted by the NTP (2005b). Effects seen in this study included thyroid follicular cell hypertrophy in both sexes of rats and female mice, bone marrow hyperplasia in male rats and female mice, and hematopoietic cell proliferation in male rats. Thyroid tumors were increased in both sexes of rats, and pancreatic tumors were increased in female mice. Chlorate was not mutagenic in several bacterial strains and did not increase micronuclei in red blood cells of mice.

Bromine. Bromine has been used in swimming pools for disinfection and in cooling towers, but it is not used in drinking water. Bromine can, however, be found in drinking water produced through desalination of seawater. It is formed by the reaction between bromide in seawater and free chlorine, which is often used as a biocide in the intake and pretreatment systems of seawater desalination plants. In water at pH 8.6, bromine exists primarily as hypobromous acid (HOBr). In this uncharged form, it may pass through reverse osmosis membranes and be present in the drinking water that is produced (NRC, 2008). Below pH 6, Br_2 , Br_3 , bromine chloride, and other halide complexes occur, and in the presence of ammonia or organic amines, bromoamines are formed.

Most health effects information is on bromide salts because of their pharmaceutical use (National Academy of Sciences Safe Drinking Water Committee, 1980). In humans and/or experimental animals, sedation, GI effects, and thyroid hyperplasia may occur from high doses of bromide salts.

Iodine. Iodine has been used to disinfect drinking water in field situations, such as camping and the military, and in swimming pools. It can occur in water as iodine (I_2), hypiodous acid (HOI), iodate (IO_3^-), or iodide (I^-). Iodoamines do not form to any appreciable extent. Iodine is an essential trace element that is required for synthesis of the thyroid hormone, with an estimated adult requirement of 80 to 150 $\mu\text{g}/\text{day}$. Most intake of iodine is from food, especially seafood, and, in the United States, table salt that has been supplemented with potassium iodide (National Academy of Sciences Safe Drinking Water Committee, 1987) to prevent goiters (thyroid enlargement) or mental retardation that can occur in populations lacking sufficient iodine in their diet during gestation or in early childhood. High doses of iodine cause irritation of the GI tract. A dose of 2 to 3 g may be fatal, although acute iodine poisoning is rare. ATSDR (2004) has developed a chronic oral minimum risk level of 0.01 mg/kg/day for iodide, based on the rate of occurrence of subclinical hypothyroidism in children in two areas of China with high or low iodide levels in drinking water.

Ozone. Ozone is used as an oxidant and disinfectant in drinking water treatment. Its chemistry and use are covered in Chaps. 7 and 17. Ozone is unstable and is dissipated largely in the ozonation unit, so that no residual ozone is present in the finished water leaving the treatment plant. Thus, concerns about its safety are related to its reactions in the formation of by-products such as bromate and formaldehyde and not to the ozone itself (Bull and Kopfler, 1991).

Bromate. Bromate is formed in water following the use of ozone in water containing bromide ion (USEPA, 1994f; Bonacquisti, 2006). Coverage of the chemistry of formation and control is found in Chap. 19.

Noncancer effects in rats exposed to bromate in drinking water for 100 weeks included decreased survival and body weight; increased liver, kidney, thyroid, and spleen weights; and kidney lesions (USEPA, 2008i). Mice were less sensitive than rats in this study. Renal effects have also been seen in several other chronic oral studies in rats. Bromate was shown to be mutagenic in several test systems (USEPA, 1993, 1998e), and effects on sperm density in male rats were seen after 35 days of exposure (Wolfe and Kaiser, 1996). Bromate in drinking water was carcinogenic to male and female rats in chronic studies, with increased incidences of kidney and thyroid tumors and peritoneal mesothelioma (USEPA, 2008i). It is classified as a probable human carcinogen (Group B2) under the 1986 USEPA cancer risk assessment guidelines and as a likely carcinogen under the more recent 2005 guidelines (USEPA, 2008i). The MCLG is zero, based on carcinogenicity, and the MCL is 0.01 mg/L (USEPA, 1994a).

Organic Disinfection By-products

Factors influencing the formation of DBPs are discussed in detail in Chap. 19. Discussion of the health effects of some important organic DBPs that have been identified in treated drinking water follows.

Trihalomethanes. The primary THMs include chloroform, dibromochloromethane, dichlorobromomethane, and bromoform, but iodinated forms have also been detected. Because all THMs are volatile, inhalation exposure occurs during showering and other household uses of water. For most drinking waters, chloroform is by far the most prevalent, but higher bromide concentrations in the water supply can significantly shift the relative

proportions of the THMs. The MCL for TTHMs is 80 µg/L, based on a running annual average of quarterly samples. Health effects information for individual THMs follows.

Chloroform. Chloroform was formerly used as an anesthetic, and inhalation of sufficient concentrations can cause CNS depression. The primary target organs in animal studies are the liver, kidney, and nasal epithelium (USEPA, 2001f). Developmental effects are likely secondary to toxicity to the mother (USEPA, 2001f). The effects on the liver and the kidney are believed to result from cellular toxicity of a reactive metabolite, phosgene. Chloroform induced liver tumors in mice when administered by gavage in corn oil, but not via drinking water, and induced kidney tumors in male rats, regardless of the carrier vehicle (oil or drinking water). It is not a strong mutagen, and neither it nor its metabolites bind readily to DNA. USEPA (2001f) has concluded that it does not cause cancer primarily through a mutagenic mode of action and that its carcinogenicity is secondary to cytotoxicity and regenerative hyperplasia. Doses that are not cytotoxic are considered unlikely to result in increased risk of cancer. Thus, chloroform is one of the few chemicals for which USEPA has concluded that there is a threshold for carcinogenicity. Prior to the USEPA (2001f) assessment, an MCLG of zero was adopted by USEPA in 1998, based on the default assumption that exposure to any level of a carcinogen results in some increase in cancer risk. The current MCLG is 0.07 mg/L and is based on an RfD of 0.01 mg/kg/day that is protective for the effects considered to be precursors to tumor formation.

Bromodichloromethane. In mice and rats, the target organs for bromodichloromethane (BDCM) toxicity are the kidney, liver, and thyroid (NTP, 2006). BDCM also caused pregnancy loss in rats, possibly through disruption of the secretion of luteinizing hormone (Bielmeier et al., 2004). The results of mutagenicity studies are mixed, and the overall results suggest BDCM is genotoxic (NTP, 2006). In a chronic study in which BDCM was given by corn oil gavage, there was an increased incidence of kidney tumors in male mice, liver tumors in female mice, and kidney and large intestine tumors in male and female rats (NTP, 1987b). Based on these results, BDCM was classified as a probable human carcinogen (Group B2) with an MCLG of zero (USEPA, 1998b). BDCM was shown to induce aberrant crypt foci, thought to be precursors of cancers of the large intestine, equally when administered by drinking water or corn oil gavage (Geter et al., 2004). However, in a more recent chronic drinking water study in male rats and female mice, BDCM did not cause benign or malignant tumors at doses up to 700 mg/L for two years (NTP, 2006).

Dibromochloromethane. Aside from its occurrence as a DBP, dibromochloromethane (DBCM) is used as a chemical intermediate in the manufacture of fire-extinguishing agents, aerosol propellants, refrigerants, and pesticides (USEPA, 1994a). In mice and rats, DBCM causes changes in kidney, liver and serum enzyme levels and decreased body weight (USEPA, 1994a). A multigeneration reproductive study of mice treated with DBCM in drinking water showed maternal toxicity (weight loss, liver pathology) and fetal toxicity (USEPA, 1994e). In a chronic study in which DBCM was given by gavage in corn oil, benign and malignant liver tumors were significantly increased in female and male mice, while rats did not develop cancer (USEPA, 1994e). Results of mutagenicity studies are inconclusive (USEPA, 1994e). USEPA has classified DBCM as a possible human carcinogen (Group C). The MCLG of 0.6 mg/L is based on the NOAEL for liver effects in a subchronic gavage study, with an additional uncertainty factor of 10 for possible carcinogenicity (USEPA, 1998b).

Bromoform. Bromoform occurs less frequently as a DBP in drinking water than the other THMs. Liver is the primary target for bromoform toxicity, with more severe toxicity seen with a bolus dose given by gavage than with drinking water exposure (ATSDR, 2005). Results of *in vitro* and *in vivo* genotoxicity studies are mixed (USEPA, 1994e). Bromoform

administered by corn oil gavage to rats produced an increased incidence of benign and malignant tumors of the large intestine and rectum (USEPA, 1994e). It is classified as a probable human carcinogen (Group B2) with an MCLG of zero.

Haloacetic Acids. Haloacetic acids (HAAs) consist of nine highly water-soluble compounds and, as a group, are the next most prevalent DBPs after THMs. The five regulated HAAs are mono-, di-, and trichloroacetic acids and mono- and dibromoacetic acid. Dichloroacetic and trichloroacetic acids are the most prevalent HAAs. In high-bromide waters, the brominated species such as bromodichloroacetic acid and bromochloroacetic acid are more prevalent, and toxicity of these has been studied recently (WHO, 2004). The MCL for the total of five HAAs is 60 µg/L, based on a running annual average of quarterly samples.

Dichloroacetic Acid. In addition to its formation as a DBP, dichloroacetic acid (DCA) is used as a chemical intermediate and as an ingredient in pharmaceuticals and medicine. It was used experimentally in the past to treat diabetes and hypercholesterolemia in human patients (USEPA, 1994a) and it is also a metabolite of trichloroethylene.

The health effects of DCA have been reviewed extensively by USEPA (2003b). DCA inhibits enzymes involved in intermediary metabolism and cholesterol synthesis and thus decreases levels of glucose, pyruvate, and lactate, as well as cholesterol. It has been used experimentally to treat lactic acidosis, diabetes, and familial hypercholesterolemia. DCA causes liver enlargement associated with hepatic glycogen deposition. It causes increased serum liver enzymes in mice, rats, dogs, and humans, but liver necrosis has been observed only in mice. DCA causes male reproductive effects, including decreased testicular weight and viable sperm production, and dogs are the most sensitive species for these effects. DCA exposure in pregnant female rats causes impaired fetal maturation and soft tissue anomalies (primarily of cardiac origin) in the offspring. Neurological effects including sedation and peripheral neuropathy have occurred in humans treated with DCA, and neurological toxicity has been reported in dogs and rats, but not mice. DCA caused increased liver tumors in male and female mice and male rats in several drinking water studies. Although DCA has been found to be mutagenic, responses generally occur at relatively high doses. USEPA (1994a, 1998b) has classified DCA as a probable human carcinogen (Group B2) with an MCLG of zero. More recently (USEPA, 2003b), it has been classified as a likely human carcinogen under the newer USEPA classification scheme.

Trichloroacetic Acid. Trichloroacetic acid (TCA) given in drinking water to male rats caused decreased spleen weight and increased liver and kidney weights (USEPA, 1994f, 1997b). Several studies have shown that TCA, like DCA, can produce developmental malformations in rats, particularly in the cardiovascular system (USEPA, 1994f, 1997b). Trichloroacetic acid was negative in bacterial mutagenicity tests but it produced bone marrow chromosomal aberrations and sperm abnormalities in mice and induced single-strand DNA breaks in rats and mice exposed by gavage. Overall, the available studies suggest that TCA does not cause cancer through a mutagenic mechanism (USEPA, 1994f, 1997b). TCA has induced liver tumors in mouse studies but it was not carcinogenic in male rats (USEPA, 1994f, 1997b). USEPA (1998b) has classified TCA as a possible human carcinogen (Group C) with an MCLG of 0.3 mg/L.

Brominated Acetic Acids. While bromoacetic acid, dibromochloroacetic acid, and tribromoacetic acid were negative in studies of reproductive toxicity in male rats, dibromoacetic acid is a male reproductive toxicant in both rats and rabbits (Melnick et al., 2007; Veeramachaneni, Palmer, and Klinefelter, 2007), causing such effects as abnormal sperm, decreased sperm count and motility, and decreased testis and epididymis weight. Bromodichloroacetic acid was found to cause reproductive toxicity in female rats (NTP, 1998).

Dibromoacetic acid in drinking water caused liver toxicity in subchronic studies in rats and mice. In chronic studies, it caused neoplasms at multiple sites in rats and mice, including mononuclear cell leukemia and mesotheliomas in rats, and liver and lung tumors in mice. Liver tumors were significantly increased in male mice at the lowest dose, approximately 5 mg/kg/day (Melnick et al., 2007). It also caused neurotoxicity in rats when administered by drinking water (Moser et al., 2004). The lowest dose in the study, 200 mg/L, caused neurobehavioral changes, while higher doses also caused neuropathological changes.

Bromochloroacetic acid was also carcinogenic to rats and mice (NTP, 2008b). It caused mesotheliomas in male rats, large intestinal adenomas in male and female rats, mammary gland fibroadenomas in female rats, and liver tumors in male and female mice.

3-Chloro-4-(Dichloromethyl)-5-Hydroxy-2(5H)-Furanone (MX). The organic DBP MX appears to be produced in water treated with chlorine and has been found in drinking water in several countries (Bull and Kopfler, 1991). It is one of the most potent mutagens in the Ames test (Bull and Kopfler, 1991). In a Finnish study (Smeds et al., 1997), it accounted for a large portion (11–70 percent) of mutagenicity in chlorinated drinking waters. Male and female rats given MX in drinking water developed cancer at multiple sites at all doses (Komulainen et al., 1997). McDonald and Komulainen (2005) provide a comprehensive review of occurrence, mutagenicity, and carcinogenicity of MX.

Nitrosamines. The reaction of amines with chlorine or chloramines results in the production of nitrosamines. Nitrosodimethylamine (NDMA) has received the most attention as an emerging drinking water contaminant. In addition to its formation as a DBP, it can form through the degradation of dimethylhydrazine, a component of rocket fuel, and has been found in water supplies near aerospace facilities (Howd and Fan, 2008; WHO, 2008). However, most exposure to nitrosamines comes from dietary sources. Exposure to exogenous NDMA is greater from food than from drinking water, and NDMA is also formed by nitrosation of proteins in food in the stomach (Fristachi and Rice, 2007), as discussed under nitrate.

The nitrosamines are considered probable human carcinogens. The drinking water concentration of NDMA estimated to result in a 1 in 10,000 lifetime cancer risk level is 0.07 µg/L (USEPA, 2008i), but no federal MCL has been promulgated. California (Howd and Fan, 2008) and Massachusetts have set 0.01 µg/L as a notification or guidance level. NDMA is one of four contaminants listed on the USEPA CCL3, which the USEPA Science Advisory Board recommended as a priority for consideration for regulation based on available data on toxicity, occurrence, and treatability (USEPA, 2009b).

RADIONUCLIDES

Introduction

Radionuclides are unstable atoms that spontaneously decay, releasing a portion of their nucleus as radioactivity in the form of one of two different types of particles with mass:

- *Alpha radiation:* Positively charged particles made up of two protons and two neutrons (the same as a helium nucleus)
- *Beta radiation:* Electrons or positrons (the positively charged antiparticle of electrons)

Any additional released energy not contained by these particles is released as gamma radiation, which is high-energy, electromagnetic, wave-type energy (equivalent to photons with energies above 100,000 electron volts). All of these constitute ionizing radiation that

can pass through tissues to produce reactive oxygen species that damage all cellular constituents, including DNA.

Elements heavier than lead, such as radon, radium, thorium, and uranium isotopes, decay by the release of alpha, alpha and gamma, or beta and gamma emissions. Radionuclides that are lighter than lead, such as radioactive isotopes of iodine, strontium, and potassium, decay by beta and/or gamma emissions. Potassium-40 is the naturally occurring long-lived isotope that is the most significant ingested source of beta radiation. However, most of the lighter radionuclides are man-made.

Radioactive decay results in the formation of a lighter isotope or element. The isotope that decays is called the parent, and the new element is called the progeny or daughter. Each naturally occurring isotope heavier than lead belongs to one of three series of stepwise decay pathways stemming from a long-lived isotope. For example, radium-226 (Ra-226) and radon-222 (Rn-222) are 2 of the 14 progenies of uranium-238 (U-238). Eventually, the progenies in this series decay to the stable isotope lead-206. Radium-228 is 1 of 10 progenies of the thorium-232 (Th-232) series that decays eventually to the stable isotope lead-208. The parent of the third series is U-235.

Different isotopes decay at different rates. The half-life of an isotope is the time required for one half of the atoms present to decay. The half-lives of various isotopes range from fractions of a second to billions of years (U-238 and Th-232). Isotopes with very short half-lives are not significant health risks because they do not survive transport through drinking water distribution systems; however, their progenies may cause significant biological effects.

Radioactivity is generally reported in units of curies (Ci). The dose as a measure of absorbed energy is reported as rads, while dose as a measure of the resulting biological damage is reported as rems. One curie equals 3.7×10^{10} nuclear disintegrations per second (the radioactivity in 1 g of radium, by Marie Curie's definition). A commonly used unit is the picocurie (pCi), which equals 10^{-12} Ci. By comparison to radium, 1 g of the relatively stable uranium-238 has 0.36×10^{-6} Ci of radioactivity. In the international system (SI), a Becquerel is equal to one disintegration per second, or 27 pCi. (Rads and rems are discussed below.)

Based on occurrence and health effects, the radionuclides of most concern in drinking water are Ra-226, Ra-228, U-238, and Rn-222 (USEPA, 1988b). Ra-224 and polonium-210 are also frequently found in drinking water. These are all naturally occurring alpha emitters, except for radium-228, which is a beta emitter.

Health Effects of Radionuclides

Each type of radiation interacts differently with cells in the human body. Alpha particles have little ability to penetrate the skin, traveling at most 50 to 70 microns. However, ingested alpha particles can be very damaging to nearby cells, due to both the electric charge they carry and to the energy imparted by their relatively high mass. Damage to DNA (particularly double-strand breaks) is a typical feature of their effect. The smaller mass of beta particles allows greater penetration but causes less damage to organs and tissue. Gamma radiation has tremendous penetrating power but has limited effect on the body at low levels.

A rad quantifies the energy absorbed by tissue or matter, without regard to the amount of damage caused. Thus, a rad of alpha particles causes more damage than a rad of beta particles, while a rad of gamma radiation causes the least damage. In contrast, a rem quantifies radiation in terms of its dose effect, such that equal doses expressed in rems produce the same biological effect regardless of the type of radiation involved. Numerically, a rem is equal to the absorbed dose (in rads) times a quality factor (Q) that is specific to the type of radiation and reflects its biological effects. (In the newer SI units, a Gray is equal to 100 rad and a Sievert is equal to 100 rem.)

The chemical nature of the radioactivity is also important. For example, radioactive iodine can cause thyroid cancer, since iodine accumulates in the thyroid gland and is incorporated there into the hormone, thyroxine, which is a tetra-iodinated amino acid. The

half-lives of different isotopes can also play a role in the disposition of the radionuclide in the body and thus its effect, such as the differing distribution patterns of different radium isotopes in bone. In addition, after a decay step, the daughter element formed may have chemical characteristics that are different than the parent isotope (see Radium, below).

Humans receive an average annual dose of radiation of about 200 to 300 mrem from all sources, and USEPA estimates that drinking water contributes about 0.1 to 3 percent of a person's annual radiation dose. Local conditions can alter this considerably, however. For example, the level of 10,000 pCi/L of radon found in some water systems corresponds to an annual effective dose equivalent of 100 mrem/yr (USEPA, 1991c).

Radioactivity can cause developmental and teratogenic effects, heritable genetic effects, and somatic effects including carcinogenesis. These outcomes result from the interactions of the various cellular effects of radiation, including cell death, induction of cell division, and repair of damage to DNA. High doses lead primarily to cell death, while low doses can stimulate repair processes that can save a cell or return a cell to normal homeostasis and cell-cycle control. Events affecting neighboring cells can also lead to changes in cells not directly impacted by radiation ("bystander effect"). The carcinogenic effects of nuclear radiation (alpha, beta, and gamma) are thought to be due to the ionization of cellular constituents leading to oxidative changes in DNA. All radionuclides are considered to be human carcinogens, although their primary target organs and relative efficiencies as carcinogens differ.

General Considerations for Drinking Water Standards for Radionuclides

The linear nonthreshold approach to extrapolating cancer risk is currently the most widely accepted risk assessment model (NRC, 2006b) for radionuclides. With this approach, lifetime risk is proportional to total exposure, but age during exposure is a modifier. Exposure during early childhood can increase lifetime risk more than predicted by simple proportional increase in years at risk.

Under the original National Interim Primary Drinking Water Regulations, MCLs were set for gross alpha emitters (not including radon) at 15 picoCuries per liter (pCi/L), for Ra-226 and Ra-228 combined at 5 pCi/L, and for gross beta emitters at 4 mrem/yr. These standards were retained under the revised regulations (USEPA, 2000d). If testing is done within 48 to 72 hours after the sample is taken, alpha radiation from the short-lived Ra-224 is also detected (see below). The gross alpha standard is meant as a trigger for further testing and is the only standard for detecting alpha radiation from unregulated emitters, such as polonium-210. USEPA has not promulgated a drinking water standard for radon.

Information on specific radionuclides is presented below. The reader can also refer to the Radionuclides Notice of Data Availability Technical Support Document (USEPA, 2000d) for more background on radionuclides and their risks.

Specific Radionuclides as Drinking Water Contaminants

Radium. Radium accumulates in bone since it distributes in the body similarly to another divalent cation, calcium. It causes bone sarcomas, particularly osteosarcoma. Ra-226 also induces head carcinomas because it decays into radon, which as a gas can enter the nasal sinuses. The half-lives of Ra-224, Ra-226, and Ra-228 are 3.6 days, 1600 years, and 5.8 years, respectively.

Health effects data for radium come from studies of radium watch-dial painters, as well as from persons medically treated with radium injections. In addition, several studies of radium in drinking water indicated that environmentally relevant concentrations are associated with measurable increases in osteosarcoma incidence in humans. The USEPA estimated that at the MCL for combined Ra-226 and Ra-228 of 5 pCi/L, the lifetime cancer risk is about 1 to 2 per 10,000 (USEPA, 2000e).

Radon. Radon is a naturally occurring noble (or inert) gas formed from the radioactive decay of radium-226, which is primarily a decay product of uranium-238 in the earth's crust. Some of the radon released through radioactive decay moves through air- or water-filled pores in the soil to the soil surface and enters the air in buildings or outdoors, while some remains below the surface and dissolves in groundwater. It quickly volatilizes to air from water, and the radon from drinking water can significantly contribute to the radon level of indoor air within a home. Because the half-life of the primary radon isotope, Rn-222, is only 3.8 days, there is significant decay to nongaseous daughters that attach to dust and other particles in air. Small, breathable particles carrying the attached radionuclides can lodge in lung tissue. For each radon atom that reaches the lungs, up to eight progeny will contribute to the radiation load, mostly as alpha radiation.

Direct association has been shown between inhalation of Rn-222 by uranium miners and lung cancer, as well as a small increased risk of other cancers (NRC, 1999b). The effect of radon was increased among smokers. There is also strong evidence for a significant lung cancer risk from radon in residential indoor air (Krewski et al., 2006). It has been estimated that volatilization during showering releases most of the radon dissolved in water and that with typical water use (especially showering), 10,000 pCi/L of radon in water results in an increase of 1 pCi/L in the air in a typical house (Hopke et al., 1996). To put this into perspective, the USEPA residential indoor air guidance level is 4 pCi/L (of air), above which remedial measures are recommended; the approximate level in outdoor air is 0.4 pCi/L. Inhalation of volatilized radon from indoor air is the primary route of exposure to radon in drinking water, with ingestion of radon dissolved in drinking water contributing a minor portion of exposure. The average lifetime cancer risk due to inhalation and ingestion exposures from 100 pCi/L in drinking water was estimated to be approximately 7 per 100,000 (NRC, 1999c).

The health risks from radon in drinking water can exceed those of most regulated drinking water contaminants. For example, radon was found in public drinking water supplies in New Jersey at concentrations ranging from nondetectable to 41,000 pCi/L, with an average concentration of 921 pCi/L. In New Jersey private wells, it was found at 50 to 170,000 pCi/L with an average concentration of 5040 pCi/L (New Jersey Drinking Water Quality Institute, 2009). The estimated lifetime cancer risks at these average concentrations exceed the upper end of USEPA's target risk range for carcinogens in drinking water of 1 in 10,000 (10^{-4}). A drinking water regulation for radon was proposed by USEPA in 1999, but it has not been adopted.

Uranium. Uranium accumulates in the bones similarly to radium. The USEPA classifies it as a human carcinogen, and it also causes kidney toxicity in humans, leading to kidney inflammation and cell death in the renal tubules. The MCL was set at 30 $\mu\text{g/L}$ (approximately corresponding to 27 pCi/L), based on these noncancer kidney effects, since they were deemed to be more critical than carcinogenicity (USEPA, 2000e). The estimated lifetime cancer risk at the MCL is approximately 1 in 10,000. It is notable that uranium represents the first instance of an MCL being set above the MCLG (20 $\mu\text{g/L}$) indicated by the RfD because of economic considerations. Health Canada has an interim maximum acceptable concentration of 20 $\mu\text{g/L}$ (<http://www.hc-sc.gc.ca/ewh-semt/pubs/water-eau/uranium/guideline-recommandation-eng.php>).

AESTHETIC QUALITY

Aesthetic complaints are regarded as important signals of changes in water quality and can potentially serve as an early warning of the presence of contaminants to alert water utility staff. For example, in the days leading up to the 1993 *Cryptosporidium* outbreak in

Milwaukee, Wis., there was an increase in the number of water quality complaints (Proctor, Blair, and Davis, 1998). USEPA advises water systems to include programs for monitoring these complaints in preparedness planning. Taste, odor, color, turbidity, and hardness are discussed below.

Taste and Odor

Certain generalizations can be made about the taste and odor of water. Foremost is that the two sensations can influence one another. Taste tends to reflect inorganic constituents, while odor mainly reflects organic constituents, often at much lower water concentrations. Taste is often influenced by temperature and pH. Both taste and odor can be difficult to measure properly, and efforts must be made to separate the two sensory paths. There can be a wide variation of taste and odor thresholds among individuals, which may exceed the range reported by taste panels. Many individuals adapt to certain tastes, so that the tastes are no longer noticed. Methods for identification and treatment of taste and odor problems are discussed extensively by Mallevalle and Suffet (1987) and in Manual 7 of the American Water Works Association (2004).

Taste and Odor of Inorganic and Organic Contaminants. Taste problems in water derive in part from salts, total dissolved solids (TDS), and the presence of specific metals such as iron, copper, manganese, and zinc. The prevalent anions can often have a larger effect on taste. In general, waters with TDS less than 1200 mg/L are minimally acceptable to consumers, although levels below about 600 mg/L are preferable (Mallevalle and Suffet, 1987). The USEPA SMCL for TDS is 500 mg/L. Specific salts may be more significant in terms of taste, notably magnesium chloride and magnesium bicarbonate. The sulfate salts, magnesium sulfate and calcium sulfate, on the other hand, have been found to be relatively inoffensive (Mallevalle and Suffet, 1987). Sulfate may also impart taste at levels above 300 to 400 mg/L, and concentrations of chloride above 250 mg/L may give water a salty taste. Fluoride can also cause a distinct taste above about 2.4 mg/L. Testing of metals in drinking water (James M. Montgomery Consulting Engineers, Inc., 2005) showed the following taste thresholds (in mg/L): Zn at 4 to 9; Cu at 2 to 5; Fe at 0.04 to 0.1; and Mn at 4 to 30. However, individual taste thresholds may vary widely; for example, the taste threshold for Fe spans a concentration range of over 6000-fold (Cohen et al., 1960). The USEPA Drinking Water Advisory (USEPA, 2003c) for sodium of 30 to 60 mg/L is based on taste.

Objectionable tastes and odors may also occur in water contaminated with synthetic organics or as a result of water treatment or from coatings used inside tanks and pipes. Odor thresholds of some common solvents identified in groundwater are shown in Table 2-5. Many consumers object to the taste of chlorine, which has an average taste threshold of about 0.2 (0.02–0.3) mg/L at neutral pH, whereas the disinfectant monochloramine has been found to

TABLE 2-5 Odor Thresholds of Chlorinated Solvents

Solvent	Detection odor threshold, mg/L
1,4-Dichlorobenzene	0.0003
Trichloroethylene	0.5
Tetrachloroethylene	0.3
Carbon tetrachloride	0.2

Source: Van Gemert, L.J. and Nettenbreijer, A.H. eds. 1977. *Compilation of Odour Threshold Values in Air and Water*. Natl. Inst. for Wtr. Supply, Voorburg, Netherlands, and Centr. Inst. for Nutr. & Food Res. TNO, Zeist, Netherlands.

have a higher taste threshold of 0.48 mg/L (Mallevalle and Suffet, 1987). Di- and trichloramine have stronger odors than monochloramine. Although chlorine can reduce many taste and odor problems by oxidizing the offending compounds, the compounds formed when it reacts with organics may have objectionable taste or odor. Most notorious is the phenolic odor resulting from reactions between chlorine and phenols. The DBP chloroform has been detected by smell at 0.1 mg/L (Mallevalle and Suffet, 1987). The formation of aldehydes from chlorinated amino acids has also resulted in problem odors (Gittleman and Luitweiler, 1996). Other oxidants can also be used to remove chemicals with objectionable taste or odor.

Taste and Odor from Microorganisms. Excessive growth of certain types of filamentous cyanobacteria (e.g., *Anabaena*, *Oscillatoria*, *Phormidium*), filamentous Actinomycete bacteria (e.g., *Streptomyces* and *Nocardia*), fungi, amoeba, and other organisms in source waters can lead to the production of taste and odor chemicals (Juttner and Watson, 2007). The most common taste and odor chemicals produced by these organisms include geosmin and 2-methylisoborneol (MIB). Geosmin and MIB are “earthy” smelling, volatile compounds. In addition to production in the water column, these compounds can also be produced by terrestrial organisms and then washed into a water body by rainfall. Organisms produce these compounds in both dissolved and protein-bound forms. Cell degradation or predator grazing can cause the release of the bound fraction to the dissolved form. Both geosmin and MIB are relatively stable in water. There are different methods to remove these compounds such as oxidation (Chap. 7) and adsorption on activated carbon (Chap. 14). Chlorination or the use of algicides in lakes and reservoirs can increase levels of these compounds due to cell disruption. Organism removal by filtration, sedimentation, or dissolved air flotation should precede the use of oxidants when treating geosmin- and MIB-containing waters.

In groundwaters and in some distribution systems, a highly unpleasant odor of hydrogen sulfide may occur as the result of anaerobic bacterial action on sulfates (Mallevalle and Suffet, 1987). This rotten egg odor can be detected at $\leq 0.1 \mu\text{g/L}$. The bacterium most often responsible for hydrogen sulfide production is *Desulfovibrio desulfuricans*. Other bacterially produced sulfur compounds creating swampy and fishy tastes and odors in distribution systems include dimethylpolysulfides and methylmercaptan. Various types of *Pseudomonas* bacteria can also produce obnoxious sulfur compounds.

Maintenance of a chlorine residual in the distribution system is an important measure in controlling growth of aesthetically significant microorganisms, many of which grow in biofilm on pipes (see Opportunistic Pathogens in the section Pathogenic Organisms). However, if nonpathogenic constituents, such as iron bacteria, nitrifying bacteria, or sulfur bacteria, have built up excessively in the distribution system, the chlorine demand can be significantly increased (American Water Works Association, 2004). The subsequent decreased chlorine residual can allow increased growth of microorganisms in the distribution system, especially in low-flow areas.

Turbidity and Color

Two important aesthetic aspects of water quality are color and turbidity. High-quality drinking water should have no noticeable color and a low level of turbidity. Typical finished waters have color unit (CU) values of less than 5 and turbidities under 1 nephelometric turbidity unit (ntu). Under the Long Term 1 Enhanced Surface Water Treatment Rule (USEPA, 2002b), drinking water cannot exceed 1 ntu and must be under 0.3 ntu in 95 percent of each month’s tests. The sources of color and turbidity are covered in Chap. 3.

Suspended particles can be a significant health concern if heavy metals and hydrophobic chemicals (e.g., many pesticides) are adsorbed to them. The association of turbidity with infectious disease is described in the Indicators of Water Quality section of this chapter.

Color and turbidity removals are typically achieved by the processes of coagulation, flocculation, clarification (sedimentation or dissolved air flotation), and filtration.

Mineralization

Waters with high levels of salts, measured as TDS, may be less palatable to consumers. For example, as discussed earlier in this chapter, sodium and sulfate can impart a taste to the water. The presence of certain salts, such as high levels of sulfate, may have a transitory laxative effect on the consumer.

High salts can also adversely affect industrial cooling operations, boiler feed, and specific processes requiring softened or demineralized waters, such as food and beverage industries and electronics firms. Typically, high salts will force these industries to pretreat their water. High levels of chloride and sulfate can accelerate corrosion of metals in both industrial and consumer systems.

Removal of salts requires expensive treatment, such as demineralization by ion exchange, nanofiltration, or reverse osmosis, and is not usually done for drinking water. Water with excessive levels of salt may be blended with source water with a lower salt level to reduce the salt concentration to acceptable levels.

Hardness

Possible health effects and association were discussed in the section on Inorganic Constituents. Hardness affects the capacity of the water for precipitating soap—the harder the water the more difficult it is to form lather. It is this aspect of hard water that is the most perceptible to consumers.

Staining

Staining of laundry and household fixtures can occur from waters with high iron, manganese, or copper in solution. In oxygenated surface waters, typical concentrations of total iron (mostly the ferric form) are low, and treated waters are well below the SMCL of 0.3 mg/L. From reservoir bottoms deficient in oxygen and from groundwater, the occurrence of ferrous iron at concentrations of 1.0 to 10 mg/L is common. If reduced Fe is carried into the distribution system, the presence of oxygen or chlorine will oxidize Fe producing a red-brown ferric hydroxide precipitate that stains fixtures and laundry. Manganese is often present in waters from the bottom of reservoirs and groundwaters and can cause staining problems—dark brown to black precipitate. As discussed in Chap. 7, drinking water treatment plants attempt to reduce Mn to 15 µg/L or less to prevent chronic staining problems. This is less than the SMCL of 0.05 mg/L.

Excess copper in water may create blue stains.

PREPAREDNESS AND HEALTH

Preparedness is a cross-cutting issue. Threats from the potential release of biological, chemical and radiological agents considered by agencies involved in homeland security can pose acute to long-term health risks. Publicly available lists of agents of concern have been in existence for many years because of past public discussions about preparedness

and prohibition of the use of these agents as weapons by militaries (NRC, 1995; Christen, 2001), but potential threats range from the “hardware store” variety to esoteric agents. A subset of these agents may be relevant to drinking water because of resistance to treatment and disinfection or because of the potential for intentional intrusion into a system. It is suggested that the reader make use of the various reports and Websites provided at the end of the section for more detail and updates.

The biological agents of concern for drinking water include anthrax because of its resistance to disinfection (Rice et al., 2005). Other agents, including those that have caused disease outbreaks in the past, could pose a hazard if the disinfectant residual is low or compromised. Bacterial or fungal toxins also have received attention as potential threats.

Chemical warfare agents of concern include the nerve agents that inhibit human acetylcholinesterase, which is a critical enzyme located at the neuromuscular junction, in the autonomic nervous system and the brain. Inhibition causes a dangerous buildup of the neurotransmitter, acetylcholine (see discussion in the introduction to the section on Insecticides). Insecticide inhibitors of acetylcholinesterase can also pose a risk for some individuals and exposure scenarios, but many insecticides have a toxicity profile that affects humans much less than insects. Other chemicals of concern include well-known poisons, such as cyanide, which inhibits the ability of animal cells to respire, arsenic, and thallium, as well as protein based plant- and animal-derived toxins, like ricin.

Among the various sources of information are the Water Contamination Information Tool (USEPA, 2007b); USEPA National Homeland Security Research Center, including its initiative to establish Provisional Advisory Levels for hazardous agents (USEPA, 2008k); the CDC (2008) Website for Bioterrorism Agents and Diseases; and the Water Information Sharing and Analysis Center (<http://www.watersisac.org>). In addition, the USEPA has developed a number of emergency response tools, including the Response Protocol Toolbox Modules, found at: http://cfpub.epa.gov/safewater/watersecurity/home.cfm?program_id=8.

FINAL COMMENT

Health and aesthetic aspects of water quality are the driving forces behind water quality regulations and water treatment practice. Because of the complexity of the studies summarized in this chapter, the reader is urged to review the cited literature, Health Advisories and IRIS documents from USEPA, the Toxicological Profile series from the ATSDR, and other information sources provided below for more details on any contaminant of particular interest. Furthermore, because new information on organisms causing waterborne disease and chemical contaminants is constantly becoming available, review of the literature since the publication of this chapter is recommended to supplement the information herein during the process of decision making.

MRDL	maximum residual disinfectant level
MRDLG	maximum residual disinfectant level goal
MTD	maximum tolerated dose
NOAEL	no observed adverse effect level
NCI	National Cancer Institute
NRC	National Research Council
NTP	National Toxicology Program
ntu	nephelometric turbidity unit
PAH	polynuclear aromatic hydrocarbon
PALs	Provisional Advisory Levels
PAM	primary amoebic meningoencephalitis
PWS	public water system
RfD	reference dose
RSC	relative source contribution
SDWA	Safe Drinking Water Act
SMCL	secondary maximum contaminant level
TC	total coliform
TCR	Total Coliform Rule
TDS	total dissolved solids
THM	trihalomethane
TSH	thyroid-stimulating hormone
USEPA	U.S. Environmental Protection Agency
VOC	volatile organic chemical
WHO	World Health Organization

ACKNOWLEDGMENTS

The authors thank the editor of this book and the reviewers of this chapter for their thorough review and comments. We also thank Dr. Keith Cooper, Rutgers University; Ms. Sandra Krietzman, New Jersey Department of Environmental Protection; Dr. Mark LeChevallier, American Water Works Company, Inc.; and Dr. Francis Mègraud, Institut National de la Santé et de la Recherche Médicale (INSERM), Bordeaux, France, for their helpful input on the sections relating to their areas of expertise.

INTRODUCTION

Chapters 1 through 5 serve as a foundation for the book. This foundation chapter has three goals. One goal is to summarize basic water chemistry principles. A second goal is to provide the reader with background on the composition of source waters with respect to their bulk water chemistry and on naturally occurring contaminants. Contaminants that enter water supplies through human activity are also summarized. Because protecting the quality of source waters is an important strategy in the drinking water field, principles and some practical material on watershed protection are presented as a third goal.

The chapter is organized in the following way. We start with a summary of chemical principles because chemical reactions affect the composition of source waters as well as treatment processes and the quality of water in distribution systems. Next, we address the composition of surface and groundwaters. Hydrogeochemical and biological geochemical cycles and their effects on the composition of water quality are described. Ranges and typical concentrations for chemical species, particles, and natural organic matter (NOM) are presented for rivers and streams, reservoirs and lakes, and groundwaters. The chapter examines the bulk chemical composition and naturally occurring contaminants in water. It also examines the presence of anthropogenic chemicals that are present in some water sources. Particles and NOM are important contaminants that affect source water quality and many treatment processes, and so they are given extensive coverage. The last section reviews important principles related to the selection and protection of drinking water sources with respect to water quality.

CHEMICAL PRINCIPLES AND CONCEPTS

The composition of source waters and water treatment processes are affected greatly by various chemical reactions such as acid-base (e.g., inorganic carbon chemistry, alkalinity, chlorination) complexation (e.g., Fe and NOM in source waters and coagulation), solubility (e.g., the occurrence of metals in source waters, softening, and coagulation), and oxidation–reduction (redox) (e.g., oxidation of Fe and Mn, disinfection, and corrosion). Kinetics of chemical reactions are not covered here but in Chap. 4. Mass transfer kinetics for describing movement or transport of gases and particles are covered in the chapters dealing with these processes.

Here, these topics are briefly summarized for use in this and other chapters. The reader should refer to primary textbooks on water chemistry such as Stumm and Morgan (1996), Snoeyink and Jenkins (1980), and Benjamin (2002) for extensive theory and applications of the topics covered in this section. Note that these water chemistry references are listed separately in the References section.

Water Properties

Polar Nature. Water is a polar molecule, and although electrically neutral it has a polar nature meaning the molecule has a region of negative charge near the O atoms and positive charge near the H atom. This dipolar nature gives water important properties such as its ability to act as a solvent. We therefore find substances (solutes) dissolved in water to varying degrees, depending on specific chemical properties. For example, simple salts such as Na^+ and Cl^- are found at high concentrations such as in the oceans, while Al is found at low concentrations at typical pH conditions of water supplies because it is insoluble. The polar nature of water leads to H bonding of water molecules and other molecules. It also affects the chemical speciation of dissolved substances.

Physical Properties. The dipolar nature of water also affects important physical properties. Compared to other liquids, water has a high boiling point (100°C) and a high freezing point (0°C). Water density depends on water temperature with a maximum value at 4°C of 1000 kg/m³. Water density as a function of temperature explains the cause of lake stratification, which is addressed later in this chapter. Water viscosity is another important physical property. Water density and viscosity affect various water treatment processes, as presented in individual chapters. Appendix D contains values as a function of water temperature.

The conductivity of water is affected by the concentration of dissolved salts. The dissolved salt concentration affects corrosion reactions and chemical reactions in general. This is addressed later in this chapter.

Water Dissociation, pH, and pX Notation

Water dissociates and is in equilibrium with H₃O⁺ (hydronium ion) and OH⁻, as shown in Eq. 3-1. Writing the hydronium ion recognizes that free H⁺ does not exist in water, it is bound through H bonding to the water molecule. We should be aware of this fact when we write a shorthand version of Eq. 3-1 as Eq. 3-2.

The equilibrium constant for the dissociation of water (K_w) and using Eq. 3-2 describes the following concentration relationships. The activity or active concentrations (a_{H^+} and a_{OH^-}) is the formal and proper way to describe the equilibrium constant relationship—more on activities later in this chapter. For dilute solutions, the molar concentrations (the brackets [] indicate molar) are approximately equal to the activities yielding Eq. 3-4.

$$K_w = a_{\text{H}^+} a_{\text{OH}^-} \quad (3-3)$$

$$K_w = [\text{H}^+][\text{OH}^-] \quad (3-4)$$

At standard temperature of 298 K or 25°C, K_w is 10⁻¹⁴. Because chemical reactions including the dissociation of water are temperature dependent, it is often essential to adjust K_w . Equation 3-5 allows calculation for other water temperatures where T is the absolute temperature. As an example of the significance of water temperature on K_w , consider that we measure pH to control processes in water treatment so the [H⁺] is known or fixed for that particular pH value; consequently, the [OH⁻] varies with water temperature for that particular pH. Many precipitation reactions such as in coagulation depend on the metal precipitating with OH⁻. For example, if you carried out a precipitation reaction at pH 6 in the summer at say 25°C, the [OH⁻] is 10⁻⁸ M, but in winter months at the same pH 6 and say 5°C (where the K_w is 1.86 × 10⁻¹⁵), the [OH⁻] is 0.19 × 10⁻⁸ M about five times less OH⁻ for precipitation. Higher pH conditions are required in the winter for effective precipitation.

$$\log K_w = \left(\frac{-4471}{T} \right) - 1.71 \times 10^{-3}(T) + 6.09 \quad (3-5)$$

pX Notation. In water treatment chemistry, the pX notation is often used to describe concentrations and equilibrium constants on a log (base 10) basis. We are most familiar with pH as minus the base 10 log [H⁺]. A summary of other pX notation is given in Table 3-1 for reference. This notation is used here and in several chapters throughout the book.

TABLE 3-1 Guide to pX Notation Used in This Chapter and throughout the Book

pX	Definition	Comments
pC	$-\log [C]$	molar concentration of C
pH	$-\log [H^+]$	molar concentration of H^+
pK	$-\log K$	equilibrium constant
pe°	$1/n \log K$	standard oxidation reduction potential, where K is the equilibrium constant for the half reaction and n is the number of electrons transferred

Concentrations

Moles and Mass. We use various measures of concentration in evaluating water quality and in water treatment process chemistry. A fundamental chemical measure of concentration is moles per liter, which is expressed as M. At low concentrations, it may be expressed as millimolar (mM). One mole of a substance is the gram atomic weight of a substance. We usually describe concentrations of substances in water on a mass basis (e.g., the alum or chlorine dose at a water plant is expressed on a mass concentration basis). To convert from moles to mass concentrations, our conversion factor is the gram atomic weight of the substance. We usually express mass concentrations as g/L, mg/L, or $\mu\text{g/L}$, depending on the relative concentration.

Equivalents: Charge and Alkalinity Concentrations. We also use equivalent concentrations to describe the charge concentration of ions—more on this under the principle of electroneutrality—and to describe alkalinity. The concept of alkalinity is addressed later in the chapter. Fundamentally, alkalinity is measured in units of eq/L (equivalents per liter) or meq/L (milliequivalents per liter), and it is the concentration of H^+ that can be neutralized or the acid neutralizing capacity of water. In our field, it is reported in terms of an equivalent concentration as CaCO_3 . CaCO_3 has an equivalent weight of 50, so the conversion is 1 meq/L of alkalinity is 50 mg/L as CaCO_3 .

Other Cases. Some other cases of interest in describing concentrations are for hardness and in reporting nitrogen and phosphorus concentrations. Water hardness is caused by divalent and trivalent cations in water, but because calcium and magnesium are much higher in concentrations compared to others, these are the two cations we attribute to hardness. Total hardness is the sum of Ca^{2+} and Mg^{2+} , both expressed in terms of equivalent concentrations as CaCO_3 . The equivalent concentration of Ca^{2+} is its mass concentration times the atomic weight of CaCO_3 divided by the atomic weight of Ca^{2+} , i.e., 1 mg/L of Ca^{2+} equals 100/40 or 2.5 mg/L as CaCO_3 . Likewise, 1 mg/L of Mg^{2+} equals 100/24.31 or 4.11 mg/L as CaCO_3 . Classifications of waters with respect to water hardness are: soft < 75, moderately hard 75 to 150, hard 150 to 300, and very hard > 300 mg/L as CaCO_3 (Sawyer et al., 1994).

Phosphorus (P) can occur in water as dissolved organic P or inorganic P. Within the inorganic form, it can exist as polyphosphates and orthophosphate. The phosphorus concentration is usually reported as P. Likewise, nitrogen compounds such as NH_4^+ , NH_3 , and NO_3^- are reported as N. For example, in chloramination 1 mg/L of NH_3 added to water is reported as N, i.e., 1 mg/L of NH_3 equals 1 mg/L times the atomic weight of N divided by the molecular weight of NH_3 or 1 mg/L times 14/17 or 0.82 mg/L as N.

Gas Phase. Gas phase concentrations are expressed in terms of pressures, partial pressures, or vapor pressures, and they are addressed in the following chapters depending on the application. Units are in atmosphere, Pa (Pascal) or kPa, and bar.

Ionic Strength, Conductivity, and Dissolved Solids

Chemists describe the ion concentration of water in terms of the ionic strength. Ionic strength affects the active concentrations (activities) participating in chemical reactions. It affects acid-base reactions, solubility of solids and gases in water, scaling of solids, corrosion chemistry, and colloidal particle double layer theory and stability. Ionic strength effects are covered in Chap. 8 for colloidal particle stability and in other chapters dealing with specific applications. Here it is defined, and expressions for estimating it from conductivity and dissolved solids measurements are presented.

The ionic strength (*I*) is defined by Eq. 3-6 where *C_i* is the ion molar concentration of ion *i*, and *Z_i* is the charge of ion *i*.

$$I = \frac{1}{2} \sum_1^n C_i Z_i^2 \tag{3-6}$$

A complete water analysis of all ions is required to use Eq. 3-6. Because this is often impractical, correlations have been developed relating the ionic strength to more practical measurements (Snoeyink and Jenkins, 1980). Equation 3-7 is a correlation equation between *I* and conductivity (*κ*), and Eq. 3-8 relates *I* to total dissolved solids (*TDS*).

$$I = 1.6 \times 10^{-5} (\kappa) \tag{3-7}$$

$$I = 2.5 \times 10^{-5} (TDS) \tag{3-8}$$

Values for *I*, *κ*, and *TDS* are given in Table 3-2. Most natural fresh waters have ionic strengths between 5×10^{-4} M and 10^{-2} M, corresponding to estimated conductivities of about 30 to 625 $\mu\text{S/cm}$ and *TDS* of 20 to 400 mg/L.

Principle of Electroneutrality

Water is electrically neutral, meaning the cations must equal the anions on an equivalent charge basis. This is expressed as Eq. 3-9 where *i* and *j* refer to cations and anions.

$$\sum_i C_i Z_i = \sum_j C_j Z_j \tag{3-9}$$

TABLE 3-2 Ionic Strength (*I*), Conductivity (*κ*), and Total Dissolved Solids (*TDS*) for Several Water Types

<i>I</i> (M)	<i>κ</i> ($\mu\text{S/cm}$)	<i>TDS</i> (mg/L)	Comments
1.2×10^{-5}	0.75	0.5	dimineralized water open to atmospheric CO ₂ (g) of 380 ppm
5×10^{-4}	31	20	soft groundwater
10^{-3}	63	40	low to moderate hardness surface or groundwater
5×10^{-3}	312	200	high hardness surface or groundwater
10^{-2}	625	400	very hard and brackish water
10^{-1} *	7000	5000	estuarine water
0.68^\dagger	~50,000	35,000	seawater at salinity of 35.2 parts per thousand

*Outside of correlation range of data

†Seawater values vary with salinity but are well-known

The principle of electroneutrality has useful applications. These are (1) to determine the accuracy of a reported chemical composition and (2) to determine an anion or cation that was not measured. Example 3-1 shows use of the principle in evaluating the composition of a bottled spring water.

Example 3-1 Principle of Electroneutrality

A bottled water company gives the following chemical composition for their spring water: pH 7.1; calcium, 91 mg/L; magnesium, 4.0 mg/L; sodium, 4.0 mg/L; sulfate, 170 mg/L; bicarbonate, 63 mg/L; fluoride, 0.4 mg/L; and nitrate, 0.26 mg/L. Check on whether the reported composition satisfies the principle of electroneutrality.

Solution Equation 3-9 is applied to solve the problem. The results are presented in the table.

Cations					
Ion	mg/L	Atomic Wgt	C_i (mM)	Z_i	$C_i Z_i$ (meq/L)
Ca^{2+}	91	40	2.275	2	4.550
Mg^{2+}	4	24.31	0.164	2	0.329
Na^+	4	23	0.173	1	0.174
H^+		1	$<10^{-4}$	1	$<10^{-4}$
Sum					5.053
Anions					
Ion	mg/L	Atomic Wgt	C_j (mM)	Z_j	$C_j Z_j$ (meq/L)
HCO_3^-	63	61	1.033	1	1.033
SO_4^{2-}	170	96	1.770	2	3.540
F^-	0.4	19	0.021	1	0.021
NO_3^-	0.26	62	0.004	1	0.004
OH^-		17	$<10^{-3}$	1	$<10^{-3}$
Sum					4.598

The total cation charge is much higher (5.053 meq/L) compared to the total anion charge (4.598 meq/L). This can mean either that there are errors in the chemical analysis or that one or more anions were not measured and reported. The latter is most likely since all natural waters contain chloride, which is not reported. If we assume that the reported concentrations of cations and anions are accurate, then we can calculate the missing chloride concentration using Eq. 3-9. The missing anion (chloride) concentration is 0.455 meq/L, which is a chloride concentration of 16 mg/L. ▲

Stoichiometry

Stoichiometry is the subject of chemistry that allows us to make calculations of how much of a chemical undergoes reaction and how much of a chemical is produced for known chemical reactions. Chemical reactions actually take place in terms of numbers of ions or molecules or atoms. However, because the numbers are so high the chemist invented the mole concept where 1 mole is the gram atomic weight of the substance. In other words 1 mole of a substance is the gram atomic weight of a substance and it contains 6.023×10^{23} ions or molecules or atoms. A list of atomic weights is given in App. A. In using stoichiometric calculations, one assumes the reactions go to completion. This is true for many types of reactions in water treatment such as dissolving chemicals in water. Example 3-2 illustrates stoichiometric calculations involving the use of alum as a coagulant.

Example 3-2 Alum Dosing and Residuals Produced

In Part a, find the relationship between alum dosing as alum and as Al. Alum dosing in the United States is expressed as dry alum in which alum is $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$. In many other countries, alum dosing is expressed as Al. Determine the relationship between 1 mg/L of alum and mg/L as Al. In Part b, determine the production of residuals (sludge) from precipitation of $\text{Al}(\text{OH})_3(\text{s})$ ((s) refers to a solid phase) from use of alum.

Solution *Part a.* Dissolution of alum ($\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$) follows the stoichiometric equation below. The calculation shown equating 1 mg/L of alum to x mg/L as Al comes from the mole concept expressed through the stoichiometry of the chemical equation.

$$1 \frac{\text{mg alum}}{\text{L}} \times \frac{\text{mmole alum}}{594 \text{ mg}} \times \frac{2 \text{ mmole Al}}{\text{mmole alum}} \times \frac{27 \text{ mg Al}}{\text{mmole Al}} = 0.0909 \text{ mg/L Al}$$

Thus, 1 mg/L of alum equals 0.0909 mg/L as Al or 1 mg/L of Al equals 11 mg/L of alum.

Part b. The amount of solids (residuals) produced on a dry basis is calculated from the following stoichiometric equation. Assuming all the Al precipitates, which is a good assumption since alum coagulation is often practiced at pH conditions that maximizes the precipitation reaction leaving little residual dissolved Al. The solid ($\text{Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}(\text{s})$) has three appended waters and this is sometimes considered in sludge calculations—see Chap. 22. Calculating for 1 mg/L alum or 0.0909 mg/L Al follows.

$$\begin{aligned} & \frac{0.0909 \text{ mg Al}}{\text{L}} \times \frac{\text{mmole Al}}{27 \text{ mg}} \times \frac{1 \text{ mmole Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}(\text{s})}{\text{mmole Al}} \\ & \quad \times \frac{132 \text{ mg Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}(\text{s})}{\text{mmole Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}(\text{s})} \\ & = 0.44 \text{ mg/L Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}(\text{s}) \end{aligned}$$

Thus, we find that 1 mg/L alum (or 0.0909 mg/L Al) produces 0.44 mg/L of residuals from the precipitation of the metal coagulant. If we did not include the three appended waters to the solid, the sludge generated would be 0.26 mg/L. So we can estimate the solids generated from alum would be about 0.3 to 0.4 mg/L. Additional residuals would come from the particles (turbidity) and organic matter in the raw water that are removed through coagulation. ▲

Chemical Equilibrium

Chemicals in water are either at equilibrium or seeking an equilibrium condition. By equilibrium we mean there is no net change in the concentrations, they have reached a steady state concentration. When we add an acid or base to water, the reactions are extremely fast ($\ll 1$ sec) because they involve only the donation of H^+ (acid) or the acceptance of H^+ (base). Other reactions may take longer (many seconds or minutes or longer) such as precipitation of solids or oxidation-reduction reactions. We use chemical equilibrium principles to describe the speciation of chemicals in water, for example, the fraction of hypochlorous acid (HOCl) versus hypochlorite (OCl^-) in disinfection applications. Other examples of the use of chemical equilibrium include the solubility of metal coagulants

(Al and Fe salts), water softening precipitation reactions for $\text{CaCO}_3(\text{s})$ and $\text{Mg}(\text{OH})_2(\text{s})$, oxidation of iron and manganese, and corrosion chemistry for copper and lead. In the material that follows, some basic principles are presented that are applied in this and later chapters.

Equilibrium Constant. Consider the following general reaction occurring in water where the capital letters represent chemical species, the lower case letters are the stoichiometric coefficients, and the symbol (\rightleftharpoons) depicts a system at equilibrium between the reacting species and the products. In this book an equal sign is often used for an equilibrium reaction rather than the symbol (\rightleftharpoons). The reader will know it is an equilibrium reaction from the description of the subject matter.

The equilibrium constant relationship follows setting the equilibrium composition distribution of reactants and products for standard conditions of 25°C and 1 atm pressure. The equilibrium constant depends on the activity (a_i) of the species (i) raised to the power of the stoichiometric coefficient. The activity is used in formal development because reactions depend on an active or apparent concentration of the species.

$$K = \frac{a_Y^y a_Z^z}{a_A^a a_B^b} \quad (3-11)$$

The activities for dissolved substances are related to molar concentrations of species [i] by use of activity coefficients (γ_i). The activity coefficients account for non-ideal behavior of the solutions. Expanding Eq. 3-11, we obtain the following expression:

$$K = \frac{a_Y^y a_Z^z}{a_A^a a_B^b} = \frac{\gamma_Y^y [Y]^y \gamma_Z^z [Z]^z}{\gamma_A^a [A]^a \gamma_B^b [B]^b} \quad (3-12)$$

The non-ideal behavior of reactions is accounted for by use of activity coefficients for aqueous systems that are not dilute solutions in terms of the ionic strength or dissolved salt content. For ions, the fundamental model accounting for ionic strength effects and their charge is the Debye-Hückel theory. The reader should consult the water chemistry references for presentation of this model, other models, and details regarding calculation of activity coefficients. Here, the practical Davies equation is presented and can be used for ionic strength (I) up to ~ 0.5 M. In Eq. 3-13, z_i is the charge on the ion and A depends on the dielectric constant (ϵ) of water and absolute temperature (T) according to Eq. 3-14. A has a value of 0.5 for a water temperature of 298 K (25°C).

$$\log \gamma_i = -Az_i \left(\frac{I^{0.5}}{1+I^{0.5}} - 0.3I \right) \quad (3-13)$$

$$A = 1.82 \times 10^{-6} (\epsilon T)^{-3/2} \quad (3-14)$$

Most water supplies and treatment processes are sufficiently dilute in ionic strength that we can assume ideal solutions. In assuming ideal solutions, we set the activity coefficients to 1, which is a reasonable approximation for ionic strength conditions of about 0.001 M and less. These ionic strength conditions apply to many fresh waters. Some values are presented later in the chapter. For waters or processes at higher ionic strength such as brackish

waters, seawater, scaling on membranes, and desalination, we must account for the ionic strength effects on the equilibrium constant reactions.

Concentration Scales for Ideal Systems. The following concentration scales are used for ideal aqueous systems:

- Dissolved substances: molar concentrations
- Water: mole fraction, which is 1 for water (even for seawater it is nearly 1)
- Solid phases: mole fraction of 1 for pure solids, which is assumed
- Gas phase: partial pressure traditionally in atm or may be expressed in bar

In presenting many of the concepts regarding equilibrium chemistry and for making approximate calculations describing the chemistry of fresh waters and water treatment process chemistry, activities are ignored (setting activity coefficients to 1), and hence we consider the waters as ideal solutions. For an ideal solution, Eq. 3-12 is written then as Eq. 3-15. It is noted that in some cases, equilibrium constants are given for specified ionic strength conditions, meaning the effect of non-ideal solutions has been accounted for in determining the equilibrium constant.

$$K = \frac{[Y]^y [Z]^z}{[A]^a [B]^b} \quad (3-15)$$

Effects of Temperature and Pressure. Equilibrium constants must be adjusted for temperature in order to make equilibrium calculations for the temperature of interest. This is done by using a form of the van't Hoff equation as follows:

$$\log \frac{K_2}{K_1} = \frac{\Delta H_r^\circ (T_2 - T_1)}{2.303(R)(T_2)(T_1)} \quad (3-16)$$

where K_2 is for the temperature of interest at T_2 in degrees Kelvin, K_1 is for standard temperature of T_1 at 298 K, ΔH_r° is the standard enthalpy of the reaction, and R is the universal gas constant (8.314 J/mole · K). Values for the standard enthalpy of the reaction may be found in the books listed under water chemistry references or from chemistry handbooks.

Only pressures at 100s of atmospheres and higher affect the equilibrium constants, so pressure effects on the equilibrium constants are ignored in this book.

Reaction Quotient. To determine whether actual measured concentrations are at equilibrium for the reaction of interest, the reaction quotient (Q) is used. The actual measured concentrations are inserted into the right-hand side (RHS) of Eq. 3-17. If Q equals K , then the system is at equilibrium; if Q is $> K$ then the reaction will move to the left, seeking equilibrium; and if Q is $< K$, then the system will proceed to the right, seeking equilibrium.

$$Q = \frac{[Y]^y [Z]^z}{[A]^a [B]^b} \quad (3-17)$$

Solubility and Stripping of Gases—Henry's Law. Henry's law describes the equilibrium partitioning of gases with water. In Chap. 6 the stripping of volatile organic compounds (VOCs) is described by the following equation in which the gas phase (i.e., the VOC of interest in the gas phase) is on the RHS of Eq. 3-18; the resulting Henry's law expression is shown by Eq. 3-19. The gas phase concentration is expressed in terms of its partial pressure.

In the stoichiometric description depicted by Eq. 3-18, our interest is in stripping VOCs, so the aqueous phase concentration is shown on the left-hand side (LHS) and leaving solution to the gas phase. Here H has units of atm/molar.

$$H = \frac{P_A}{[A_{aq}]} \quad (3-19)$$

In other applications we may be interested in the saturation concentration of a gas in water—its solubility. Examples are $O_2(aq)$ and $N_2(aq)$ in dissolved air flotation applications (Chap. 9), $O_2(aq)$ in source waters, and $CO_2(aq)$ in source waters and in treatment processes. For these applications, the stoichiometric equation is written in the reverse direction from Eq. 3-18. Our interest is in dissolving the gas into water. The gas phase is written on the LHS of Eq. 3-20, while the dissolved equilibrium concentration (solubility or saturation concentration) is written on the RHS. Henry's law is shown as Eq. 3-21.

$$H^* = \frac{[A_{aq}]}{P_A} \quad (3-21)$$

Here, the Henry's law constant is designated as H^* , and it has units of molar/atm. H^* equals $1/H$. Some values are presented in Table 3-3.

TABLE 3-3 Henry's Law Constants (H^*) at 25°C for Selected Gases (Stumm and Morgan, 1996)

Gas	Units of molar/atm
Ammonia (NH ₃)	57
Carbon dioxide (CO ₂)	3.39×10^{-2}
Hydrogen (H ₂) [†]	8.04×10^{-4}
Hydrogen sulfide (H ₂ S)	1.05×10^{-1}
Nitrogen (N ₂)	6.61×10^{-4}
Oxygen (O ₂)	1.26×10^{-3}
Ozone (O ₃)	9.4×10^{-3}

[†]Benjamin (2002)

Solubility of Carbon Dioxide. Dissolved carbon dioxide (CO₂(aq)) is hydrated by water molecules according to Eq. 3-22, forming a diprotic acid, i.e., contains 2H⁺. The reaction lies far to the left, so mostly we have CO₂(aq), but the almost infinite number of water molecules provides for maintenance of equilibrium for the acid, H₂CO₃. To account for both species, they are combined according to Eq. 3-23.

The solubility of CO₂(g) is defined then with respect to H₂CO₃^{*}, as shown by Eq. 3-24. Henry’s law is applied to give the dissolved concentration of H₂CO₃^{*} as a function of the partial pressure of CO₂(g), as presented in Eq. 3-25.

$$H_{\text{CO}_2}^* = \frac{[\text{H}_2\text{CO}_3^*]}{P_{\text{CO}_2}} \tag{3-25}$$

The value for the Henry’s constant ($H_{\text{CO}_2}^*$) at 25°C is 3.388×10^{-2} M/atm. Air at atmospheric pressure of 101.3 kPa (1 atm) contains 380 ppm CO₂(g) by volume or expressed as partial pressure (P_{CO_2}), 3.80×10^{-4} atm. Applying Eq. 3-25 for this condition yields an equilibrium dissolved H₂CO₃^{*} concentration of 1.29×10^{-5} M or 0.16 mg/L as C. It should be noted that many water systems are not in equilibrium with respect to dissolved inorganic carbon (H₂CO₃^{*}) because of other reactions adding CO_{2(aq)} such as bacterial decomposition or removing CO_{2(aq)} from water such as algae growth. However, if equilibrium is established between the water and air phases, then the concentration of dissolved H₂CO₃^{*} is fixed at 1.29×10^{-5} M assuming 25°C. For a colder water temperature of say 5°C, the equilibrium concentration of H₂CO₃^{*} is 2.39×10^{-5} M or 0.29 mg/L as C.

Acid-Base Chemistry. Acids and bases are defined by the Brønsted-Lowrey concept. An acid is a substance that donates a proton (H⁺), and the corollary is that a base is a substance that accepts a proton. Monoprotic acids have only one proton to donate. Generically, they are defined as HA (e.g., hypochlorous acid (HOCl)). Some acids are diprotic and have two protons and are generally defined as H₂A (e.g., dissolved H₂CO₃^{*}) and some are triprotic with three protons (H₃A, e.g., H₃PO₄). The strength of an acid has to do with the tendency of the acid to donate the proton to water and it is quantified by acidity constants (K_a). Table 3-4 lists p*K_a* values for several acids of interest. Acids with high acidity constants (or p*K_a* of low values) are called strong acids; practically, one can assume complete dissociation when they are added to water. Examples are sulfuric, hydrochloric, and nitric acids. There are several weak acids and bases of interest in natural waters and in water supply and treatment, so principles regarding the equilibrium distribution of acids and their conjugate bases are covered next, and several applications are given.

TABLE 3-4 Acidity Constants for Some Important Acids at 25°C (from Stumm and Morgan, 1996 and Benjamin, 2002)

Acid	Formula	p <i>K_{a1}</i>	p <i>K_{a2}</i>	p <i>K_{a3}</i>	Applications
Sulfuric	H ₂ SO ₄	~ -3	1.99		Coagulation, pH control, membrane cleaning
Phosphoric	H ₃ PO ₄	2.16	7.20	12.3	Speciation in lakes, corrosion control
Arsenic	H ₃ AsO ₄	2.24	6.76	11.6	Oxidized As—in water treatment
Carbonic	H ₂ CO ₃ [*]	6.35	10.33		Many; see inorganic carbon section
Hydrogen Sulfide	H ₂ S	6.99	12.92		Found in some groundwaters
Hypochlorous	HOCl	7.60			Chlorination
Arsenous	H ₃ AsO ₃	9.23	12.1	13.4	Reduced As found in some groundwaters
Ammonium	NH ₄ ⁺	9.25			Chloramination

Acid-Base Equilibria. We begin with monoprotic acids and consider generically the acid HA and its conjugate base A^- . The stoichiometric and equilibrium constant equations follow:

$$K_{a1} = \frac{[A^-][H^+]}{[HA]} \quad (3-27)$$

K_{a1} is the acidity constant. Because there is only one proton involved, it may be written simply as K_a . Taking base 10 logs of both sides of Eq. 3-27, invoking the pX notation for $[H^+]$ and K_a , and rearranging, we obtain Eq. 3-28.

$$\log \frac{[A^-]}{[HA]} = \text{pH} - \text{p}K_a \quad (3-28)$$

Applying Eq. 3-28 to the equilibrium distribution of HOCl/OCl⁻ (free chlorine), we obtain Eq. 3-29.

$$\log \frac{[\text{OCl}^-]}{[\text{HOCl}]} = \text{pH} - \text{p}K_a = \log \frac{[\text{OCl}^-]}{[\text{HOCl}]} = \text{pH} - 7.6 \quad (3-29)$$

If we practice free chlorination at pH 7.6, then chlorine in the form of HOCl equals OCl⁻. For lower pH conditions, HOCl is the dominant form of free chlorine, whereas at pH > pK_a, OCl⁻ dominates. This simple acid (HOCl) and base (OCl⁻) chemistry is important in chlorination because HOCl is a far more effective disinfectant than OCl⁻. In Chap. 17 the chemistry of free chlorine is covered in detail.

Another important application is the use of ammonia in combined chlorination or chloramination (see Chap. 17). Equation 3-30 shows the dependence of ammonium ion (NH₄⁺) and dissolved ammonia (NH₃) on pH. It shows that when ammonia is used in chloramination at pH < 9.25, ammonium ion dominates.

$$\log \frac{[\text{NH}_3]}{[\text{NH}_4^+]} = \text{pH} - \text{p}K_a = \log \frac{[\text{NH}_3]}{[\text{NH}_4^+]} = \text{pH} - 9.25 \quad (3-30)$$

Two diprotic acids of interest are hydrogen sulfide and dissolved inorganic carbon (H₂CO₃^{*}). Because reduced inorganic sulfur can occur in groundwaters, the distribution of H₂S/HS⁻/S²⁻ as a function of pH is important to understand. Its occurrence is presented later in this chapter; the removal of H₂S by stripping is covered in Chap. 6, and the removal of reduced sulfur by oxidation is covered in Chap. 7. Inorganic carbon has many important applications presented later in this chapter.

Generically, we describe the diprotic acid systems as H₂A/HA⁻/A²⁻. Note that H₂A is an acid, HA⁻ is both an acid and a base, and A²⁻ is a base. The total molar concentration of A ($C_{T,A}$) containing species must equal the sum of all species, as shown by Eq. 3-31.

$$C_{T,A} = [\text{H}_2\text{A}] + [\text{HA}^-] + [\text{A}^{2-}] \quad (3-31)$$

Using this equation and writing the equilibrium constant equations, one can obtain expressions for the fraction of each species (α expressions) as a function of pH, $K_{a,1}$, and $K_{a,2}$. Details are found in any of the water chemistry references.

$$\alpha_0 = \frac{[\text{H}_2\text{A}]}{C_{T,A}} = \frac{1}{1 + \frac{K_{a,1}}{[\text{H}^+]} + \frac{K_{a,1}K_{a,2}}{[\text{H}^+]^2}} \quad (3-32)$$

$$\alpha_1 = \frac{[\text{HA}^-]}{C_{T,A}} = \frac{1}{1 + \frac{[\text{H}^+]}{K_{a,1}} + \frac{K_{a,2}}{[\text{H}^+]}} \quad (3-33)$$

$$\alpha_2 = \frac{[\text{A}^{2-}]}{C_{T,A}} = \frac{1}{1 + \frac{[\text{H}^+]}{K_{a,2}} + \frac{[\text{H}^+]^2}{K_{a,1}K_{a,2}}} \quad (3-34)$$

Three triprotic acids are of interest, as indicated in Table 3-4—phosphoric acid (orthophosphate) and oxidized and reduced arsenic. Reduced As (III) occurs in some groundwaters primarily as H_3AsO_3 , because of its high $\text{p}K_a$ (see Table 3-4). Oxidized As (V) is the form of As subject to removal by water treatment processes. Its speciation ($\text{H}_3\text{AsO}_4/\text{H}_2\text{AsO}_4^-/\text{HAsO}_4^{2-}/\text{AsO}_4^{3-}$) depends on pH. The speciation of triprotic acids as a function of pH is shown through their alpha expressions, which can be found in any of the water chemistry references. Oxidation and removal of As from water supplies are covered in Chaps. 7 and 12.

Precipitation and Dissolution of Metal Solids. Precipitation and dissolution of metal solids are governed by chemical principles of metal solubility. Some examples of precipitation reactions are: metals undergoing precipitation in coagulation, water softening to remove Ca and Mg, scaling on membranes or pipe walls, precipitation of ferric iron and oxidized manganese in treatment processes and in distribution systems, and precipitation of Ca in lakes at high pH conditions. Dissolution reactions are important in treatment processes and in affecting the chemistry of water supplies. Dissolution of minerals imparts various cations and anions to waters, affecting the chemical composition of source waters; this is discussed later in the chapter.

Metal solubility is classified as follows: simple metal solubility, metal oxide and hydroxide solubility involving hydrolysis of the metal and thus pH effects on solubility, metal carbonate solubility involving effects of pH and inorganic carbon concentration, and metal solubility with other anions or ligands such as sulfate, sulfide, phosphate, and organic matter. A few principles are presented here, and simple solubility of metals is considered. In Chap. 13 there is additional presentation of principles pertaining to water softening and the solubility of calcium carbonate and magnesium hydroxide.

By convention solubility reactions are written with the solid on the LHS of the equation (see Eq. 3-35), and the solubility constant is written as K_{s0} . The subscript 0 (zero) means the metal (Me) does not form a soluble complex with the anion or ligand (L). Sometimes the solubility constant is written as K_{sp} , indicating a solubility product constant.

$$K_{s0} = [\text{Me}^{b+}]^a [\text{L}^{a-}]^b \quad (3-36)$$

For simple salts, the dissolution and precipitation depend only on the free metal; there is no complexation with OH^- (metal ion hydrolysis) or complexation with other anions. Simple metal solubility is largely restricted to monovalent metals (Na^+ , K^+ , Ag^+) and can apply to some solubility reactions for Ca^{2+} . A good example of simple solubility for Ca^{2+} is the scaling of gypsum on nanofiltration and reverse osmosis membranes.

Solubility reactions are temperature and ionic strength dependent. In most cases, solids are more soluble as temperature increases. However, an important case where the solid is more insoluble with increasing temperature is the solubility of $\text{CaCO}_3(\text{s})$. In many references, solubility constants are given for various temperatures. If not available, one can calculate for the temperature of interest using the van't Hoff equation (Eq. 3-16). For high ionic strength (I) applications, activity coefficients must be used to account for the effect of I or by using equilibrium constants determined for the ionic strength of interest.

Example 3-3 Precipitation (Scaling) of Gypsum

Consider scaling due to buildup of Ca^{2+} and SO_4^{2-} on the reject side of nanofiltration or reverse osmosis membranes. The solid formed is gypsum. Because the ionic strength (I) can be high on the reject side, activity coefficients must be calculated and used. In this example, I is varied to examine its effect on what concentrations produce scaling.

Solution Gypsum is $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}(\text{s})$ and its equilibrium constant for zero I is $10^{-4.58}$. Writing the equilibrium constant expression with activity coefficients, we have

$$K_{s0} = \gamma_{\text{Ca}} [\text{Ca}^{2+}] \gamma_{\text{SO}_4} [\text{SO}_4^{2-}]$$

Solving for the case of the molar concentration of Ca^{2+} equal to SO_4^{2-} , we obtain the following.

$$[\text{Ca}^{2+}] = [\text{SO}_4^{2-}] = \left(\frac{K_{s0}}{(\gamma_{\text{Ca}})(\gamma_{\text{SO}_4})} \right)^{0.5}$$

Ionic strength is varied from 0 to 0.5 M. The Davies equation (Eq. 3-13) is used to calculate activity coefficients. The results are shown in the table.

I (M)	γ_{Ca}	γ_{SO_4}	Ca = SO_4 (M)	Ca (mg/L)	SO_4 (mg/L)
0	1	1	5.1×10^{-3}	204	490
0.001	0.867	0.867	5.9×10^{-3}	236	566
0.01	0.667	0.667	7.77×10^{-3}	311	746
0.1	0.380	0.380	1.35×10^{-2}	540	1296
0.5	0.296	0.296	1.73×10^{-2}	692	1660

The results show that the formation of gypsum occurs at Ca^{2+} and SO_4^{2-} concentrations of 100s of mg/L. Note that the activity coefficients (γ_i) decrease as I increases. This means that the background concentration of salt interferes with the precipitation of gypsum so that the concentrations of Ca^{2+} and SO_4^{2-} at which a solid is formed increase with I . The above calculations were made for equal molar concentrations of Ca^{2+} and SO_4^{2-} , but any concentration conditions in which the reaction quotient (Q) exceeds K_{s0} will cause scaling. ▲

Oxidation-Reduction Chemistry. Redox is an abbreviation referring to oxidation-reduction reactions or chemistry. Redox chemistry can often appear complicated because scientists and engineers working in the water field only deal with it occasionally. There are

several applications of importance to us, as the following examples illustrate. Reducing conditions (low or no dissolved oxygen [DO]) can exist in reservoir water supplies leading to reduced Fe(II) and Mn(II) at concentrations high enough to cause problems. Likewise, Fe(II) and Mn(II) can occur in groundwaters, and under high reducing conditions we can also find reduced S(II) and the odor of hydrogen sulfide. Another important reduced species that occurs in some groundwater supplies is As(III). Later in this chapter the occurrence and concentrations of some of these chemicals are discussed. In water treatment we make use of oxidation (Chap. 7) processes to transform reduced chemicals to oxidized species. In the oxidized form, these chemicals are more amenable to removal. It is also noted that chemical disinfectants (Chap. 17) are oxidants so knowledge of redox chemistry helps us understand disinfection. Pb(II) and Cu(II) in the consumer's tap water arise from corrosion of metal pipes (Chap. 20) that involve redox chemistry.

Many redox reactions are biologically mediated. Some examples follow: (1) algae in reservoirs use photosynthesis to convert dissolved carbon dioxide to algal biomass, (2) respiration of algal biomass within reservoirs or bacterial decomposition of the organic carbon consuming oxygen and producing dissolved carbon dioxide, (3) microbial growth in filters and in water distribution systems, and (4) use of microorganisms in slow sand filters and riverbank filtration systems to biodegrade organic contaminants.

The reader is referred to the water chemistry references at the end of the chapter for comprehensive coverage of redox chemistry. Some definitions and principles are covered here to serve as a foundation for other chapters.

Definitions. Oxidation reactions involve the loss of electrons (e^-) and, conversely, reduction reactions involve the gain of electrons. Since we cannot have free e^- in water, whenever an oxidation reaction occurs there is also a reduction reaction occurring or vice versa. An oxidizing agent, what we usually call an oxidant, is a substance capable of gaining e^- and, conversely, a reducing agent is a substance capable of accepting e^- . In simple terms, redox reactions are e^- transfer reactions in which oxidized substances or oxidants are e^- acceptors, and reduced substances or reducing agents are e^- donors. A useful analogy to redox reactions is acid-base reactions. Recall that acids are proton donors and bases are proton acceptors. We will make further use of this analogy later in this section.

The oxidation state, or number, is a hypothetical number or charge an atom might have when all the electrons are counted according to a set of rules. The assigning of oxidation state by the rules are not so important here; see the water chemistry references on how to determine oxidation states. Roman numerals are used in specifying oxidation states except, of course, when it is zero. For oxidation reactions there is an increase in the oxidation state, while there is a decrease in the oxidation state for substances that are reduced. Some examples of oxidation states follow:

- Reduced Fe and Mn are Fe(II) and Mn(II)
- Oxidized Fe and Mn are Fe(III) and Mn(IV); for permanganate (MnO_4^-) Mn is Mn(VII)
- Dissolved gases in water such as oxygen ($O_2(aq)$) and chlorine ($Cl_2(aq)$); the O and Cl atoms have an oxidation state of zero
- The oxidation state of reduced S in H_2S is S(-II), while in SO_4^{2-} it is S(VI)
- Reduced As and oxidized As are As(III) and As(V)

Nernst Equation. An overall oxidation-reduction reaction (or galvanic cell) is shown by Eq. 3-37. Applying the Nernst equation (see the water chemistry references), which describes the electromotive force (EMF) or electrical potential, we obtain Eqs. 3-38a and 3-38b. These are general forms of the Nernst equation where R , T , n , F , and Q are, the

universal gas constant ($8.314 \text{ J mole}^{-1} \text{ K}^{-1}$), temperature in K, number of e^- transferred, Faraday constant ($96.485 \text{ kJ V}^{-1} \text{ mole}^{-1}$), and reaction quotient, respectively.

$$aA + bB = cC + dD \quad (3-37)$$

$$E = E^\circ - \frac{RT}{nF} \ln \frac{[C]^c [D]^d}{[A]^a [B]^b} \quad (3-38a)$$

$$E = E^\circ - \frac{RT}{nF} \ln Q \quad (3-38b)$$

Inserting values for R and F , converting to base 10 log, and setting the temperature to 298 K (25°C), we obtain the following practical form of the Nernst equation:

$$E = E^\circ - \frac{0.059}{n} \log Q \quad (3-39)$$

At equilibrium E is zero, Q is K , and therefore E° is related to the equilibrium constant. E° is a thermodynamic property that is tabulated for half-cell reactions. By definition, the reference half-cell is the hydrogen half-cell and has a value of 0 V (E_H°). Standard potentials (E°) for half-cell reactions can be combined to obtain overall cell reactions.

The Nernst equation can be applied to half-cell reactions because we can add the standard hydrogen half-cell reaction with a value of E_H° of 0 V to any other half-cell reaction to complete the overall reaction since all reactions must be a combination of both oxidation and reduction. Applying the Nernst equation to half-cell reactions without an effect of H^+ (Eq. 3-40), we obtain Eq. 3-41.

$$E = E^\circ - \frac{0.059}{n} \log \frac{[\text{Red}]}{[\text{Ox}]} \quad (3-41)$$

A pX notation is used in redox reaction chemistry where $pe = -\log\{e^-\}$ and $pe^\circ = (1/n) \log K$ (note the positive sign for defining pe° to $1/n \log K$; see Table 3-1).

The Nernst equation for a half-cell reaction written in terms of p notation follows, where pe equals $E/0.059$ or $16.95 E$ and pe° equals $E^\circ/0.059$ or $16.95 E^\circ$.

$$pe = pe^\circ - \frac{1}{n} \log \frac{[\text{Red}]}{[\text{Ox}]} \quad (3-42)$$

Oxidation-Reduction Potential Measurements. The electric potential (E) or oxidation-reduction potential (ORP) is measured to evaluate the reducing or oxidizing conditions of waters—see *Standard Methods* (APHA, AWWA, and WEF, 2005). It is recognized that there are limitations of measured E values and interpretation of their meaning because E in the Nernst equation relates it to a thermodynamic property (E°) and other conditions that are not strictly valid such as the presence of a single redox pair (waters contain multiple pairs). Nonetheless, E is used as an *indicator* of the extent of reducing or oxidizing conditions and of which species of a redox pair tends to dominate.

Whether a reduced or oxidized species dominates in concentration depends on the measured E with reference to the standard potential (E°). It is analogous to acid-base chemistry in which measured pH is compared to the pK_a of the acid-base pair. When the pH is $< pK_a$,

the acid species is high in concentration relative to the base species. For a redox pair, from the *pe* form of the Nernst equation (Eq. 3-42), when the *pe* is $> pe^0$ (or E is $> E^0$ [Eq. 3-41]), there is low electron activity (low $\{e^-\}$) or oxidizing conditions and the oxidized species dominates. Conversely, for high $\{e^-\}$ or reducing conditions, $pe < pe^0$ and the reduced species are at a high concentration for the redox pair. Consider, for example, the Fe^{2+}/Fe^{3+} pair, the pe^0 is 13.03 ($E^0 = 0.769$ V). For $pe < pe^0$, we would expect reducing conditions and Fe^{2+} to be at a greater concentration than Fe^{3+} .

Figure 3-1 shows stability limits for water. The figure provides guidelines of redox and pH conditions for waters saturated with oxygen, conditions for transition zones with oxygen at low to anoxic conditions, and conditions for water-logged soils and sediments.

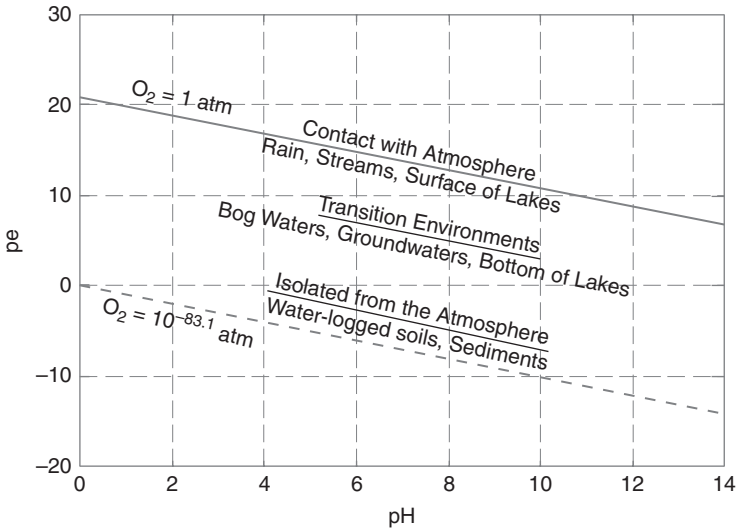

FIGURE 3-1 Redox stability limits for water with respect to *pe* and pH at 25°C (E [ORP] in volts = $pe/16.95$).

Inorganic Carbon Chemistry

The total molar inorganic carbon concentration in water is defined by Eq. 3-43.

$$C_{T,C} = [H_2CO_3^*] + [HCO_3^-] + [CO_3^{2-}] \quad (3-43)$$

Recall (see previous section on the solubility of carbon dioxide) that $H_2CO_3^*$ is the sum of $CO_2(aq)$ and H_2CO_3 , but it is mostly $CO_2(aq)$. Because $CO_2(aq)$ (i.e., $H_2CO_3^*$) is an acid, inorganic carbon is important in many processes in surface waters and groundwaters in which it can affect pH. Several of these processes are summarized in Table 3-5 and include various weathering reactions, algal reactions, and biological degradation reactions. All of these reactions affect the inorganic carbon concentration, pH, and chemical composition of water.

TABLE 3-5 Processes in Surface and Groundwaters Affecting Inorganic Carbon and pH

Process	Inorganic carbon	pH
Weathering of Al-Silicate Minerals	Increases HCO_3^-	Increases
Weathering of Carbonate Minerals	Increases HCO_3^-	Increases
Precipitation of $\text{CaCO}_3(\text{s})$ (In hard water lakes with algal growth)	Decreases CO_3^{2-}	Decreases
Photosynthesis (algal growth)	Decreases $\text{CO}_{2(\text{aq})}$	Increases
Respiration of Algae	Increases $\text{CO}_{2(\text{aq})}$	Decreases
Bacterial Degradation of Organic Matter	Increases $\text{CO}_{2(\text{aq})}$	Decreases
Anaerobic Degradation of Organic Matter	Increases $\text{CO}_{2(\text{aq})}$	Decreases

Table 3-6 summarizes inorganic carbon concentrations for various types of waters. Of course, the system with the lowest concentration is pristine rainwater, which would give an estimate for harvested rainwater systems ignoring interaction with any materials in the collection system (roofs, concrete, etc.). An approximate average concentration for surface waters is 10^{-3} M (12 mg/L). Hard waters contain higher concentrations and soft waters lower concentrations. Groundwaters can contain lower and higher concentrations depending on the minerals in the aquifer and bacterial decay of organic matter in the soils and aquifer.

TABLE 3-6 Dissolved Inorganic Carbon Concentrations* in Various Water Types

Water type	C_T M	C_T mg/L as C
Pristine rainwater	1.52×10^{-5}	0.18
Rivers		
Range	$10^{-4} - 5 \times 10^{-3}$	1.2–60
Average	$\sim 10^{-3}$	12
Groundwaters		
Range	$5 \times 10^{-4} - 8 \times 10^{-3}$	6–96
Seawater	2.3×10^{-3}	28

*Pristine rainwater calculated based on open system in equilibrium with atmospheric $\text{CO}_2(\text{g})$ at 380 ppm; other values from Stumm and Morgan (1996).

Inorganic carbon chemistry is important in many water treatment processes including coagulation, water softening, corrosion, oxidation processes, and any processes involving acid-base reactions. Alkalinity is due mainly to inorganic carbon and is discussed in detail later.

Acid-Base Chemistry of Inorganic Carbon. The stoichiometric equations (Eqs. 3-44 and 3-46), equilibrium constant expressions (Eqs. 3-45 and 3-47), and alpha equations (Eqs. 3-48 through 3-50) are given here. General development of alpha equations for diprotic acids was presented earlier. Adjusted values for the equilibrium constants for waters at 10^{-3} M ionic strength (a common condition for water supplies) for K_1 and K_2 are $10^{-6.30}$ and $10^{-10.25}$ at 25°C, respectively, and are given in Eqs. 3-45 and 3-47. A summary of

TABLE 3-7 Inorganic Carbon and Water Equilibrium Constants (K) at 25°C for Zero Ionic Strength (Values from Stumm and Morgan (1996))

Reaction	5°C	10°C	15°C	20°C	25°C	40°C
$\text{CO}_2(\text{g}) + \text{H}_2\text{O} = \text{H}_2\text{CO}_3^*$	1.20	1.27	1.34	1.41	1.47	1.64
$\text{H}_2\text{CO}_3^* = \text{HCO}_3^- + \text{H}^+$	6.52	6.46	6.42	6.38	6.35*	6.35
$\text{HCO}_3^- = \text{CO}_3^{2-} + \text{H}^+$	10.56	10.49	10.43	10.38	10.33†	10.22
$\text{H}_2\text{O} = \text{H}^+ + \text{OH}^-$	14.73	14.53	14.34	14.16	14.0	13.53

* K_1 for 10^{-3} M ionic strength is $10^{-6.3}$

† K_2 for 10^{-3} M ionic strength is $10^{-10.25}$

equilibrium constants for inorganic carbon and water dissociation is given in Table 3-7 as a function of water temperature and ionic strength approaching zero.

$$K_1 = 10^{-6.30} = \frac{[\text{HCO}_3^-][\text{H}^+]}{[\text{H}_2\text{CO}_3^*]} \quad (3-45)$$

$$K_2 = 10^{-10.25} = \frac{[\text{CO}_3^{2-}][\text{H}^+]}{[\text{HCO}_3^-]} \quad (3-47)$$

$$\alpha_0 = \frac{[\text{H}_2\text{CO}_3^*]}{C_{T,C}} = \frac{1}{1 + \frac{K_1}{[\text{H}^+]} + \frac{K_1 K_2}{[\text{H}^+]^2}} \quad (3-48)$$

$$\alpha_1 = \frac{[\text{HCO}_3^-]}{C_{T,C}} = \frac{1}{1 + \frac{[\text{H}^+]}{K_1} + \frac{K_2}{[\text{H}^+]}} \quad (3-49)$$

$$\alpha_2 = \frac{[\text{CO}_3^{2-}]}{C_{T,C}} = \frac{1}{1 + \frac{[\text{H}^+]}{K_2} + \frac{[\text{H}^+]^2}{K_1 K_2}} \quad (3-50)$$

Alpha (α) expressions are useful in calculations of inorganic carbon concentrations. Table 3-8 provides a summary of alpha values between pH 2 and 12.

Open System. An open system means there is a gas phase as well as the aqueous phase and any solid phases. Consider the case of an open system for inorganic carbon without any solid carbonate phase. Figure 3-2a shows the distribution of the inorganic species and $C_{T,C}$ as a function of pH. The following are important points that will be useful in understanding the composition of water and water treatment processes. First, for water in equilibrium with air at 101.3 kPa (1 atm) it means that H_2CO_3^* is in equilibrium with $\text{CO}_2(\text{g})$ at 380 ppm. The dissolved equilibrium concentration of H_2CO_3^* from Henry's law (Eq. 3-25) is 1.29×10^{-5} M. It is fixed by Henry's law and is independent of pH as shown in Fig. 3-2a. Second, as we increase pH $C_{T,C}$ increases because H_2CO_3^* dissociates forming HCO_3^- and

TABLE 3-8 Inorganic Acid-Base Alphas for K 's at 25°C and Adjusted for 10^{-3} M Ionic Strength ($pK_1 = 6.30$ and $pK_2 = 10.25$)

pH	H^+ M	α_0	α_1	α_2
2	1.0×10^{-2}	0.9999	5.01×10^{-5}	2.82×10^{-13}
3	1.0×10^{-3}	0.9995	5.01×10^{-4}	2.82×10^{-11}
4	1.0×10^{-4}	0.9950	4.99×10^{-3}	2.81×10^{-9}
4.5	3.16×10^{-5}	0.984	0.0156	2.78×10^{-8}
5	1.0×10^{-5}	0.952	0.0477	2.69×10^{-7}
5.5	3.16×10^{-6}	0.863	0.137	2.43×10^{-6}
6	1.0×10^{-6}	0.666	0.334	1.88×10^{-5}
6.3	5.01×10^{-7}	0.500	0.500	5.61×10^{-5}
7	1.0×10^{-7}	0.166	0.833	4.68×10^{-4}
7.5	3.16×10^{-8}	0.059	0.939	1.67×10^{-3}
8	1.0×10^{-8}	0.019	0.975	5.48×10^{-3}
8.3	5.01×10^{-9}	0.010	0.979	0.011
9	1.0×10^{-9}	1.88×10^{-3}	0.945	0.053
9.5	3.16×10^{-10}	5.30×10^{-4}	0.849	0.151
10	1.0×10^{-10}	1.30×10^{-4}	0.640	0.360
10.25	5.62×10^{-11}	5.50×10^{-5}	0.500	0.500
11	1.0×10^{-11}	3.0×10^{-6}	0.151	0.849
12	1.0×10^{-12}	3.4×10^{-8}	0.0175	0.983

CO_3^{2-} (see Eqs. 3-44 and 3-46), and through Henry's law, $H_2CO_3^*$ is replaced from the gas phase (air) to keep it constant. Third, HCO_3^- is the dominant form of inorganic carbon for pH conditions slightly greater than 6 to about 10; above pH 10, CO_3^{2-} dominates.

We usually do not have equilibrium with the atmosphere because of various biological and chemical reactions in water supplies that add or remove inorganic carbon. However, open systems such as streams and the surface waters of lakes are seeking equilibrium. Certain water supply systems such as stored water in open distribution reservoirs may be at equilibrium with the atmosphere and the effluent water from gas transfer processes (addition of or stripping of gases using air) is at or near equilibrium.

Closed System. For many applications, inorganic carbon chemistry occurs for closed system (cut off from the atmosphere or, more generally, no gas phase ($CO_2(g)$)). Closed system conditions occur for groundwaters, water in the bottom stratified layer in lakes and reservoirs, water in pressurized transmission mains and distribution pipes, and in many water treatment processes. In some water treatment processes, we assume a closed system even though the water is open to the atmosphere, and thereby assume the gas transfer kinetics are slow for the timescale of our problem; thus we can ignore the gas phase.

C_{TC} is constant for a closed system because there is no gas exchange. Consider C_{TC} at a concentration of $10^{-3}M$ (a common value for many water supplies, see Table 3-6). Figure 3-2b shows the distribution of the inorganic carbon species as a function of pH. The following important points are made. First, $H_2CO_3^*$ is the dominant form of inorganic carbon and approaches 100 percent for $pH < 5$ (Fig. 3-2b), Second, HCO_3^- dominates between pH 6.3 and pH 10.3. Third, CO_3^{2-} is not an important fraction of inorganic carbon unless the pH is > 10 . This figure is invaluable for many applications, as listed above, and for understanding alkalinity, which is covered next.

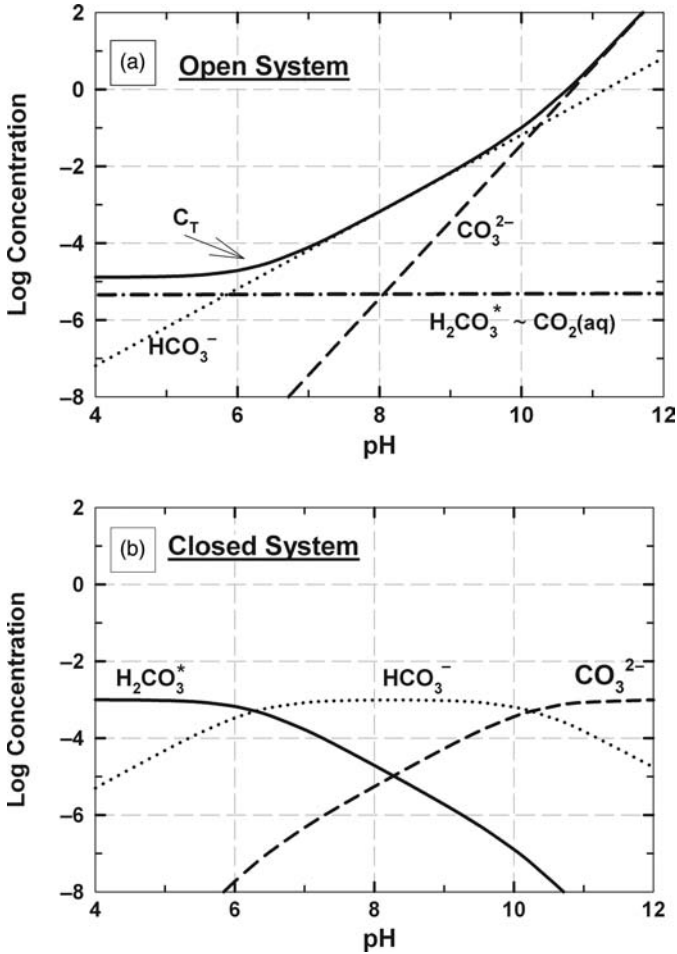

FIGURE 3-2 (a) Open system for inorganic carbon as a function of pH (no carbonate solid phase). (b) Closed system for inorganic carbon at $10^{-3}M$ (conditions: $25^\circ C$ and $10^{-3} M$ ionic strength).

Alkalinity

Definition, Causes, and Laboratory Measurement. Alkalinity (Alk) is the acid neutralizing capacity (ANC) of a water. The causes of Alk are the presence of conjugate bases in water that can consume acid (H^+) when added to the water. In general, the conjugate bases that can potentially contribute to alkalinity are those from inorganic carbon (HCO_3^- and CO_3^{2-}), orthophosphate ($H_2PO_4^-$, HPO_4^{2-} , and PO_4^{3-}), borate (e.g., in seawater ($B(OH)_4^-$)), and others such as NH_3 , silicates, sulfides, and conjugate bases of organic acids. Alk can also be due to OH^- when it is in excess relative to H^+ . For most water supplies and water treatment applications, the dominant conjugate bases present are those from inorganic carbon, meaning that the others are relatively low and insignificant. Here and subsequently we describe Alk with respect to inorganic carbon and the net difference between OH^- and H^+ .

Alk of water is measured in the laboratory by titrating a water sample with a strong acid to a defined theoretical or operational end point under closed system conditions, i.e., no exchange of the carbon dioxide with the atmosphere. Theoretically, the end point depends on the inorganic carbon concentration ($C_{T,C}$). The greater $C_{T,C}$ is, the lower the pH end point. However, for most water supply and treatment applications, the theoretical end point is near pH 4.5 so this is often set as an operational end point (APHA, AWWA, and WEF, 2005) and is determined by actually measuring the pH during the titration or using a color indicator. The concentration of strong acid required to reach this end point is measured and reported in meq/L. This is the total alkalinity of the sample. Sometimes, different components of Alk are measured such as caustic Alk (due to OH^-) and carbonate Alk (due to CO_3^{2-}), as well as the total Alk (see APHA, AWWA, and WEF, 2005; and water chemistry references). For most water supply and water treatment applications, it is the total Alk that is of interest and that is our focus.

Some people confuse the meaning of Alk, thinking of it as a measure of the resistance to a decrease in pH with strong acid addition for some particular pH condition. This is not the case. The resistance to a pH change at a particular pH is the buffer intensity. Alk is a *capacity* measurement—it is the total concentration of strong acid required to reduce the pH to an end point of say 4.5.

Measurements are made in meq/L of acid required to reach the end point; however, in the water field Alk is reported in terms of an equivalent concentration of CaCO_3 . The conversion is 1 meq/L equals 50 mg/L as CaCO_3 .

Basic Equations for Inorganic Carbon and Alkalinity. We can relate the Alk to the concentrations of HCO_3^- and CO_3^{2-} in water and to the net deficiency of protons with regard to OH^- and H^+ (stated another way, the net excess of OH^- relative to H^+). Equation 3-51 is the theoretical description of Alk due to the conjugate bases of inorganic carbon. The millimolar (mM) concentration of HCO_3^- is multiplied by 1 meq/mM because it can neutralize 1 meq of strong acid. Likewise, the mM concentration of CO_3^{2-} is multiplied by 2 meq/mM because it can neutralize 2 meq of strong acid. Thus, the Alk is in units of meq/L and can be converted to mg/L as CaCO_3 by multiplying by 50.

$$\text{Alk} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-] - [\text{H}^+] \quad (3-51)$$

Equation 3-51 is rewritten by replacing HCO_3^- with α_1 times $C_{T,C}$ and CO_3^{2-} with α_2 times $C_{T,C}$.

$$\text{Alk} = (\alpha_1 + 2\alpha_2)C_{T,C} + [\text{OH}^-] - [\text{H}^+] \quad (3-52)$$

We can learn some interesting and practical things from Eq. 3-52. First, the Alk of water depends simply on the actual pH and $C_{T,C}$ of the water sample when collected. Waters with higher pH (alphas are pH dependent) and higher $C_{T,C}$ have higher Alk. Second, we can rearrange the equation and make $C_{T,C}$ the dependent variable, meaning that its concentration can be calculated from pH and Alk measurements. Finally, using Eq. 3-52 and Fig. 3-2b, we can make the following observations. For waters with $\text{pH} < 9$, CO_3^{2-} and OH^- are low relative to HCO_3^- , so these waters do not contain caustic and carbonate Alk. For waters with pH between about 6 and 9, we can ignore CO_3^{2-} , OH^- , and H^+ , yielding the following approximation for Alk.

$$\text{Alk} = [\text{HCO}_3^-] = \alpha_1 C_{T,C} \quad (3-53)$$

As stated above, the total inorganic carbon concentration ($C_{T,C}$) and pH of a water sample sets the Alk. $C_{T,C}$ in these equations applies to whatever the inorganic concentrations

are and may not necessarily be in equilibrium with atmospheric $\text{CO}_2(\text{g})$, i.e., H_2CO_3^* is not in equilibrium with the atmosphere. In other words, Alk is set by pH and C_{TC} whether the latter is in equilibrium with the atmosphere or not. Often, it is not! Consider closed systems such as groundwaters, the bottom of lakes, and water distribution pipes. Even surface waters and waters within treatment plants, C_{TC} may be seeking equilibrium, but it is often out of equilibrium with the gas phase.

Classifications. There is no standard classification system for waters with respect to Alk concentrations. In establishing enhanced coagulation requirements for total organic carbon (TOC) removal as a function of alkalinity (see Chap. 8), the U.S. Environmental Protection Agency (USEPA) classifies waters into three Alk groups: low Alk waters, $< 60 \text{ mg/L CaCO}_3$; intermediate or moderate Alk waters, $60 \text{ to } 120 \text{ mg/L CaCO}_3$; and high Alk waters, $> 120 \text{ mg/L CaCO}_3$. Other classifications exist depending on the problem or application. For example, in assessing the sensitivity of water bodies to acidification, five Alk groups of decreasing sensitivity are used: $< 2.5 \text{ mg/L CaCO}_3$, $2.5 \text{ to } 5 \text{ mg/L CaCO}_3$, $5 \text{ to } 10 \text{ mg/L CaCO}_3$, $10 \text{ to } 20 \text{ mg/L CaCO}_3$, and $> 20 \text{ mg/L CaCO}_3$.

Example 3-4 Alkalinity of Pristine Rainwater and for a Water Supply

Calculate the Alk of pristine rainwater in equilibrium with atmospheric $\text{CO}_2(\text{g})$, and calculate the Alk for a water supply with a pH of 7.5 and C_{TC} of 10^{-3} M assuming 25°C .

Solution Pristine rainwater has a C_{TC} concentration of $1.52 \times 10^{-5} \text{ M}$ (Table 3-6). Its pH is 5.60 and $[\text{HCO}_3^-]$ is $2.29 \times 10^{-6} \text{ M}$. Applying Eq. 3-51 and recognizing that OH^- and CO_3^{2-} are small and can be ignored, we have

$$\text{Alk} = [\text{HCO}_3^-] - [\text{H}^+] = 2.29 \times 10^{-6} - 10^{-5.6} = 2.29 \times 10^{-6} - 2.51 \times 10^{-6} \cong 0 \text{ meq/L}$$

Thus, pristine rainwater has no Alk and is susceptible to strong acid inputs decreasing its pH. Because pristine rainwater has no Alk or acid neutralizing capacity, strong acids such as sulfuric and nitric acids, if present in the atmosphere, affect rainwater pH causing acid rain with pH values less than 5.

The water supply has a pH of 7.5 and C_{TC} of 10^{-3} M . Using the alpha tables (see Table 3-8), we have α_1 of 0.939 and α_2 of 1.67×10^{-3} . We see that α_2 is low (CO_3^{2-} is low) and can use Eq. 3-53.

$$\begin{aligned} \text{Alk} &= [\text{HCO}_3^-] = \alpha_1 C_{TC} = 0.939 \times 10^{-3} \text{ eq/L} \\ &= 50 \times (0.939) \text{ mg/L} = 47 \text{ mg/L as CaCO}_3 \quad \blacktriangle \end{aligned}$$

Acidity

A converse concept to Alk is the acidity (Acy) of water. Acy is the base neutralizing capacity of water, and it is due to the presence of conjugate acids of weak bases and the net excess of protons (i.e., $[\text{H}^+] - [\text{OH}^-]$). As done for Alk, we consider only the inorganic carbon excess conjugate acids resulting in Eqs. 3-54 and 3-55 as the basic equations describing Acy.

$$\text{Acy} = 2[\text{H}_2\text{CO}_3^*] + [\text{HCO}_3^-] + [\text{H}^+] - [\text{OH}^-] \tag{3-54}$$

$$\text{Acy} = (2\alpha_0 + \alpha_1)C_{TC} + [\text{H}^+] - [\text{OH}^-] \tag{3-55}$$

The total A_{cy} when measured in the laboratory is the total concentration of strong base added to a pH end point of about 10.6. The concentration of base added in the titration is measured as meq/L; it is multiplied by 50 and reported in mg/L as $CaCO_3$. It can be shown that by adding Eqs. 3-51 and 3-54, we can obtain Eq. 3-56. This equation shows that if we measure or know the Alk and A_{cy} of water, we can calculate the total inorganic carbon concentration ($C_{T,C}$). Likewise, if we measure and know the Alk and $C_{T,C}$, we can calculate the A_{cy} of a water.

$$Alk + A_{cy} = 2(C_{T,C}) \quad (3-56)$$

Following up on pristine rainwater, which has a $C_{T,C}$ of 1.52×10^{-5} M (Table 3-6) and no Alk (Example 3-4), from Eq. 3-56 its A_{cy} is about 3×10^{-5} eq/L or 1.5 mg/L as $CaCO_3$.

SOURCE WATER COMPOSITION

Introduction

The primary objectives of this section are to (1) describe the dissolved chemical composition of rainwaters, rivers and streams, lakes and reservoirs, and groundwaters; (2) present principles with reference to the roles of hydrogeochemical and biochemical cycles that affect the composition of water and water quality; (3) summarize the presence of anthropogenic chemicals in water supplies; and (4) highlight important dissolved chemicals that affect water quality and treatment. The chemical compositions for specific cases are presented as well as typical concentrations and ranges. Before getting into this material, some terminology is defined and the hydrogeochemical and biochemical cycles are introduced.

Terminology

Naturally Occurring and Anthropogenic Chemicals. Naturally occurring chemicals in water bodies consist of inorganic and organic chemicals derived from hydrogeochemical and biochemical cycles. Major and minor constituents are presented below for rainwaters, rivers, lakes, and groundwaters. Anthropogenic chemicals enter waters from human activities. These chemicals may be inorganic in nature such as acids and metals or they may be organic. Both naturally occurring and anthropogenic organic chemicals are grouped as summarized in Table 3-9. This table is referred to in the material below.

Chemical Phases, Total and Dissolved Concentrations. Chemists classify chemicals according to gas, dissolved, and solid phases. Dissolved chemicals may be ions (cations and anions) or neutral molecules. The sizes of dissolved chemicals are small, about 10 Å or less for simple and low molecular weight substances. Molecular weights and apparent sizes are greater for many organic compounds, especially macromolecules (e.g., fulvic and humic acids with apparent molecular weights of 100s–1000s and apparent sizes of 10–100 Å).

Practically, we must also consider operational definitions of dissolved versus particulate matter used in measuring chemicals. In the water field, particulate matter is separated from a water sample by membrane filtration either in the field or in the laboratory. Often a nominal pore size, such as 0.45 μm , is prescribed for the membrane filter. This means

TABLE 3-9 Organic Compounds in Natural Waters (Sources for Information: Domenico and Schwartz (1990); Koplin et al. (2002))

Name	Naturally occurring	Anthropogenic
Misc., non-volatile	Humic substances, chlorophyll, enzymes, xanthophylls	Tannic acids, dyes
Halogenated		Solvents, pesticides (aldrin, DDT, dieldrin), industrial chemicals (vinyl chloride, methyl chloride, PCBs)
Hydrocarbons		
Amino acids	Glycine, alanine, aspartic acid	
Phosphorus compounds		Pesticides (diazinon, malathion, parathion)
Organometallic compounds	Metal complexes with humic substances (Fe, Al)	Tetraethyl lead, diethyl mercury, copper phthalocyanine
Carboxylic acids	Acetic acid, benzoic acid, butyric acid, formic acid	Acetic acid, benzoic acid, butyric acid, formic acid, phenoxy acetic pesticides (dinitroresol, 2,4-dinitrophenol)
Phenols	Phenol, cresol, p-hydroxybenzoic acids	Phenol, cresol, pyrocatechol, naphthol, pesticides (dinitroresol, 2,4-dinitrophenol)
EDCs*		
50–80%		Coprostanol (estrogen); cholesterol (steroid); N-N-diethyltoluamide (mosquito repellent); caffeine (stimulant); tris (2-chloroethyl) phosphate (fire retardant); triclosan (antibiotic); 4-nonylphenol & 4-nonylphenol monoethoxylate (surfactants)
30–45%		Ethanol, 2-butoxy-phosphate & Bisphenol A (plasticizers); 4-octylphenol monoethoxylate & 4-nonylphenol diethoxylate (surfactants); cotinine (nicotine metabolite); 5-methyl-1H-benzotriazole (antioxidant); fluoranthene (PAH); 1,7-dimethylxanthine (caffeine metabolite); Pyrene (PAH); trimethoprim, erythromycin-H ₂ O, lincomycin, sulfamethoxazole (antibiotics); 1,4 dichlorobenzene (deodorizer); acetaminophen (analgesic); tetrachloroethylene (solvent); 4-octylphenol diethoxylate (surfactant); estrriol (estrogen); phthalic anhydride (plasticizer); carbaryl (insecticide)
15–25%		
Amines		Diethylamine, dimethylamine, benzidine, pyridine
Ketones		Acetone, 2,-butane, methyl propenyl
Aldehydes		Formaldehyde
Esters		Dimethrin, omite, vinyl acetate
Ethers	Diethyl ether, diphenyl ether	Tetrahydrofuran, 1,4-dioxane
PAHs		Anthracene, benzol[a]pyrene
Aromatic hydrocarbons		Benzene, ethylbenzene, toluene
Alkanes, alkenes, and alkynes	Methane, propane, propene, 2-hexene, 2-hexyne	Methane, propane, propene, 2-hexene, 2-hexyne

*Endocrine Disrupting Compounds; frequency of detection in U.S. streams

by operational definition we are defining the chemicals that we measure after passing through the membrane filter as dissolved matter, when in fact some colloidal particulate matter may pass through the filter and be measured. In some chemical analysis to eliminate colloidal matter, ultrafilters are used. With this background, we classify measurements as follows:

- Total = dissolved + particulate

The dissolved concentration is sometimes referred to as total dissolved without distinguishing the forms or species that compose the chemical. In this section, the dissolved concentration is understood to mean total dissolved, unless otherwise noted. Some examples of total dissolved and speciation follow:

- Total inorganic P or orthophosphate = $\text{H}_3\text{PO}_4 + \text{H}_2\text{PO}_4^- + \text{HPO}_4^{2-} + \text{PO}_4^{3-}$
- Total inorganic N = $\text{NO}_2^- + \text{NO}_3^- + \text{NH}_4^+ + \text{NH}_3$
- Total Al = free Al (Al^{3+}) + inorganic complexes (e.g., $\text{Al}(\text{OH})^{2+}$, $\text{Al}(\text{OH})_2^+$) + organic complexes (Al-humates)

Hydrogeochemical and Biochemical Cycles

All waters contain naturally occurring chemicals that enter water through the hydrogeochemical cycle (Fig. 3-3). This cycle includes effects of the hydrologic cycle and geochemical reactions that include acid-base, mineral dissolution and solubility, and redox reactions. Figure 3-3 is used in the material below when discussing the major constituents in waters,

FIGURE 3-3 Hydrogeochemical cycle.

recognizing that local soil and mineral geology play major roles affecting individual source water composition.

Biochemical cycles in water also affect water quality and the biological and chemical composition of water. Figure 3-4a depicts the effects of photosynthesis, algal biomass mineralization, and decomposition effects on major nutrients (C, N, and P) in water. Figure 3-4b depicts the N cycle. The cycling of nutrients involves redox reactions that affect inorganic carbon, organic carbon, P, N, and $O_2(aq)$. Reducing conditions affect the chemistry of Fe, Mn, and S in waters, especially in lakes and groundwaters. The significance of these cycles are incorporated later in the discussion of the water quality of surface waters and groundwaters.

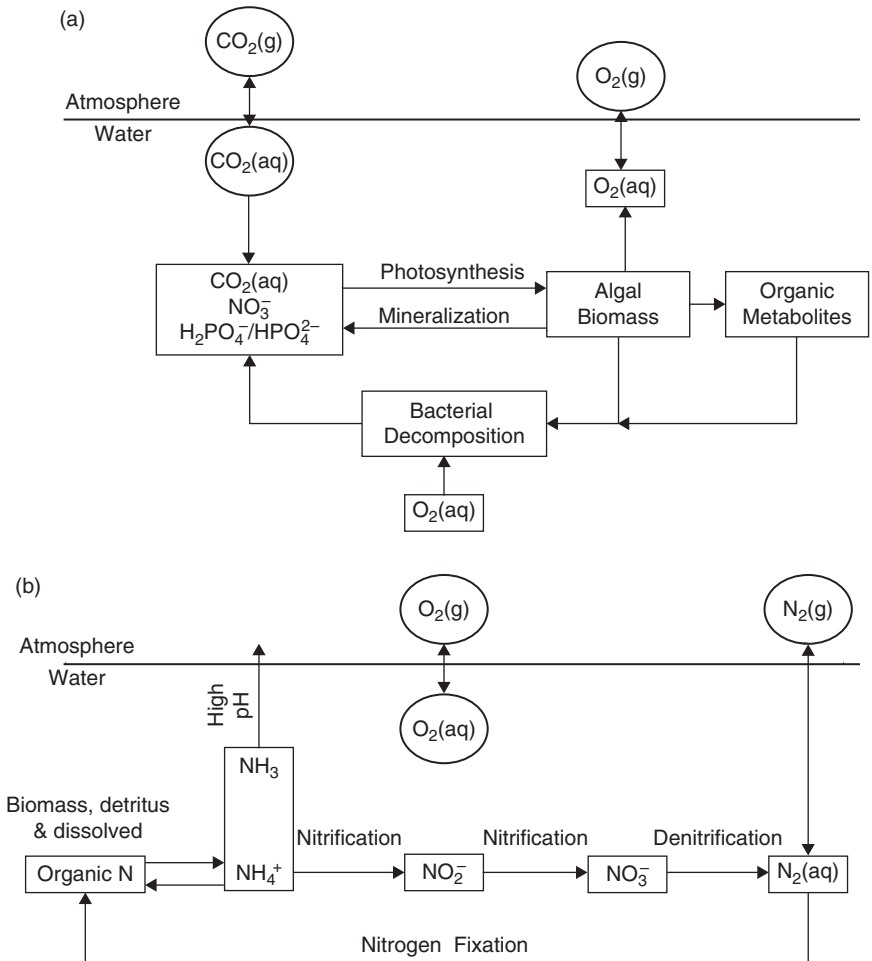

FIGURE 3-4 (a) Photosynthesis and decomposition effects on primary nutrients. (b) Nitrogen cycle in water.

Rainwaters

We begin with rainwater chemistry. This provides reference conditions for the chemistry of water not impacted by geochemical cycles and biochemical cycles in a watershed and water body. The impacts of naturally occurring and anthropogenic chemicals on rainwater are, however, presented.

The hydrologic cycle provides an important means of purification via evaporation (distillation process). Pristine rainwater chemistry is affected only by $\text{CO}_2(\text{g})$ in the atmosphere, which in turn affects the rainwater pH and inorganic carbon concentration (Table 3-10). Pristine rainwater has a pH of 5.6. This acid content comes from $\text{CO}_2(\text{aq})$ (i.e., H_2CO_3^*), and it is a major factor in affecting natural geochemical weathering in watersheds.

Note that pristine rainwater has no alkalinity (acid neutralizing capacity) and a small amount of acidity (Acy) or base neutralizing capacity (3.06×10^{-2} meq/L or 1.5 mg/L as CaCO_3). Consequently, rainwater is affected by airborne contaminants, natural or anthropogenic origin. Naturally occurring contaminants can be sea-salt aerosols (mostly NaCl), dust from urban and farm areas, and particulate matter and gases from volcanic eruption. These contaminants can dissolve into the rainwater. Anthropogenic chemicals can include volatile organic chemicals (VOCs) and acids from fossil fuel combustion, particularly sulfuric and nitric acids. It is important to note that cations in rainwater may be simple salts derived from sea salts or from mineral particles in dust, such as Na^+ , K^+ , Ca^{2+} , and Mg^{2+} , or they may be base cations, such as Ca^{2+} from carbonate mineral particles in dust or lime dust. Anions in rainwater may be from sea salts (Cl^- , SO_4^{2-}) or dust (SO_4^{2-}), and these do not affect rainwater pH. On the other hand, acid rain is largely due from conversion of sulfur oxides and nitrous oxides in the atmosphere to sulfuric and nitric acids. Therefore, large fractions of the acid anions SO_4^{2-} and NO_3^- are present in acid rain.

TABLE 3-10 Composition of Rainwaters Concentrations (mg/L Except pH and Alk)

Parameter	Pristine rain or demineralized water*	Rainwater Coastal Washington†	Acid rain Penn State, PA‡

†from Eby (2004).

‡NR: not reported.

§Calculated from cation and anion concentrations.

Table 3-10 shows the composition of rainwater from Coastal Washington, which is slightly more acid at a pH of 5.1 than pristine rainwater. Its pH is not affected much by fossil fuel combustion since the acid anions are low compared to the acid rainwater (Penn State location) with a pH of 4.15 and relatively high concentrations of the acid anions. The Coastal Washington rainwater chemistry is greatly affected by sea-salt aerosols, as evidenced by the relatively high Na^+ and Cl^- concentrations.

Use of rainwater harvesting is increasing in developing and developed countries (UNEP-IETC, 2002; Han, 2004). It is being considered and used as a potable and non-potable water supply in developing countries. In developed counties, the interest is in non-potable uses (e.g., toilet flushing, watering lawns and gardens, irrigation) and as part of a green engineering strategy of sustainable water use. The chemical quality of the collected water depends on the rainwater chemistry, which varies with location and time. Table 3-10 provides guidance on the concentrations of major inorganic cations and anions that may be present in pristine rainwater, rainwater from a coastal location, and acid rainwater. Generally, rainwater is low in ionic strength, about 10^{-4} M or less (low in conductivity), and even pristine rainwater is acidic. Because rainwater does not contain alkalinity, it is susceptible to reductions in pH with the addition of acids. Furthermore, rainwater has little acidity (base neutralizing capacity), so any addition of bases will increase its pH. Therefore, in rainwater harvesting, the materials used for storage containers and reservoirs may affect the water's chemistry; for example, concrete materials are likely to leach some lime, increasing the pH. Collected rainwater may contain microorganisms that enter the water from wind or from contact with the collection system; consequently, the microbiological quality, particularly with respect to the presence of pathogens, is of paramount interest for any potable use.

Rivers and Streams

The major dissolved inorganic chemicals and nutrients found in surface waters (rivers and streams) are identified and typical concentrations are presented. Ranges in expected concentrations are summarized that reflect their naturally occurring concentrations and effects from human activities. Data are also summarized for alkalinity, hardness, ionic strength, and DOC.

The hydrogeochemical cycle (Fig. 3-3) causes various cations, anions, and silica to be present in surface waters through weathering reactions of rocks (minerals), soils, and sediments. The chemical reactions that take place involve acid-base (dissolved $\text{CO}_2(\text{aq})$, i.e., H_2CO_3^* is an acid), solubility, and redox reactions. Here we consider rivers and streams containing oxygen, which is the case for most water supplies. It is realized that deep rivers and run-of-the-river reservoirs may have sufficient depth and organic matter to produce reducing conditions at or near the bottom—these systems are considered under lakes and reservoirs. Figure 3-5 shows oxidized-reduced pairs along a vertical line. The y-axis gives standard potentials adjusted to pH 7—called pe° (W). Recall that $\text{pe} = 16.95 E$. ORPs (i.e., E) are used as indicators of the oxidizing-reducing conditions of water. Because the presence of many oxidized-reduced pairs and interferences makes precise use of ORPs infeasible, the ORP is used as an indicator.

If we measured pe equal to say about 13.7, which is approximately the pe° (W), then we have high oxidizing conditions in which H_2O can be oxidized to O_2 . Moving downward along the vertical line, reducing conditions increase. The vertical line shows conditions in which we have both the oxidized and reduced pairs, i.e., when the measured pe equals the pe° (W). Note that oxidized species exist to the left of the vertical line and would dominate for $\text{pe} > \text{pe}^\circ$ (W). Considering oxic surface waters, the pe values would be high but less than 13.7, so we would not have oxidation of H_2O . We would expect to have all the oxidized species to the left of the vertical line. Fe exists as ferric iron (Fe(III)) but would be low in

FIGURE 3-5 Sequence of microbially mediated redox processes in natural waters (pe° (W) is pe° adjusted to pH 7).

concentration because of low solubility. Mn exists as oxidized Mn (Mn(IV)), and would also be at low concentration because it has low solubility. S exists in the oxidized form as SO_4^{2-} , and N mainly as NO_3^- .

Upland Rivers and Streams. The chemical composition of upland water supplies is due mainly to the hydrogeochemical cycle and is not greatly affected by human activities (anthropogenic sources of chemicals). Therefore, chemicals are largely naturally occurring. Two examples of weathering reactions from Table 3-11 are used to illustrate related principles. The first example deals with the weathering of granitic rocks, which are representative of mountainous watersheds. A sodium feldspar (Na-Plagioclase), a component of granitic rocks, is used in the example along with its incongruent dissolution by dissolved carbon dioxide ($H_2CO_3^*$), a weak acid in rainwater.

(3-57)

The above equation is an acid-base reaction in which $H_2CO_3^*$ is the acid and the feldspar is the base. It is an incongruent dissolution of the rock to a kaolinite (clay mineral) solid phase. From the acid-base reaction, we see that Na^+ , HCO_3^- , and Si are imparted to the water. The dissolution is not extensive so we would expect to find fairly low Na^+ and HCO_3^- (i.e., alkalinity) for these waters. A good example of this geochemical weathering and water composition is the Quabbin Reservoir (Chicopee River Basin and a Boston, MA, water supply), which has in part a granitic bedrock geology (see Table 3-12). In general, watersheds with this type of geology have low concentrations of Na^+ and alkalinity or buffering. Furthermore, the solubility of dissolved Si is present as H_4SiO_4 and is independent of pH below 9. Its concentration depends on water temperature and whether it is controlled by amorphous or quartz ($SiO_2(s)$). Consequently, it is found at concentrations between 2 and 30 mg/L in most water sources, as indicated in the last column of Table 3-12.

TABLE 3-11 Weathering Reactions for Common Primary Minerals

Mineral	Composition	Commonly occur in rock type	Reaction
Olivine	(Mg,Fe)SiO ₄	Igneous	Oxidation of Fe Congruent dissolution* by acids
Pyroxenes	(Mg,Fe)SiO ₃ or Ca (Mg,Fe)Si ₂ O ₆	Igneous	Oxidation of Fe Congruent dissolution by acids
Amphiboles	Ca ₂ (Mg,Fe) ₅ Si ₈ O ₂₂ (OH) ₂ (also some Na and Al)	Igneous Metamorphic	Oxidation of Fe Congruent dissolution by acids
Plagioclase feldspar	NaAlSi ₃ O ₈ to CaAl ₂ Si ₂ O ₈	Igneous Metamorphic	Incongruent dissolution† by acids
K-feldspar	KAlSi ₃ O ₈	Igneous Metamorphic Sedimentary	Incongruent dissolution by acids
Biotite	K(Mg,Fe) ₃ (AlSi ₃ O ₁₀)(OH) ₂	Metamorphic Igneous	Incongruent dissolution by acids Oxidation of Fe
Muscovite	KAl ₂ (AlSi ₃ O ₁₀)(OH) ₂	Metamorphic	Incongruent dissolution by acids
Volcanic glass (not a mineral)	Ca,Mg,Na,K,Al,Fe-silicate	Igneous	Incongruent dissolution by acids Incongruent dissolution by water
Quartz	SiO ₂	Igneous Metamorphic Sedimentary	Resistant to dissolution
Calcite	CaCO ₃	Sedimentary	Congruent dissolution by acids
Dolomite	CaMg(CO ₃) ₂	Sedimentary	Congruent dissolution by acids
Pyrite	FeS ₂	Sedimentary	Oxidation of Fe and S
Gypsum	CaSO ₄ · 2H ₂ O	Sedimentary	Congruent dissolution by water
Anhydrite	CaSO ₄	Sedimentary	Congruent dissolution by water
Halite	NaCl	Sedimentary	Congruent dissolution by water

*Congruent dissolution: simple dissolution.

†Incongruent dissolution: mineral breaks down into ions in solution and a solid of different composition.

A second and contrasting example is the weathering of calcite and dolomite minerals. Specifically, calcite is used in the example below.

Calcite is rather soluble in water at pH less than 9 to 10 and can produce fairly high Ca^{2+} and HCO_3^- concentrations. In general, water sources that drain calcite and dolomite watersheds have moderate to high levels of hardness and alkalinity. An example in Table 3-12 is the Missouri River.

Downstream Rivers. Larger rivers as they move to the sea become influenced by anthropogenic chemicals imparted in the drainage from agricultural and urban areas and from industrial and community wastewater discharges. Many major ions such as Ca^{2+} , Mg^{2+} , K^+ , and HCO_3^- (see Table 3-12) are generally not affected. Levels of other chemicals increase significantly, especially in rivers in arid regions where irrigation water is used in the watershed. An example is the Colorado River near Phoenix (Table 3-12), which has a high concentration of dissolved solids, as indicated by its high ionic strength. Note the high concentrations of Cl^- and SO_4^{2-} compared to the other surface waters. Na^+ is not reported, but most likely it is high.

Anthropogenic Organic Chemicals. Anthropogenic organic chemicals are listed according to general categories in Table 3-9. These chemicals are normally low in concentration or not detected in upstream and protected water sources. Downstream rivers can contain pesticides and herbicides from agricultural and urban drainage. Other chemicals that may be found are site specific and can be found in major downstream rivers, such as the Mississippi, Ohio, Missouri, and Delaware rivers. A recent problem that is addressed next is the presence of EDCs (endocrine disrupting compounds) in source waters and drinking waters.

A widely quoted study is that of the United States Geological Survey (USGS) performed in 1999 to 2000 (Kolpin et al., 2002). The study sampled 139 streams downstream of urban and agricultural (livestock) drainage areas. The data collected included endocrine disrupting compounds (EDCs) associated with pharmaceuticals and hormones as well as other wastewater organic compounds. Organic contaminants were found in 80 percent of the streams sampled but at low concentrations, generally less than 1 $\mu\text{g/L}$. The most frequently detected compounds were two steroids (coprostanol and cholesterol), an insect repellent (N,N-diethyltoluamide), caffeine, an antimicrobial disinfectant (triclosan), a fire retardant (tri(2-chloroethyl) phosphate), and a detergent metabolite (4-nonylphenol).

A more recent study of the occurrence of EDCs in drinking water supplies and actual drinking water was reported by Benotti et al. (2009). Source water, finished drinking water, and distribution system tap water were sampled from 2006 through 2007 for 51 pharmaceuticals, other known or potential EDCs, and other organic chemicals. A summary of their findings regarding tap water is given with respect to what was found in the distribution systems of 15 water utilities. No pharmaceuticals or other EDCs were found in two of the systems. The following compounds and median concentrations were found in at least six of the systems at concentrations $>1 \text{ ng/L}$: (1) pharmaceuticals: carbamazepine at 6.8 ng/L and phenytoin at 3.6 ng/L ; (2) known or potential EDCs: atrazine at 50 ng/L ; and (3) other chemicals: TCEP (tris(2-chloroethyl) phosphate) at 150 ng/L , and TCP (tris(1,3-dichloro-2-propyl) phosphate) at 220 ng/L .

Summary. Common inorganic ions found in both upstream and downstream river sources are Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , and SO_4^{2-} . Typical ranges in concentration are shown in the last column of Table 3-12. The variations in concentration are due largely to differences

in minerals found in rocks, soils, and sediments in the watersheds. Higher concentrations of Cl^- , SO_4^{2-} , and Na^+ are found in downstream rivers influenced by human activities. Rivers that drain areas containing calcite and dolomite minerals have higher concentrations of hardness and alkalinity. Watersheds that drain granitic areas have lower concentrations of all ions and therefore low hardness and alkalinity. The ionic strength of waters varies from about 10^{-3} to 10^{-2} M. High ionic strength waters have high concentrations of dissolved salts or solids. The nutrients of N and P stimulate the growth of algae. This can be a problem in some rivers, but it is more of a problem for lakes and reservoirs and is addressed below. Arsenic (As) usually does not occur except in those areas containing certain minerals and under reducing conditions that occur in groundwaters (see discussion under groundwaters).

Anthropogenic organic chemicals are generally not detected in protected supplies and upstream rivers and streams. Several EDCs and other organic chemicals are found at concentrations generally less than $1 \mu\text{g/L}$ in downstream rivers that drain urban and agricultural areas. Few EDCs have been detected in drinking waters and at very low concentrations of several ng/L . Atrazine (herbicide) was found at a median concentration of 50 ng/L and two flame retardants were detected: TCEP at 150 ng/L and TCPP at 220 ng/L . See Chap. 2 for information about health effects of EDCs.

All water supplies contain natural organic matter (NOM). Table 3-9 groups NOM by different classes of organic compounds. NOM is the dominant fraction of organic carbon as it occurs at levels of mg/L compared to anthropogenic organic chemicals, which occur at levels of $\mu\text{g/L}$ or much less. For protected water supplies and upstream rivers, NOM accounts for nearly 100 percent of the dissolved organic carbon (DOC). For polluted supplies containing say $10 \mu\text{g/L}$ of anthropogenic organic chemicals, these organic chemicals would make up much less than 1 percent of the DOC. Extensive information on NOM is presented later in this chapter. NOM is important because it is a precursor to disinfection by-products (DBPs) and affects many treatment processes some of which are designed to remove it.

Lakes and Reservoirs

Classes of Lakes According to Stratification and Mixing. The chemistry of lakes and reservoirs is affected greatly by the mixing and stratification that occurs in most of these water bodies. Stratification occurs in lakes unless they are too shallow and are able to maintain mixing throughout their depth. Stratification occurs because the water's density is temperature dependent. The maximum density of water occurs at 4°C , and the density decreases as water temperature decreases from 4°C to ice formation at 0°C . Likewise, the density decreases as the water temperature increases above 4°C (see App. D).

Whether lakes stratify or not depends on their size, depth, and the extent of wind protection. Shallow lakes do not stratify and are considered as having continuous mixing. Lakes with small surface areas that are protected from the wind can stratify when depths are 3 m or more; while lakes with larger surface areas, stratification can occur at greater depths. Some classes of stratification and mixing are identified here and taken from Kalff (2002).

Cold Polymictic Lakes. These lakes are ice-covered for a large part of the year and free of ice during a summer period. The shallow lakes within this category stratify on sunny summer days and overturn (mix) during the night. Deeper lakes stratify for a period in the summer. Lakes in this category would be found in mountainous areas of the United States and in northern and mountainous areas of Canada.

Warm Polymictic Lakes. These are relatively shallow lakes or deeper lakes with extensive wind exposure. There is no ice cover at any time during the year. Stratification only occurs on a daily basis or for days. Lakes in this category include ponds found in southern warm climates.

Warm Monomictic Lakes. These lakes do not have an ice-cover during the year. They stratify during the warm period of the year and turnover once a year in late fall or winter. They are generally deeper, temperate, and tropical lakes found in southern warm climates.

Dimictic Lakes. These lakes have two periods of stratification and two periods of turnover. Stratification occurs during the winter ice-cover period and in the summer. Overturn occurs in the spring and autumn. These lakes are found extensively in temperate regions of the United States and Canada. Because these lakes are quite common, an extensive description of their mixing and stratification is covered next.

Stratification and Mixing of Dimictic Lakes. The physical aspects of stratification and mixing are explained here. The effects of stratification and mixing on water quality are discussed below in a separate section. Figure 3-6 depicts the four seasons: two stratification and two mixing periods.

During the summer stratification period, lakes stratify into three zones. At the top is the epilimnion, which contains warmer water and is mixed by wind. The epilimnion's surface is in contact with the atmosphere, allowing light penetration and exchange of gases. Below the epilimnion is a transition zone called the metalimnion. This is a temperature gradient region that separates the warm water of the epilimnion from the cold water in the bottom zone. It is often referred to as the thermocline, as labeled in Fig. 3-6. It is a barrier that restricts mixing between the epilimnion and hypolimnion. The hypolimnion contains the cold, dense water in the deeper part of the lake. This zone is separated from the atmosphere and wind, so little mixing occurs.

FIGURE 3-6 Lake stratification and seasonal overturn.

During autumn, the air temperatures decrease causing the water to cool in the epilimnion. The density difference between the epilimnion water that is cooled causes the water to sink and mix with the thermocline water, and causes the thermocline to erode. Continued cooling of the air and water along with wind-induced mixing creates an autumn overturn that is marked by circulation and mixing of the lake and what is called turnover. At or near 4°C (can be slightly less or greater), the water temperature becomes approximately constant vertically. This occurs as early as October in northern areas and later in the autumn in southern areas. In the winter, additional cooling produces water that is less dense than the deeper water. At the surface, an ice cover forms, preventing mixing, and a winter stratification period develops. In the spring, the ice cover melts and as the water warms to 4°C, it becomes denser and sinks. With spring winds, the lake is mixed, producing turnover or circulation. This event is called spring overturn, which occurs as late as May in northern regions and as early as March in southern areas.

Water Quality. Algae in lakes affect water quality directly and indirectly. Some direct effects are described here. Algae are particles and therefore affect turbidity. They are low-density particles that may not be removed efficiently in pretreatment sedimentation processes. If this occurs, then some algae may deposit within the pore openings of granular media filters, causing excessive head loss. These algae are referred to as filter-clogging algae. Some filter-clogging algae are listed in Table 3-13. Although only certain algae classes are shown, it is important to note that algae of all classes can clog filters. A common problem for many water utilities in temperate climates is the clogging of filters by diatoms in the spring when this type of algae often dominate over other algae due to the colder water temperatures.

Major problems associated with algae are taste and odor compounds that they produce. A partial list of taste and odor causing algae is found in Table 3-13. All classes of algae produce taste and odor compounds. Common taste and odor compounds are geosmin and 2-methylisoborneol (MIB) that impart earthy and musty odors to waters. These compounds are produced by many of the Cyanobacteria and by the Actinomycetes (bacteria) that are responsible for the decomposition of Cyanobacteria. A good reference on taste and odors identification is Suffet and Rosenfeld (2007). Cyanobacteria also produce microcystins, which can be toxic to animals and humans. Another water quality effect is formation of DBPs from algae. Both the cells and extracellular organic matter imparted into the bulk water serve as DBP precursors (Plummer and Edzwald, 2001). Any algae that pass through a water treatment plant can serve as an organic carbon source for bacteria and biological growth in the water distribution system. For treatment plants that remove particles via clarification and filtration, this should not be a problem; however, it can be a problem for unfiltered supplies.

Within a lake, algae affect water quality including DO and nutrients. Lakes are classified according to their trophic status, as shown in Table 3-14. Oligotrophic lakes are of the highest quality and are usually deeper and characterized by low concentrations of primary nutrients (N and P); low algae concentrations, measured as chlorophyll; and maintain DO in the hypolimnion. At the other end are eutrophic lakes, which are usually shallow compared to oligotrophic lakes and contain high nutrient concentrations, high algae, and anoxic conditions in the hypolimnion. Water supplies should be taken from oligotrophic lakes to avoid water quality problems. Mesotrophic lakes lie in between the other types with regard to nutrient and algae concentrations and characteristically lose oxygen in the hypolimnion in the late summer. When the hypolimnion becomes anoxic in mesotrophic and eutrophic lakes, iron and manganese are soluble in reduced states and affect water treatment.

TABLE 3-13 Common Cyanobacteria and Planktonic Algae in Lakes and Reservoirs

Taste and odor types		
Class	Associated odors	Comments
Cyanobacteria (Blue-Green Algae)		
<i>Anabaena</i>	Earthy, musty	Grassy
<i>Aphanizomenon flos-aquae</i>	Earthy, musty	Grassy
<i>Microcystis aeruginosa</i>	Earthy, musty	
<i>Oscillatoria</i>	Earthy, musty	
<i>Synechocystis minuscula</i>		
Chlorophyceae (Green Algae)		
<i>Chorella vulgaris</i>	Musty	When abundant
<i>Scenedesmus quadricauda</i>	Grassy	When abundant
<i>Selenastrum</i>		
<i>Staurastrum</i>	Grassy	
Bacillariophyceae (Diatoms)		
<i>Asterionella</i>	Geranium	Fishy when abundant
<i>Cyclotella</i> sp.	Geranium	Fishy when abundant
<i>Fragillaria</i>	Geranium	Musty when abundant
<i>Synedra</i>	Grassy	Musty when abundant
<i>Tabellaria</i>	Geranium	Fishy when abundant
Dinophyceae (Pigmented Flagellates)		
<i>Ceratium</i>	Fishy	
<i>Dinobryon</i>	Violet	
<i>Peridinium</i>	Cucumber	Fishy when abundant
<i>Synura</i>	Cucumber	Fishy when abundant
Filter-clogging algae		
Class	Size (µm)	Comments
Cyanobacteria (Blue-Green Algae)		
<i>Anabaena</i>	6–7 (diameter) (colonies much larger)	Single cells and bead-like colonies
<i>Microcystis aeruginosa</i>	5 (colonies much larger)	Forms colonies
<i>Oscillatoria</i>		
Chlorophyceae (Green Algae)

Algal Photosynthesis and Respiration. Equation 3-59 is a stoichiometric equation that shows the relationships between primary nutrients (C, N, and P) and algal biomass from photosynthesis (P). The reader is also referred to Fig. 3-4a for the following discussion.

The average dry weight composition of algae, which comes from the classical work of Redfield et al. (1963) is used here. Redfield identified the molar ratios of C:N:P at 106:16:1, which is widely quoted. The photosynthesis equation is a redox equation in which oxidized carbon is reduced to organic carbon. It is also an acid-base equation in which H^+ are removed from the water. There are diurnal effects from the photosynthetic reaction during the day and algal respiration (R) during the night. During the day when algae are growing, $\text{CO}_2(\text{aq})$ is removed and the pH increases. By the end of the afternoon, water utilities may observe a substantial increase in pH that requires adjustment of coagulation pH conditions within their treatment plants. Overnight, algal respiration increases $\text{CO}_2(\text{aq})$ and increases H^+ , as indicated in Eq. 3-59. In the morning, water utilities may observe a much lower pH than existed on the prior evening.

The molar relationship between N and P is 16 to 1. For water supplies with higher molar ratios, P is the limiting nutrient. For oligotrophic and mesotrophic lakes, P is usually the limiting nutrient because the available N:P ratio in fresh water lakes is usually greater than needed according to the biomass ratio of 16:1. P is also considered a limiting nutrient because blue-green algae can use $\text{N}_2(\text{aq})$ through nitrogen fixation (see Fig. 3-4b).

For stratified lakes in the summer (see Fig. 3-6), photosynthesis exceeds respiration and decay reactions in the euphotic zone (light penetration zone). Therefore, oxic conditions are maintained throughout the epilimnion and into the thermocline. For oligotrophic lakes, oxic conditions are maintained due to low concentrations of organic matter (dead algal cells and other organic matter). For mesotrophic and especially eutrophic lakes, dead algae sink to the bottom and undergo bacterial decomposition consuming DO. This can lead to anoxic

TABLE 3-14 Trophic Status and Water Quality of Lakes (Values Compiled from Kalff (2002); Thomann and Mueller (1987))

Trophic status	Hypolimnetic	Inorganic	Total	Total	Chlorophyll	Transparency	
	O_2	N	Total	P		Secchi disc (m)	Mean
	(% saturation)	($\mu\text{g/L}$)	N ($\mu\text{g/L}$)	($\mu\text{g/L}$)	($\mu\text{g/L}$)		
Oligotrophic	>80	<200	<350	<10	<4	≥ 6	≥ 3
Mesotrophic	10–80	200–400	350–650	10–30	4–10	3–6	1.5–3
Eutrophic	<10	300–650	650–1200	>30	>10	1.5–3	0.7–1.5

conditions in the hypolimnion during the summer whereby these reducing conditions can cause Fe and Mn problems.

Iron and Manganese. Under anoxic conditions, Mn and Fe are reduced and are more soluble in reduced states than oxidized states. Mn is reduced first due to its higher standard potential compared to Fe reduction (Fig. 3-5). Therefore, in lakes as DO becomes low and approaches zero from bacterial oxidation of organic matter, reduced Mn appears first. Oxidized Mn (Mn(III) and (IV)) is insoluble and occurs as solids of MnOOH(s) or $\text{MnO}_2\text{(s)}$ with little soluble Mn present. Upon reduction, the oxidized Mn is reduced to Mn(II), which is soluble at mg/L levels.

Oxidized Fe(III) is quite insoluble and occurs primarily in solid forms such as $\text{Fe(OH)}_3\text{(s)}$ (fresh precipitate) or as a mineral such as goethite (FeOOH(s)). Under reducing conditions that are lower than for Mn (Fe has a lower standard potential), Fe is reduced to Fe(II), which is quite soluble,

Cycling of Nutrients, Fe, and Mn. With reference to stratification and turnover periods for lakes, as depicted in Fig. 3-6, we get cycling of nutrients, Fe, and Mn. For mesotrophic and especially eutrophic lakes, the cycles are as follows. During summer stratification, bacterial decay of algal biomass releases N and P (called mineralization) to the hypolimnion. Fe and Mn are reduced and become soluble. During the fall overturn, mixing occurs and the water is oxygenated. Fe and Mn are oxidized, but these reactions take time. Consequently, for a period of time, reduced Fe and Mn may exist throughout the lake and cause problems for water utilities. The amount of time it takes to oxidize the Fe and Mn depends on the lake water pH (more rapid oxidation occurs at higher pH). These oxidation reactions may take from hours to days depending on the pH. During the late fall and early winter, because Fe and Mn are oxidized and are quite insoluble, low dissolved concentrations are found. During the winter stratification period at the bottom of ice-covered oligotrophic lakes, DO is maintained, and Fe and Mn are oxidized and dissolved concentrations are low. For eutrophic lakes, even though bacterial decomposition is slow due to low water temperatures, there may be sufficient organic matter to produce anoxic reducing conditions and increases in dissolved Fe and Mn. With spring overturn, mixing occurs in the lake and nutrients, Fe, and Mn are recycled. Spring overturn lasts for a short period and then summer stratification is established again.

Groundwaters

Major Ions and Other Chemical Characteristics. Groundwater is an important component of the hydrogeochemical cycle (Fig. 3-3). The chemical composition of groundwater is influenced by the cycle. Figure 3-7 shows a part of the cycle and is used in the following development of principles. The chemical composition of water is affected as the water flows downward through soils and minerals within the unsaturated zone and as it flows within the aquifer (saturated zone) in contact with soils, rocks, and minerals. Many reactions occur such as dissolution (solubility) of the mineral solid phases, acid-base reactions involving H_2CO_3^* and the base minerals, and redox reactions. The chemical composition of a groundwater aquifer reflects the major soils and minerals that the water contacts. A listing of major minerals is found in Table 3-11.

The compositions of major dissolved constituents for several groundwaters associated with different minerals and regions are summarized in Table 3-15. The following points are made:

- Groundwater chemistry varies greatly depending on the mineralogy
- Groundwaters associated with granitic minerals, feldspars, and micas have lower concentrations of base cations, lower alkalinity, lower hardness, and lower ionic strength
- Groundwaters associated with limestone and carbonate mineralogy have higher concentrations of base cations, higher alkalinity, higher hardness, and higher ionic strength

FIGURE 3-7 Depiction of groundwater system. (Source: USGS, <http://pubs.usgs.gov/gip/gw/>.)

Nitrates. Nitrate concentrations are often higher in groundwaters, especially, those that are shallow and occur in agricultural areas. When nitrate reaches 10 mg/L (as N) and greater, it exceeds the primary drinking water standard (Chap. 1) and is considered a health concern (Chap. 2). Nolan et al. (2002) published data showing areas of the United States according to probabilities that nitrate concentrations exceed certain levels.

Redox Effects. As water moves downward through the unsaturated zone, bacterial reactions occur involving decay of organic matter in soils and production of $\text{CO}_2(\text{aq})$ (increase in H_2CO_3^*). Microbial-mediated reactions produce reducing conditions that affect the oxidation states of Fe, Mn, S, and As. Figure 3-5 shows the order of reduction as follows: Mn, Fe, S, As.

Fe and Mn. As stated previously, Mn is reduced prior to the reduction of Fe. It is common to find reduced Mn in groundwaters at concentrations of 0.1 to 1 mg/L. It is common to find Fe at 1 to 10 mg/L in groundwaters with concentrations as high as 50 mg/L in waters of low pe and low bicarbonate (MWH, 2005).

As and S. Arsenic has both natural (rocks, soils, volcanic activity) and anthropogenic sources. Anthropogenic sources include lumber preservatives, pesticides, insecticides, and various industrial applications. Arsenic at low concentrations poses health problems (Chap. 2). The USEPA drinking water standard is 10 $\mu\text{g}/\text{L}$ (Chap. 1). Arsenic in water has two oxidation states: As(V) and As(III), and both forms are toxic (Chap. 2).

Figure 3-5 shows that As is reduced at low pe conditions, lower than Fe reduction. In evaluating the occurrence of As in source waters, the total dissolved As concentration is usually reported. Although As tends to occur in groundwaters in certain areas such as the southwest and some areas in the Rocky Mountains, it can be a problem in many other areas. Table 3-16 shows As occurrence data in groundwaters for community water systems in 17 states. The mean values are below 10 $\mu\text{g}/\text{L}$; however, the standard deviations indicate that many systems exceed this value.

Sulfur can exist in several oxidation states. Common oxidation states for dissolved S in groundwaters are the oxidized form occurring as SO_4^{2-} and the reduced forms occurring primarily as HS^- above pH 7 and as $\text{H}_2\text{S}(\text{aq})$ below pH 7. $\text{H}_2\text{S}(\text{aq})$ partitions with the gas

TABLE 3-15 Composition of Major Dissolved Constituents in Groundwaters (SiO₂, Cation, and Anion Information from Eby (2004), Other Parameters Calculated by Authors)

Parameter	Concentrations (mg/L (except Ionic Strength))					
	Rhode Island (granite)	North Carolina (mica, schist)	Maryland (gabbro (igneous basalt))	AL (limestone)	Central PA (carbonate)	New Mexico (gypsum)

phase, creating the characteristic rotten egg odor. Figure 3-5 shows that SO_4^{2-} is reduced at lower pe conditions than ferric reduction.

PARTICLES

This section describes the importance, types, sources, properties, and measurement methods for particles (particulate matter) in drinking water systems. A more in-depth coverage of particles is provided by Gregory (2005).

Importance

Particles in water are significant due to impacts on water quality and treatment process performance. Water quality effects can be aesthetic and or related to human health. The light-scattering properties of particles can cause significant turbidity, i.e., an undesirable cloudy appearance, even if the particles have no health consequences. In contrast, low levels of certain particles may have no visual impact but may be significant to human health, i.e., pathogenic microorganisms such as *Giardia* cysts, *Cryptosporidium* oocysts, *Escherichia coli* bacteria, or enteric viruses. Particles may also have surface-associated contaminants such as heavy metals and synthetic organics that are of human health concern. Many important aspects of particles in aquatic systems reviewed more than 30 years ago remain relevant (Stumm, 1977; O'Melia, 1980; Kavanaugh and Leckie, 1980).

The amount and nature of particles have significant effects and underlying importance for many treatment processes. For processes that are intended to remove dissolved constituents from water, particulate matter can cause undesired impacts or fouling of processes. Examples include the shielding of microorganisms from disinfectants, fouling of granular activated carbon adsorption and ion exchange media, fouling of reverse osmosis membrane

filters, and fouling of heat exchangers. More importantly, many treatment processes are inherently based on the formation, alteration, and removal of particles in water. Coagulation and flocculation involve formation and aggregation of particles; clarification (i.e., dissolved air flotation, sedimentation) and filtration (i.e., media filtration, micro- and ultrafiltration membranes) processes are used for particle removal. Removal of certain dissolved constituents is often based on production of particles, e.g., oxidation and precipitation of iron and manganese, transformation of dissolved NOM to particulate form, and precipitative softening for calcium and magnesium removal. In concentrated form, removed particles are the solids in water treatment residuals, or the sludge, that must be properly managed (see Chap. 22).

Types of Particles: Sources and Materials

Characterization of particles based on their source and materials of composition is useful and important in understanding treatment process performance. Herein, two different sources are defined: raw water particles and particles formed during treatment or distribution. Materials are divided into inorganic and organic categories. Table 3-17 summarizes sources and types of particles.

Raw Water Sources. Most particles in raw surface waters are naturally occurring as a result of watershed and water body processes. Inorganic mineral particles (i.e., aluminosilicate clays, metal oxides and hydroxides, silica oxides) may be present due to soil erosion

TABLE 3-17 Sources and Types of Particles

Category	Type/description/examples	Sources
Inorganic		
Clays	Aluminosilicates (montmorillonite, kaolinite, illite)	Raw water
	Asbestos fibers	
Metal oxides, hydroxides	Al(OH) ₃ (amorphous) precipitate	Coagulant addition
	Fe(OH) ₃ (amorphous) precipitate	Coagulant addition
	MnO _x (i.e., MnO ₂) precipitate	Fe(II) oxidation Mn(II) oxidation
	Mg(OH) ₂ precipitate	Softening
	SiO ₂ (mineral)	Raw water
Carbonates	CaCO ₃ precipitate (calcite)	Ballasted sedimentation
	Ca,MgCO ₃ precipitate (dolomite)	Raw water, softening Raw water, softening
Organic		
Adsorbent	Powdered activated carbon	Added during treatment
Microorganisms	Pathogens (viruses, bacteria, protozoa)	Raw water
	Algae	Raw water
	Bacteria	Bioactive filtration Other process tanks
Detritus	Debris from plants and animals	Raw water
NOM	Macromolecular, colloidal NOM	Raw water
	NOM sorbed to particle surfaces	Raw water
		Flocs from coagulant addition

during stormwater runoff; levels in treatment plant source water depend on the hydrodynamics of the source water. Run-of-river sources with high velocities maintain higher levels of suspended particles than do lake or reservoir sources with low velocities and long detention times, which allow for sedimentation of most suspended particle mass. Thus, particle levels in the Missouri River, which is one source water for St. Louis, MO, are significant (10s to 100s of mg/L), while the mass of suspended particles is insignificant (order of 1 mg/L) in many Great Lakes intakes and New England reservoir sources. In general, levels of inorganic particles in raw groundwater sources are low due to natural filtration, with transport of the water through the subsurface porous media. As discussed below, exposure of groundwaters to the atmosphere may result in formation of particles that were not present in the source water.

Aquatic biota, from fish to microorganisms as well as aquatic plants, are important sources of naturally occurring organic particles in raw waters. Algae and Cyanobacteria are important types of microorganisms because they can occur at significant concentrations and may cause associated taste and odor problems and, possibly, low levels of toxins (see earlier discussion and Table 3-13). Levels of photosynthetic organisms are dynamic and a result of complex interactions of climate, hydrology, and nutrient cycling. Particle removal processes must be able to respond to periodically elevated levels of microorganisms, and other processes may be needed to address associated dissolved constituents. In general, particulate organic matter includes microorganisms as well as detritus from decaying biomass of both watershed (trees, plants) and water body origin. As noted in the section to follow on NOM, the particulate fraction of NOM is typically small, i.e., 1 to 10 percent of the TOC.

Another important class of raw water microorganisms is human pathogens (viral, bacterial, protozoa). The sources of pathogens include mammals, livestock, and wastewater from humans. Because actual and potential levels of pathogens in source waters are variable on both temporal and spatial scales, treatment processes for removal and inactivation of pathogens are designed to provide desired performance under expected worst-case source water quality. In the United States, federal regulations addressing pathogen occurrence and treatment include the suite of surface water treatment rules (Surface Water Treatment Rule [SWTR], Long Term 1 Enhanced Surface Water Treatment Rule, Long Term 2 Enhanced Surface Water Treatment Rule), the Information Collection Rule, and the Ground Water Rule (see Chap. 1). One goal of source water protection programs is to minimize pathogen input to source waters through best management practices including livestock management, source water selection, and wastewater management.

In addition to pathogens, there are some anthropogenic contaminants that may be present as raw water particles. As noted earlier, contaminants such as heavy metals and hydrophobic synthetic organic chemicals that are released to the environment are often associated with particle surfaces. The occurrence and level of such contaminants are rarely an issue and site specific; investigation should be based on knowledge of potential anthropogenic impacts to source waters. An issue of emerging concern is the potential for the presence of nanoparticles in source waters due to increasing manufacturing and use of nanomaterials (Ju-Nam and Lead, 2008; Wiesner et al., 2008), including nanoparticles made from carbon (i.e., fullerene, carbon nanotubes), silver, gold, titanium, silica, zinc, and many other elements. Little is currently known about the occurrence or levels of anthropogenic nanoparticles in source waters, including their association with other particulate matter. Again, concern and investigation should be based on knowledge of potential inputs to the source water of interest.

Treatment System Sources. An understanding of the types and levels of particles formed (or added) during treatment processes is important for overall process design as well as assessment of treatment performance. Particles formed during treatment must be removed by downstream processes and ultimately become process residuals. Assessment of particle

removal across treatment processes may be influenced by lack of knowledge of the source of particles. For example, assessing the potential to remove protozoan pathogens based on levels of protozoan-sized particles in raw and filtered waters ignores the fact that most of the protozoan-sized particles in filtered waters were formed during treatment and as a result have limited relationship to the raw source water particles.

For low-turbidity lake and reservoir source waters, the number and mass of particles formed during treatment are much greater than levels in the raw source water. The most common treatment process source of particles is the formation of amorphous aluminum or iron hydroxide particles ($\text{Al}(\text{OH})_3(\text{s})$, $\text{Fe}(\text{OH})_3(\text{s})$) by the addition of sparingly soluble salts for coagulation purposes. The primary coagulants also directly precipitate and adsorb or coprecipitate dissolved NOM, creating a mixed inorganic-organic particle. These particles formed during coagulation comprise most of the particle mass to be removed in particle separation processes—raw water particles are a minor component. In some plants such as direct filtration, only synthetic organic polymer coagulants are used, so the precipitated NOM is primarily an organic material.

The precipitative softening process is another significant treatment process source of particles. Calcium hardness is removed by formation of calcite ($\text{CaCO}_3(\text{s})$), a carbonate mineral, while magnesium is removed at higher pH by formation of magnesium hydroxide ($\text{Mg}(\text{OH})_2(\text{s})$). For many surface or groundwater-based hard water sources, raw water particle levels are low such that particles formed during treatment are dominant. Raw waters may contain naturally occurring calcite or dolomite ($\text{CaMgCO}_3(\text{s})$) particles; however, these dense crystalline particles generally settle out within the surface waters where they were formed. This can occur seasonally.

Another important source of particles formed during treatment occurs when reduced iron and manganese are oxidized and precipitate as $\text{Fe}(\text{OH})_3(\text{s})$ and $\text{MnO}_x(\text{s})$, respectively. This can be a continuous process for groundwaters with consistent levels of reduced Fe or Mn or a periodic process for surface waters that have seasonal occurrence of increased raw water Mn and Fe levels. Knowledge of the form of Fe and Mn in both raw and process waters is essential for the proper design, operation, and troubleshooting of Fe and/or Mn control processes.

Some treatment processes involve the addition of specific particles to the main process flow. One example is the addition of powdered activated carbon (PAC) for adsorption of low levels of organic compounds. PAC addition may occur periodically due to seasonal water quality problems (i.e., taste and odor) or continuously. Mass loadings may be significant relative to other particles, and the PAC typically becomes incorporated within overall plant residuals.

Another process involving the addition of particles is the sand-ballasted high-rate sedimentation process. Dense silica sand particles are added and flocculated with other process particles (i.e., from coagulation and flocculation) to form larger, faster settling floc that are removed via gravity sedimentation. Most of the sand is mechanically recovered from the settled flocs and reused in the process, resulting in little impact on downstream processes or residuals (see Chap. 9).

Particle Characteristics

The interaction of particles and treatment processes is significantly affected by important particle characteristics such as size, density, shape, and surface properties.

Size is perhaps the single most defining characteristic of a particle. Figure 3-8 shows that aquatic particulate matter size can range over five to six orders of magnitude, from millimeter size flocs (aggregates of smaller particles) to colloids on the order of a few nanometers in size. There are a number of generally agreed upon terms used for describing

FIGURE 3-8 Size range for particulate matter in water.

size classes of particles, many based on operational definitions using specific methods to separate size classes. Suspended particles are those that are retained on a fibrous laboratory membrane filter, i.e., as defined in *Standard Methods* (APHA, AWWA, and WEF, 2005). These particles are generally in the range of 1 μm to several millimeters. In contrast, colloids are submicrometer particles in the nanometer to micrometer size range, while nanoparticles generally refers to particles with size less than approximately 100 nm; thus, all nanoparticles are also colloids.

The operational distinction between dissolved and particulate matter is based on use of laboratory fiber/membrane filters with pore sizes of a few tenths to several micrometers. Thus, the “dissolved” fraction (the filtrate) often includes colloidal material (and nanoparticles); methods that provide solid/liquid separation at smaller size scales (such as ultrafiltration or centrifugation) are needed to isolate colloidal matter.

Density. Particle density (mass per unit volume) can have important impacts on the fate of particles in natural waters, their removal during treatment, and management of solid residuals. Particle density directly affects the gravitational force on particles, impacting particle removal in natural lakes and reservoirs as well as by many engineered particle separation processes (flotation, sedimentation, media filtration). The mass and volume of solid residuals to be managed is also directly affected by particle density.

Particle density depends on material type and particle (or floc) formation processes. Higher-density particles include crystalline mineral materials such as certain iron oxides (4000–5000 kg/m³ or 4–5 g/cm³), silica sand (2650 kg/m³), and calcium carbonate (2400 kg/m³); particles of such high density are typically naturally removed from lake and reservoir source waters but may be significant in run-of-river sources. Many source and formed-in-treatment particles have a density that is only a few percent (1–10) greater than water. Examples include microorganisms (including some algae that are buoyant in water) and precipitated amorphous metal hydroxides such as from coagulation using iron or aluminum salts.

Aggregates of smaller particles, or flocs, typically include water-filled pore space as well as solid matter. The net density of flocs is affected by floc porosity and the density of the solid material, or

$$\rho_{\text{net}} = \frac{V_{\text{water}} \rho_{\text{water}} + V_{\text{solid}} \rho_{\text{solid}}}{V_{\text{total}}} \quad (3-60)$$

where V refers to volume (water, solid, or total floc) and ρ is density. One important floc characteristic is their fractal nature, where flocs become more porous and less dense as they grow in size. This is addressed in other chapters on flocculation (Chap. 8) and clarification (Chap. 9) processes.

Shape. The shape of particles, both naturally occurring and those formed in treatment, can be quite varied and can impact treatment performance. In most mathematical models involving particles and in many measurement techniques for particle sizing, it is common to assume a spherical shape for particles. This assumption can be valid for some biological and inorganic particles (e.g., coccoid bacteria, *Cryptosporidium* oocysts, some algae, some manufactured particles), while it is invalid for others (e.g., rod-shaped bacteria, many algae, flocs). The actual shape of particles can be described qualitatively (e.g., rod, star, oblong) and by some quantitative measures (e.g., aspect ratio of longest to shortest dimension, ratio of perimeter to cross sectional area). Assessment of shape requires analysis of particle images. It may be important to understand particle shape, even if quantitative analysis is not possible, when assessing impacts on removal and process performance (e.g., filter-clogging algae may be filaments with high aspect ratio).

Nature of Particle Surfaces: Stability. An especially important characteristic of particles is the nature of the particle surface or the particle-water interface. The fate and transport of particles in natural waters and engineered water treatment processes is affected greatly by the net force that results when the surfaces of particles interact with each other or with other solid surfaces. If interactions between particles result in repulsive forces that prevent aggregation of particles into larger flocs, the suspension of particles is said to be stable. Similarly, repulsive forces might result during the interaction of a particle with the surface of a sand grain in a media filter or with the synthetic polymer surface of a hollow fiber membrane filter, preventing deposition to that surface. Thus, one objective of coagulation is to destabilize particles, leading to effective flocculation, clarification, and deposition in a media filter.

The net force between interacting surfaces in water is affected in a complex manner by the materials of the surfaces and the chemistry of the water phase. Repulsive forces can result when surfaces have the same electrostatic charge (positive or negative), when portions of surface-associated macromolecules interact unfavorably, and if surfaces are strongly hydrated by water molecules. The distance over which such forces are important is on the order of a few angstroms to tens of nanometers, small compared to many particles but on the order of the size of the smallest colloids. Fundamental aspects of forces between particle surfaces are described in books on colloid and physical chemistry (e.g., Verwey and Overbeek, 1948; Israelachvili, 1992; Hiemenz and Rajagopalan, 1997).

Repulsive forces due to like electrostatic surface charge are common for aquatic particles. Stumm (1992) and Stumm and Morgan (1981) describe three origins for surface charge: (1) isomorphous substitution of elements within a crystal structure, (2) chemical reactions at surfaces (surface complex formation), and (3) sorption of charged macromolecules.

The classic example of isomorphous substitution occurs for clay particles where a permanent net negative "surface" charge results from substitution of Al(III) for Si(IV) in a tetrahedral structure or Fe(II) or Mg(II) substituted for Al(III) in an octahedral layer. This charge is not affected significantly by solution chemistry (pH, etc.), although clay particles can have edges with hydroxyl ($-OH$) groups that are affected by pH. Interlayer net negative charge can be balanced by sorbed cations, giving rise to the cation exchange capacity of a clay material.

Chemical reactions involving surface-bound atoms (surface complex formation or chemisorption) can also significantly affect surface charge. If " $>XO$ " represents a surface-bound metal atom with a covalently bonded oxygen atom (i.e., $>AlO^-$, $>FeO^-$), often

referred to as a surface site or surface functional group, then reversible surface complex formation reactions involving protons (H^+), thus solution pH affected, can control the formation of charged surface groups as illustrated.

As pH decreases, more surface sites are protonated, and the surface becomes more positive while the reverse is true as pH increases. The pH at which the surface has a zero net charge is referred to as the pH of zero point of charge (pH_{ZPC}) or the isoelectric point (pH_{IEP}). The pH of zero net charge depends on particle material as well as solution chemistry. For some metal hydroxides, pH effects on surface charge are significant within the pH range often encountered in water treatment. For example, iron or aluminum hydroxide precipitates may have significant positive charge at pH 5, while at pH 9 or 10 the surface charge is negative. For other oxides, such as silica, the pH of zero charge is low such that bare silica surfaces are negatively charged for pH conditions of water supplies. The effect of pH on surface charge is illustrated schematically in Fig. 3-9.

FIGURE 3-9 Illustration of the effect of pH on surface charge.

Surface charge can also be significantly affected by surface complex formation that involves other charged species in solution (Morel, 1983; Stumm 1987, 1992). Complexation of calcium (Ca^{2+}) adds positive surface charge, while a ligand substitution reaction such as phosphate for hydroxide can add negative surface charge. The effective removal of arsenic as As(V) (arsenate) by adsorption to iron oxyhydroxides surfaces is an example of surface complex formation that affects surface charge and results in removal of a trace level contaminant.

Particle surfaces interact with macromolecules such as dissolved NOM and polyelectrolytes (or polymers) added during treatment. These macromolecules often adsorb favorably to surfaces and affect surface charge if they are charged molecules. Thus, in natural waters, most particle surfaces have adsorbed NOM that is negatively charged due to deprotonated carboxyl ($R-COO^-$) functional groups (protonation to uncharged $R-COOH$ would occur at low pH, i.e., $< 3-4$).

As described in Chap. 8, the surface charge of particles after coagulation and flocculation is a complex result of the precipitation of metal hydroxides; the precipitation, coprecipitation and adsorption of NOM; and the adsorption of charged species from coagulant addition. However, coagulation typically involves the use of positively charged dissolved species to precipitate and destabilize negatively charged NOM and raw water particles to produce approximately net neutral particles, which can aggregate to form flocs that can be removed effectively by processes such as sedimentation, dissolved air flotation, and filtration.

As noted above, in addition to electrostatic surface charge, surface interaction forces can be affected by the interaction of adsorbed macromolecules and by surface hydration. The interaction of particles with adsorbed macromolecules that have long tails and loops extending into solution can lead to repulsive steric interactions if the macromolecule segments have segment-solvent (water) interactions that are more favorable than between segment-segment interactions. Conversely, high molecular weight (MW) hydrophobic polymers may be used to effectively attach particles together despite other repulsive forces if the particle-molecule interactions are very favorable. The use of high MW synthetic polymers as flocculation or media filtration aids is an example of this. Strongly hydrated surfaces may give rise to repulsive surface interaction forces if the displacement of the water molecules is unfavorable. Repulsive interaction of certain uncharged silica surfaces is one example of this.

Measurements of Particle Concentration

Various analytical measurements are used to quantify the amount of particulate matter in water. Measurements are needed for a variety of purposes including regulatory compliance; process performance assessment; particle detection; and development, calibration, and validation of process theories and models.

Turbidity. The turbidity, or cloudiness, of water is measured as a surrogate for the presence of particles and is a regulated parameter for drinking water quality. As used in the drinking water industry, turbidity is the amount of visible light (400–700 nm wavelength) scattered at a 90 degree angle to the incident light source. Turbidity is measured in nephelometric turbidity units (ntu) using a nephelometer (or turbidimeter). The intensity of scattered light, in ntu, is based on a standard (but arbitrary) concentration of a primary reference colloidal material (formazin) that is used to calibrate a turbidimeter. Various secondary standards comprised of other material are typically used for daily instrument validation and calibration. Turbidity measurements range from the low levels for filtered waters of 0.01 to 0.3 ntu, to typical values in lakes of 0.5 to 10 ntu, to erosion-prone run-of-river levels of 100s to 1000s of ntu.

The turbidity of a sample does not convey any information about fundamental characteristics of particles since the scattered light is the aggregate response for all particles, which is a function of the amount of particles as well as the size, refractive index, and shape of the particles. As shown in Fig. 3-10, for a given mass concentration of particles, measured turbidity is significantly affected by particle size because particle number concentration is inversely proportional to diameter cubed and visible light-scattering efficiency is affected by particle size. Turbidity per unit mass of particles is at a maximum for particles with size similar to the wavelength of visible light (0.4–0.7 μm), decreasing as particles get smaller due to poor scattering and decreasing as particles get larger due to decreased number concentration. Thus, a decrease in turbidity may not always signify a decrease in particle mass concentration if significant size change occurs.

Mass and Volume Concentration. The mass concentration of particles (dry mass/unit volume), for which the total suspended solids (TSS, mg/L) is a common example, is important with respect to solids loading to treatment processes and the management of residuals (sludge). Because finished drinking water has essentially no significant mass concentration of particles, the solids mass in raw water as well as mass added or formed during treatment essentially all becomes residual solids that must be properly managed.

The volume of residuals to be managed is a direct function of the mass concentration and the density of the solids. Total mass concentrations may be the basis for fees for sludge management, while the volume of solids may significantly impact the design and

FIGURE 3-10 Effect of particle size on turbidity (polystyrene particles).

operation of residuals management processes. Because volume and mass scale with the cube of diameter, larger particles typically control overall mass or volume in heterodisperse suspensions.

Surface Area Concentration. The surface area associated with particulate matter (i.e., concentration in m^2/L) is important when considering the interaction of dissolved species with particle surfaces, i.e., the adsorption of trace contaminants or of added coagulants. Surface area is directly proportional to mass concentration and inversely proportional to particle size; smaller particles have more surface area per unit mass. Some solids are characterized by their specific surface area (area per unit mass) which can be measured; multiplying this parameter by mass concentration yields surface area concentration.

Number Concentration. Particle number concentration (number of particles per unit volume) is important in performance models for many treatment processes (e.g., rate of aggregation in flocculation, rate of removal in clarification and filtration). Measurement of number concentration requires the counting or detection of individual particles in a known sample volume. Measurement methods include microbiological assays, microscopic observation (such as optical, electron), and various particle counting techniques based on light blockage, light scattering, and electrical resistance, among others.

The 1989 USEPA SWTR (see Chap. 1) focused attention on particle number concentration with its requirements to achieve specified log reduction levels for *Giardia* cysts and enteric viruses. The log reduction achieved by disinfection (or inactivation) and the degree of removal achieved (or credited) for clarification and filtration processes are based on number concentration of microorganisms; 2-log removal is a decrease in number concentration by a factor of 100. The requirements of the SWTR and the availability of light blockage based particle counters for particles larger than $2\ \mu\text{m}$ led to consideration by some of the use of the measured number concentration of cyst-sized particles to assess protozoa removal performance across treatment plants. This practice is not advised for two reasons. The first is that actual concentrations of cysts (or oocysts) in the most contaminated source

waters would not be detected by particle counters (i.e., a source water with 10 oocysts/L, highly contaminated, would have only 0.01 oocysts/mL, compared to raw water particle counts of 1000 to 10,000 particles/mL for high-quality, low-turbidity sources). The second reason is that comparison of cyst-sized particles in raw and finished waters is illogical because coagulation processes form high concentrations of cyst-sized particles, the particles most likely to be detected in filtered waters, and they have no relationship to actual cysts in the raw water. On a site-specific basis, monitoring of particle counts in filtered waters can be a very useful and sensitive process-control tool to be used in combination with other performance measures.

Particle characteristics such as size, density, and number concentration can be used to calculate equivalent mass, volume, or surface area concentrations; equations are shown in Table 3-18.

TABLE 3-18 Summary of Measures of Particle Concentration

Measure of concentration*	Equations and comments
Mass (<i>C</i>) [M/L ³]	Measured dry mass/unit volume i.e., Total Suspended Solids (mg/L)
Number (<i>N</i>) [# /L ³]	$N = C / (\rho_p (\pi/6) d_p^3)$ (for spheres) – ρ_p = particle density – d_p = particle diameter
Volume (<i>V</i>) [L ³ /L ³]	$V = N (\pi/6) d_p^3$ (for spheres) $V = C / \rho_p$ $V \times 10^6$ = parts per million by volume (ppm _v)
Surface area (<i>S</i>) [L ² /L ³]	$S = N \pi d_p^2$ (for spheres) $S = (6 C) / (\rho_p d_p)$ (specific surface area of material = S/C)

* [], M = mass, L = length, # = number.

Example 3-5 Particle Concentrations

Consider a raw water supply with 3 mg/L of TOC and 1 mg/L of mineral particles. An alum dose of 20 mg/L is added for coagulation. Calculate the volume, number, and surface area concentrations that result from coagulation if the particles have diameters of 50 nm, 5 μm, and 500 μm with assumed densities of 1.5, 1.05, and 1.01 g/cm³, respectively. Assume that 35 percent of the TOC is converted to particulate form via coagulation and that all of the mineral particles are included. Use the equations in Table 3-18 and assume spherical particles.

Solution Use the result of Example 3-2 and assume that all the added aluminum precipitates as Al(OH)₃(s) without any appended water molecules, i.e., 0.26 mg Al(OH)₃(s)/mg of alum. Assume that NOM contains about 50 percent carbon (see upcoming section on Natural Organic Matter), so the amount of NOM precipitated is 0.35 × 3 mg/L × 1/0.5 = 2.1 mg/L.

$$\begin{aligned} \text{Mass of Al(OH)}_3\text{(s) formed} &= (20 \text{ mg/L alum})(0.26 \text{ mg Al(OH)}_3\text{(s) per mg of alum}) \\ &= 5.2 \text{ mg/L} \end{aligned}$$

$$\begin{aligned} \text{Total mass concentration of particles} &= 5.2 + 2.1 \text{ mg/L NOM} + 1 \text{ mg/L mineral} \\ &= 8.3 \text{ mg/L} \end{aligned}$$

Equations from Table 3-18 are used to determine the following:

$$\text{Volume concentration} = [\text{mass conc.}]/[\text{density}]$$

$$\text{Number concentration} = [\text{volume conc.}]/[\text{volume per particle}]$$

$$\text{Surface area concentration} = [\text{number conc.}] [\text{surface area per particle}]$$

Summary of results is in the table below. Calculations require attention to units.

Particle diameter (μm)	Particle density (g/cm^3)	Volume conc. (ppm by volume)	Number conc. ($\#/\text{L}$)	Surface area conc. (cm^2/L)
0.05	1.5	5.5	8.4×10^{13}	6600
5	1.05	7.9	1.2×10^8	95
500	1.01	8.2	1.3×10^2	0.99

As density decreases (due to aggregation and porosity), volume concentration increases. The results illustrate the sensitivity of number concentration to particle size for a given mass or volume concentration. The very large numbers of 50 nm (0.05 μm) particles aggregate to approximately 120 million 5- μm particles per liter, which in turn can aggregate to only 130 500- μm particles per liter (the kind of particles desired for sedimentation processes). Surface area increases inversely with particle size. ▲

Measurements of Particle Size and Size Distributions

Particle size and concentration are important in fundamental aspects of treatment process performance (see Lawler et al., 1980; Elimelech et al., 1995) and because of the relationship between particle size and specific types of particles (as noted in the example above). Particle size distributions are discussed here, followed by a discussion of particle sizing in general and some specific methods of particle sizing and counting.

Particle Size Distributions. In general, there are particles in a range of different sizes in any sample of source or treated water. Characterization of the concentration of particles in a set of specific, narrow size ranges (or windows, channels, bins, etc.) yields a particle size distribution (PSD). Each size range has an average size (arithmetic or geometric mean of the range, $d_{p,i}$), usually an equivalent spherical size, and the concentration may be expressed on a number, volume, mass, or surface area basis. PSDs can be presented as absolute or relative (fraction of total) differential concentrations versus size or on a cumulative basis (concentration or fraction greater than a certain size); examples of these approaches are shown in Fig. 3-11. A useful approach is to examine absolute, differential PSDs of number concentration (ΔN_i) versus size ($d_{p,i}$) at different locations along a treatment process. A set of representative PSDs for raw, filter influent (flocculated), and filter effluent waters for a direct filtration treatment plant is shown in Fig. 3-12. These PSDs have 16 logarithmically distributed sizes over the 1 to 204 μm size range. The number concentrations are dominated by small particles, with coagulation and flocculation (the filter influent) producing many more, smaller and larger particles as compared to the raw water (3.2×10^4 versus 1.2×10^4 total particles/mL), while the filtered water has very few particles remaining (314 particles/mL).

In order to compare PSDs measured using different particle counting instruments and for research purposes, it can be useful to normalize a PSD by dividing the absolute differential concentration by the width of the size range channel (or window) for that concentration, using a logarithmic basis. Plotting normalized number and volume concentrations ($\Delta N_i / \Delta \log d_{p,i}$ and $\Delta V_i / \Delta \log d_{p,i}$) versus the log of the particle size for samples along a treatment

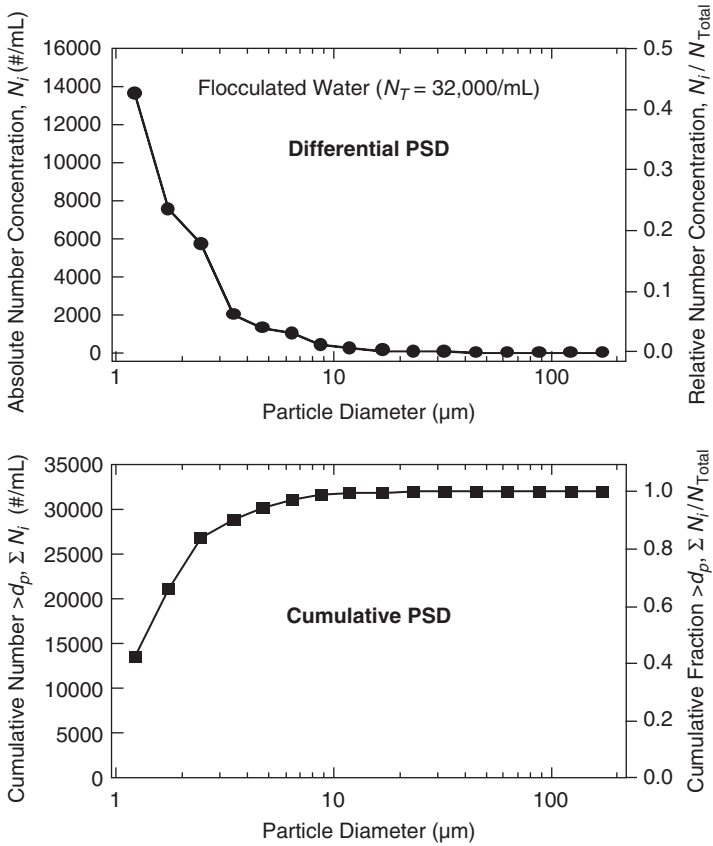

FIGURE 3-11 Comparison of differential and cumulative particle size distributions on both absolute and relative scales.

train show changes due to treatment. The example in Fig. 3-13 shows that although smaller particles dominate on a number basis, the larger (10–50 μm) particles dominate particle volume (and thus particle mass). Additional descriptions of PSDs can be found in *Standard Methods* (APHA, AWWA, WEF, 2005).

It may be convenient or necessary to describe a PSD using a single average size and a total number of particles. Average particle size for a PSD can be calculated using several methods depending on the characteristic of the PSD being emphasized. The most common average size is a number weighted average or mean size for the distribution (d_N). In contrast, the total surface area of a PSD can be captured by determining the surface area weighted average size (d_S), while the total volume of a suspension can be described by a volume weighted average size (d_V). Table 3-19 shows the equations for calculating these characteristic average sizes. Note that the relative order of average size is $d_V > d_S > d_N$.

Particle Sizing and Counting: General. Particles in water are three dimensional and of various shapes. However, it is common to use a single dimension, typically the diameter of a sphere, to characterize particle size. Furthermore, particle size is often

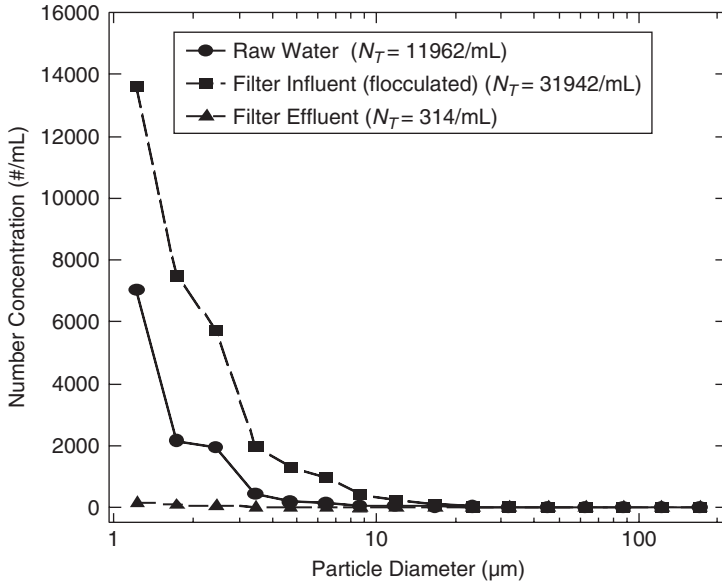

FIGURE 3-12 Representative number based PSDs for raw, flocculated, and filter effluent waters.

inferred, or calculated, based on measured perturbations or phenomena caused by a particle (or particles), such as the scattering or blockage of light, electrical resistance, or motion, in contrast to direct observation via microscopy and image analysis. Thus, particles are most often characterized by a single dimension that is equivalent to a sphere of that diameter that would yield the result that was measured. Particles might also be characterized by major and minor length dimensions that reflect a two-dimensional aspect of the particle shape; such a characteristic is only possible from examination of some type of particle image.

Particle sizing and counting generally require the ability to detect, or sense, an individual particle and to assign the particle to an appropriate size range. Direct microscopic observation using visual light or electron beams produces images of individual particles that can be scaled and assigned to size classes based on major or minor axis length, perimeter, or cross-sectional area. Indirect observation of size involves detecting the magnitude (or timing) of a perturbation or phenomena caused by the particle and relating that magnitude (or timing) to size via calibration using particles, often spheres, of known size. In general, the sizing and counting of suspensions with multiple particle sizes is more easily accomplished for particle sizes greater than approximately 1 μm as compared to submicrometer sized particles. Several books, research reports, and journal articles describing particle counting methods are available (e.g., Lewis et al., 1992; Hargesheimer et al., 1992, 2001; Chowdhury et al., 2000; Broadwell, 2001). A recent book chapter with a focus on nanoparticles provides an excellent summary of particle characterization methods (Hassellöv and Kaegi, 2009).

Particle Sizing and Counting: Light Blockage. The most commonly used particle sizing and counting technology in drinking water treatment applications is the light-blockage-based particle counter. Laser light (visible wavelengths) is directed across a sensing chamber through which a water sample passes at a known flow rate (typically, 50–100 mL/min). A photodiode detects the laser light (photons); when a particle passes through the sensing

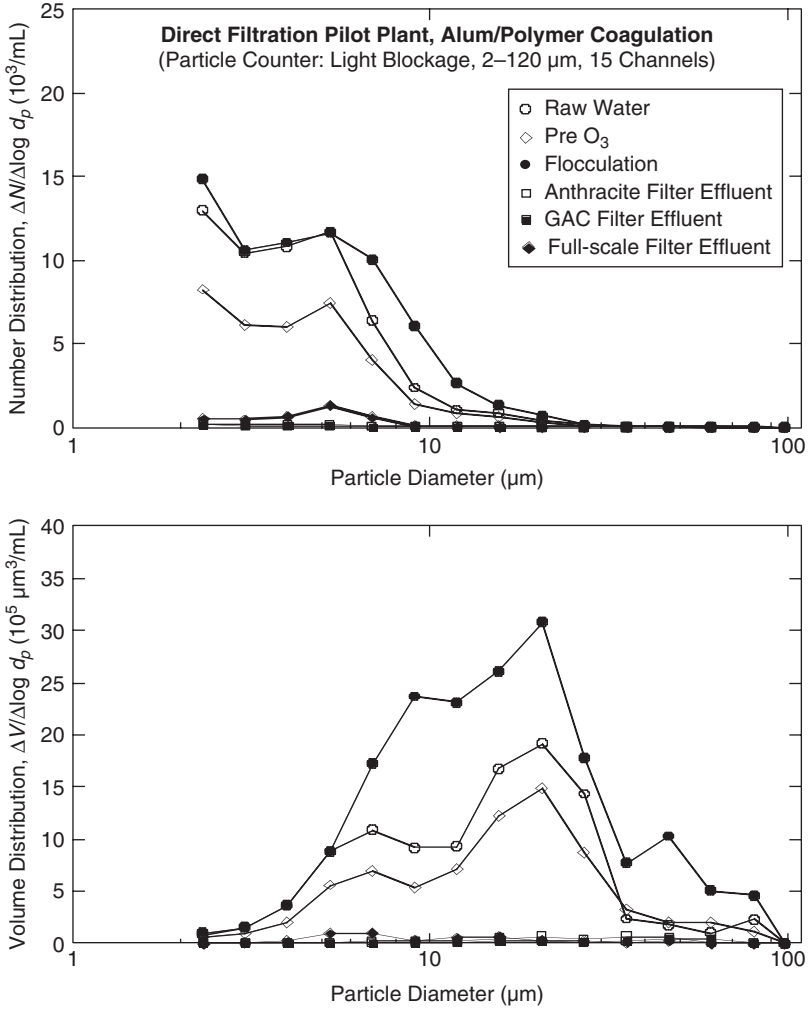

FIGURE 3-13 Comparison of number and volume particle size distribution functions across treatment.

zone, less light reaches the photodiode and a voltage pulse proportional to the blocked area of light is detected. Instrument electronics count and sort the pulses into defined voltage ranges; these voltage ranges are factory calibrated using spheres of known size. Light blockage sensors are most often utilized for particles larger than 2 μm, although sensors with 1 μm detection limits have been utilized. Use of this technology began in the 1970s (e.g., Tate and Trussell, 1978) and saw significantly increased use in the 1980s and 1990s as on-line instruments were developed and concern over *Giardia* cysts and *Cryptosporidium* oocysts increased (e.g., LeChevallier and Norton, 1992). Limitations to light-blockage sensors include maximum concentration limits (avoid coincidence), operation and maintenance (flow control, sensor cleaning, etc.), need for particles that block light (not opaque),

TABLE 3-19 Equations for Calculation of Characteristic Average Particle Sizes

Basis for averaging	Equation for average diameter
Number	$d_N = \frac{\sum_i N_i d_{p,i}}{\sum_i N_i} \quad (3-61)$
Surface area	$d_S = \left[\frac{\sum_i N_i d_{p,i}^2}{\sum_i N_i} \right]^{1/2} \quad (3-62)$
Volume (or mass)	$d_V = \left[\frac{\sum_i N_i d_{p,i}^3}{\sum_i N_i} \right]^{1/3} \quad (3-63)$

and detection of gas bubbles as particles; some of these issues are addressed by Van Gelder et al. (1999). Despite these limitations, light-blockage particle counters can be effective tools for monitoring the performance of individual filters as well as combined filter effluent because they detect low levels of larger particles that do not create significant turbidity.

Particle Sizing and Counting: Light Scattering. The scattering of monochromatic laser light can be utilized to size and count particles in water. There are both static and dynamic light-scattering techniques, and detection can be at one or more angles relative to the light sources. With respect to natural and treated water samples and continuous use, the light-scattering techniques are often limited by the need for relatively high sample concentration and an inability to effectively resolve broad particle size distributions. Most light-scattering instruments are utilized in research laboratories, although some on-line instruments have been utilized (e.g., Lewis and Manz, 1991). The main advantage of light-scattering methods is the ability to detect submicron size particles that light-blockage methods do not detect. However, the disadvantages noted above regarding the need for relatively high particle concentration and inability to describe broad or multimodal PSDs have resulted in very limited use of light-scattering-based particle counters for water treatment applications.

For many light-scattering approaches as well as for some direct observation approaches, particle sizing is based on detecting the magnitude of the random Brownian motion of a particle in water, relating that to a diffusion coefficient, and then calculating a hydrodynamically equivalent spherical size for that diffusion coefficient using fundamental theory (i.e., the Stokes-Einstein equation for particle diffusion in a liquid).

Particle Sizing and Counting: Electrical Resistance. Another particle sizing and counting technique that is used in research laboratories is based on the electrical resistance caused by the solid particle material as it disrupts an electrical circuit. The electrical circuit involves a high ionic strength solution and electrodes on either side of a small circular orifice in a glass wall. Suction causes fluid flow through the orifice while an electric potential is applied across the electrodes. As a particle passes through the orifice, it causes increased resistance, which leads to a voltage pulse that is proportional to particle solid volume. The pulses can be calibrated to particles of known size. Multiple orifice sizes can be used to measure a broad size range, from approximately 0.5 to several hundred micrometers.

Some researchers have used this technique to study changes in PSDs during treatment and compare results to fundamental theories (i.e., Lawler et al., 1983; Darby and Lawler, 1990; Moran et al., 1993; Nason and Lawler, 2008). The need to dilute the sample with electrolyte and use multiple orifice tubes to characterize a PSD indicates that this technique is not practical for on-line or routine batch sampling at a water treatment plant, despite the method's advantages of a submicron lower size limit and detailed characterization of PSDs.

Measurements of Particle Stability

The stability of particles against aggregation or deposition to surfaces is a critical characteristic with respect to the performance of treatment processes. There are some direct and indirect analytical techniques related to stability that are useful in drinking water treatment.

Electrical Charge of Surfaces. The most common measurements related to particle stability are based on the electrical charge of particle surfaces. Electric potential fields imposed in an electrolyte solution (water sample) that contains charged particles will cause ions and those particles to move; similarly, movement of charged particles (and ions) relative to fixed electrodes can induce an electric current (or potential). These electroosmotic properties are utilized to characterize particles and other surfaces in water. For example, imposing an electric potential across a solution can cause a particle to have an electrophoretic mobility (or velocity) relative to the water. Fundamental theories then relate that mobility to the electric potential at the plane of shear between the particle and the water; this potential is referred to as the zeta potential (see Hunter [1981] and Chap. 8 for schematic of charged ions adjacent to a charged surface in water). Instruments measure electrophoretic mobility and calculate the zeta potential. Often, particles aggregate well when they have no net surface charge or a near zero zeta potential; measurements can help determine at what coagulant dosage this occurs. Streaming current instruments (detectors or monitors) are another useful technique for assessing surface charge. In this method, charged particles adhere to the surfaces of reciprocating (on a piston) and fixed electrodes, inducing an electric field and current that is proportional in magnitude and sign to the charge of the intermittently attached particles. Batch and on-line instruments are available. On-line streaming current detection is typically applied after coagulant chemical addition and rapid mixing and provides an excellent monitor of chemical dosing; measurements can also be utilized for automatic chemical dosing adjustments in certain circumstances (e.g., charge neutralization coagulation with limited or no oxidant addition).

Effectiveness of Destabilization. Most methods for assessing particle stability involve measuring the net impact of chemical addition to destabilize suspensions. The most common method is the use of jar tests in which different doses of coagulant chemicals are added to sample volumes (typically, 0.2–2 L) of raw water, the samples are mixed, and then solid-liquid separation is induced; gravity settling, dissolved air flotation, and filtration may be utilized (see Chap. 8 for description of jar testing). Measurements of turbidity, particles, and NOM are then used to determine the most effective chemical dose for treatment depending on both water quality and cost criteria. Although the absolute levels of particles in treated samples may not be the same as those achieved at full-scale, the relative performance of chemical dosing variation can be assessed and the degree of conversion of dissolved NOM to particulate form that will occur at full-scale can be quantified. Other laboratory-scale techniques to assess particle destabilization include use of small columns of porous filter media as well as direct assessment of particle aggregation via changes in light scattering. These laboratory techniques can be useful tools in assessing chemical dosing impacts as part of pilot-study design as well as ongoing process operation.

NATURAL ORGANIC MATTER

NOM in water can impart color to water, causing aesthetic effects, and react with disinfectants and oxidants, causing formation of DBPs and other by-products that can have health effects. NOM can cause fouling or interfere with some water treatment processes. In addition, NOM can have effects on the quality of water in the distribution system. Several water treatment processes deal with the removal of NOM. Thus, the importance of NOM is manifold. Its many effects are listed in Table 3-20, and the table also lists other chapters in the book where NOM is covered. The reader is directed to the following references for additional information on NOM: Thurman (1985), Suffet and MacCarthy (1988), and Stevenson (1995).

In the remainder of this section, some terminology is presented about sources of NOM, and this is followed by descriptions of the types and fractions of NOM. Next, material is summarized on collective measurement for NOM, the surrogate measurement of UV absorbance at 254 nm (UV_{254}), and characterization of NOM using specific UV absorbance (SUVA).

Sources

NOM is sometimes classified with respect to its origin. Autochthonous organic matter is produced within a water body. In terms of particulate organic carbon (POC), algae are a good example. In terms of dissolved organic carbon (DOC), proteins, amino acids, polysaccharides, and other organic matter produced from algal respiration and decay processes are examples. Allochthonous organic matter is that NOM not formed in the water body

TABLE 3-20 Effects of NOM on Water Quality and Drinking Water Treatment

Effect	Comments (primary chapters of coverage)
Natural color	Aquatic humic matter: Chaps. 3, 8, and 12
Coats inorganic particles in water supplies affecting their stability	Particles: Chaps. 3 and 8
Contributes to alkalinity for waters high in humic matter	Alkalinity is due mostly to inorganic carbon
Source of tastes and odors	Aesthetic parameter: Chaps. 6, 7, and 14
DBP precursors	DBP Formation: Chaps. 8 and 19
Metal complexation—increases metal solubility	For example, Fe is complexed with NOM in water supplies
Reacts with metal coagulants—coagulant demand	Chapter 8
Reacts with metals affecting their precipitation	Chapters 7 to 9, and 13
Reacts with oxidants causing oxidant demand	Chapter 7
Fouling of GAC adsorbers and membranes	Chapters 11 and 14
Reacts with chemical disinfectants—disinfectant demand	Chapter 17
Decreases effectiveness of UV disinfection	Chapter 18
Corrosion	Chapter 20
Carbon source for biofilm growth in distribution systems	Chapter 21

under study but formed elsewhere and transported to the water body. It comes from watershed runoff and from washing out of upstream water bodies, such as bogs, swamps, and reservoirs. The DOC associated with allochthonous origin is composed of aquatic humic matter and many other types of organic compounds. The types of organic compounds are addressed in the next section.

Types and Fractions

Table 3-9 lists various types of organic compounds that make up NOM. The aims of this section are to expand on the chemistry of types of NOM and to discuss in detail aquatic humic substances.

It is convenient to discuss two classes of NOM: aquatic humic matter and non-humic matter. Specific organic compounds can be identified and attributed to non-humic substances. These compounds can be simple plant by-products and metabolites, including tannins, phenols, carbohydrates, sugars and polysaccharides, proteins, amino acids, and fatty acids. Proteins and amino acids are common algal by-products. Non-humic compounds are lower in molecular weight than aquatic humic substances, most are aliphatic, some are acids, some are bases, and some are neutral (no charge from functional groups). Their origin can be allochthonous following rain events, but most are autochthonous. They are also susceptible to further decay.

The NOM that occurs in water bodies and comes from decay reactions of plant and animal matter that take place on the watershed, yielding a residual organic matter referred to as humic matter. Soils with a high organic content or areas containing peat impart aquatic humic matter during runoff events that enters water bodies. Likewise, bogs and swamps are high in aquatic humic matter that can enter downstream water bodies, especially following rain events. Aquatic humic matter refers to both aquatic humic and fulvic acids. Differences between humic and fulvic acids are discussed below, and details can be found in Thurman (1985), Suffet and MacCarthy (1988), and Stevenson (1995). Aquatic humic matter differs from soil humic matter because it is composed of soluble humic matter not retained by soils.

Chemical Properties of NOM Fractions. Measurements for specific organic compounds are rarely done in monitoring the quality of water supplies. Furthermore, aquatic and fulvic acids are a mixture of organic molecules but do have some common properties. There has been considerable work in characterizing NOM into fractions, thereby yielding insight of certain chemical properties. A method developed by Leenheer and Noyes (1984) has been used widely and adapted (e.g., Bose and Reckhow, 1998). With this method, NOM is fractionated into eight fractions: fulvic acid, humic acid, and six non-humic ones. Aquatic humic and fulvic acids are of particular interest and are discussed in detail below. The non-humic fractions are found in all water supplies, and in some cases are the dominant fractions compared to humic substances. Examples of organic substances that compose the non-humic fractions include

- Weak hydrophobic acids: phenols, tannins, intermediate MW alkyl carboxylic acids
- Hydrophobic bases: proteins, aromatic amines, high MW amines
- Hydrophobic neutrals: hydrocarbons, aldehydes, high MW methyl ketones, alkyl alcohols, ethers
- Hydrophilic acids: hydroxyl acids, sugars, low MW alkyl carboxylic acids
- Hydrophilic bases: amino acids, purines, pyrimidines, low MW alkyl amines
- Hydrophilic neutrals: polysaccharides, low MW alkyl alcohols, aldehydes, ketones

The non-humic compounds are not removed as well as humic substances by coagulation, clarification, and filtration, but some removals do occur. Guidelines on removals of NOM are presented later in this section. Some of these compounds may be adsorbed on granular activated carbon (GAC) or oxidized by ozone to varying degrees, aiding removal by adsorption and biodegradation.

Humic and Fulvic Acids. Aquatic humic matter is an important fraction of NOM. In many water supplies it is the dominant fraction of NOM. When the TOC is more than a few mg/L, the presence of humic matter gives water a yellow-brown color. However, for water supplies in which the yellow-brown color is low, aquatic humic matter can still be an important fraction of TOC. Humic and fulvic acids are not specific molecules because they result from the decomposition of organic matter. These acids are recalcitrant in nature and have a range of molecular weights. Humic acid is more aromatic than fulvic acid. Humic acids have higher molecular size and weight, in the 1000s, compared to fulvic acids, which are only several 100. Regarding specific information on the molecular weight of aquatic fulvic acid, Perdue and Ritchie (2003) give an average of about 650 and a fairly narrow range of 540 to 900. Aquatic humic and fulvic acids have similar C, H, and O composition of about 50, 5, and 40 percent, but humic acid has a greater N content of about 2 percent compared to fulvic acid at about 1 percent. You would expect to find a greater amount of aquatic fulvic acid than humic acid in water because it is more soluble in water with its lower molecular weight, and consequently, humic acid is retained in soils to a greater degree.

A model structure for aquatic humic matter is shown in Fig. 3-14. Aquatic humic matter is a generic term referring to either humic or fulvic acids. The structure of aquatic humic substances portrayed in Fig. 3-14 shows that these substances contain acidic carboxyl and phenol-OH groups. These acid groups can donate protons (H^+), creating negatively charged macromolecules. The dissociation of the carboxyl groups occurs at fairly low pH conditions so that for the pH range of natural waters, aquatic humic matter carries a substantial negative charge. Figure 3-15 shows the charge density of fulvic acid as a function of pH.

FIGURE 3-14 Hypothetical model structures of aquatic humic matter. [Source: Thurman (1985) reprinted with permission from Springer, Copyright 1985, Dordrecht, Netherlands]

FIGURE 3-15 Aquatic Fulvic Acid Negative Charge Density as a Function of pH. [Figure developed from data in Van Benschoten (1988).]

The figure indicates that at about pH 7, the negative charge is approximately 10 µeq/mg of DOC. This negative charge is high compared to the negative charge associated with clay minerals and organic particles, such as algae, protozoan cysts, bacteria, and viruses. This high negative charge affects coagulation processes. In the example that follows, the negative charge associated with NOM and particles are discussed.

Example 3-6 Charge on Particles versus NOM

In this example we compare the negative charge associated with particles and compare it to the charge on aquatic fulvic acid. Clay minerals are used as model particles because they cause mineral turbidity, and in the past they have been viewed as important in controlling coagulation dosing. There are various types of clay minerals and so their negative charge density (analogous to a cation exchange capacity) lies in the range of 0.05 to 0.5 µeq/mg (microequivalents of negative charge per mg of clay). It is reasonable to assume that organic particles such as algae, bacteria, and protozoan cysts have negative charges equal to or less than those of clays. The charge on aquatic fulvic acid depends on pH, as shown in Fig. 3-15. In this example, a negative charge density of 10 µeq/mg (microequivalents of negative charge per mg of DOC or TOC) is used in the calculations.

Calculate the negative charge for a water supply containing clay at a mass concentration of 3 mg/L (say, turbidity of 10 ntu). Compare it to the negative charge of a water containing NOM at a TOC (DOC) of 3 mg/L in which only 50 percent of the NOM is aquatic fulvic acid, and the rest of the NOM is composed of non-humic organic matter without a charge.

Solution Clay particles have charge densities of 0.05 to 0.5 µeq/mg; a mid-range charge density of 0.1 µeq/mg is used for the water supply containing mineral turbidity.

$$\text{Particle negative charge} = 0.1 \frac{\mu\text{eq}}{\text{mg}} \times 3 \frac{\text{mg}}{\text{L}} = 0.3 \frac{\mu\text{eq}}{\text{L}}$$

For the water supply containing NOM at a TOC of 3 mg/L, but only 50 percent of the TOC is aquatic fulvic acid with a negative charge density of 10 $\mu\text{g}/\text{mg TOC}$:

$$\text{NOM negative charge} = 10 \frac{\mu\text{eq}}{\text{mg TOC}} \times 0.5 \times 3 \frac{\text{mg}}{\text{L}} = 15 \frac{\mu\text{eq}}{\text{L}}$$

The results of the calculations show that the NOM in a water supply has a negative charge that is about 50 times greater than the charge associated with particles. Obviously, the concentrations of particles and NOM can vary among water supplies, but in fact in many water supplies, the NOM has a far greater negative charge associated with it than particles, and this negative charge must be effectively neutralized by coagulation. In short, for many water supplies, coagulant dosing is controlled by NOM and not turbidity (see Chap. 8). ▲

Collective Measurements of Organic Carbon

TOC is the total concentration of organic carbon in water and is composed of DOC and POC. Measurement of DOC is an operational definition because samples are filtered through 0.45 μm pore size filters (other filters are often used such as glass fiber filters with nominal pore sizes of 1.2–1.5 μm) to obtain this fraction of organic carbon. DOC is defined as the organic carbon measured in what passes the filter. However, it may not be the true dissolved phase of organic carbon since colloidal organic matter smaller than the filter's pore size can pass through the filters. In spite of some possible error in measuring DOC, in the water field we accept this operational definition for DOC. POC is defined as the TOC minus the DOC. NOM in the particulate form (POC) can be attributed to viruses, bacteria, algae, other plant matter, and organic detritus. The largest contributor for surface waters is algae, especially in lakes and reservoirs. However, the POC of surface waters is low compared to TOC, usually less than a few percent except for eutrophic lakes. In summary, the DOC composes 90 to 99 percent of the TOC for surface waters used for drinking water. For groundwaters, POC is nearly zero so the DOC is essentially equal to the TOC.

Table 3-21 summarizes ranges and means for TOC concentrations for various types of waterbodies. One can see that rivers and streams can have a wide range in TOC, typically

TABLE 3-21 TOC Concentrations in Various Waterbodies (Based on Authors' Experience and Thurman (1985), Eby (2004), Ogawa and Tanoue (2003); ICR (Information Collection Rule Data from USEPA (2005))

Waterbody	Range (Mean)	Other
Groundwater	0.5–10 (0.7)	Many groundwaters are 2 mg/L or less
Rivers and streams	1.5–20	Typically 5 mg/L or less; higher values downstream of bogs, marshes, and swamps; some can exceed 20 mg/L
Oligotrophic lakes	1.0–3.0 (2.2)	
Mesotrophic lakes	2.0–4.0 (3.0)	
Eutrophic lakes	3.0–30 (12.0)	
Marsh	17.0	Typical
Bog	33.0	Typical
Seawater	0.72–0.96 (DOC) 1–5 (TOC)	In upper 100 m for the oceans except the Antarctic Ocean; lower DOC in deep ocean waters Typical range for upper waters and depends on algae concentration and oil spills

from 1.5 to 20 mg/L. Generally, high TOC of greater than 5 to 7 mg/L occurs primarily in these sources when they are influenced by upstream bogs and marshes. In fact, some rivers and streams that are influenced by bogs and swamps can exceed 20 mg/L TOC. For smaller lakes and reservoirs, the TOC concentrations are influenced by the watershed, so a significant fraction of the TOC can have an allochthonous origin. For larger lakes and reservoirs in watersheds in which upstream bogs are not significant, the trophic state of the lake affects the TOC concentration, and a large fraction of the TOC can be autochthonous. As indicated in Table 3-21, oligotrophic lakes (those low in nutrients and algae biomass) have the lowest TOC concentrations. As lakes and reservoirs progress to mesotrophic and eutrophic states, the TOC increases due to the effect of algae. Groundwaters have a low mean concentration of TOC. However, shallow groundwater systems can have higher TOC when under the direct influence of surface waters. Other groundwaters can have high TOC when affected by peat deposits or have other unique characteristics such as some groundwaters in Florida and parts of southern California. Excluding these latter cases, generally the TOC of groundwaters is about 2 mg/L or less.

UV₂₅₄ Absorbance as a Surrogate Parameter for DOC and TOC

Edzwald et al. (1985) showed that UV₂₅₄ can be used as a surrogate parameter for and predictor of DOC, TOC, and trihalomethane (THM) precursors. They also demonstrated its usefulness in monitoring water treatments plants for the removals of TOC and THM precursors. Over the years, UV₂₅₄ has found increasing acceptance and is now widely used for the purposes cited above, and it is also used for setting coagulant dosages for water supplies in which TOC controls coagulation (Edzwald, 1993; Edzwald and Kaminski, 2009) and for monitoring removals of organic matter by GAC and membrane processes. Measuring UV₂₅₄ is simple, rapid (grab sampling or on-line instrumentation), and inexpensive making it a good surrogate parameter. Details on its measurement can be found in *Standard Methods* (APHA, AWWA, and WEF, 2005).

UV light at 254 nm is absorbed by a variety of organic and inorganic molecules, but especially organic compounds with an aromatic structure or compounds that have conjugated C=C double bonds. Aquatic humic matter has these structural features so they absorb more light per unit concentration of DOC (called the specific UV absorbance, or SUVA) than other types of NOM in water supplies, such as hydrophilic acids, hydrophobic bases (e.g., proteins and aromatic amines), and hydrophobic neutrals (e.g., aldehydes); see Edzwald (1993) and Bose and Reckhow (1998). Because the C=C double bonds are sites for donating electrons, oxidants and disinfectants attack and chemically react with these compounds, making UV₂₅₄ a particularly good surrogate and predictor of DBP formation and oxidant demand (ozone and other oxidants and chlorine demand). As stated above, coagulation is controlled by TOC for many water supplies and so UV₂₅₄ can be related to coagulant dosing (Chap. 8). Some water treatment plants operate their coagulant dosing based on achieving a treated water UV₂₅₄ goal (Edzwald and Kaminski, 2009).

Figure 3-16 illustrates the utility of UV₂₅₄ as a surrogate for TOC for two water plants (Edzwald and Kaminski, 2009). The data used to develop the correlations and prediction equations were water treatment plant monthly TOC and UV₂₅₄ measurements on both raw and treated waters. The advantages of pooling the raw and treated water data are that it provides a wide spread in the variables and provides the water plants with the ability to predict raw and treated water TOC concentrations. The two plants control coagulant dosing to achieve UV₂₅₄ (routinely measured as coagulant operating parameter) goals of 0.03 to 0.035 cm⁻¹ that correlates with TOC ≤ 2 mg/L.

What are raw water UV₂₅₄ levels for water supplies? These can vary from about 0.04 cm⁻¹ for water supplies low in TOC and aquatic humic matter to about 0.8 cm⁻¹

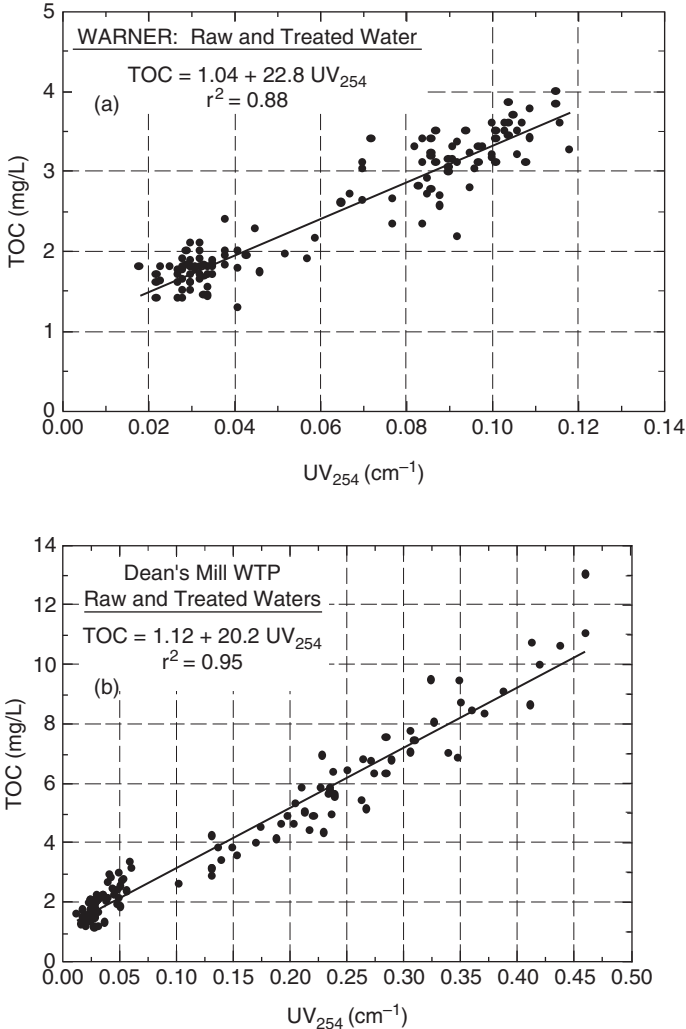

FIGURE 3-16 TOC versus UV_{254} correlation for the Warner and Dean's Mill water plants for the period of 2002–2006. (Source: Edzwald and Kaminski (2009), reprinted with permission from the Journal of the New England Water Works Association, Copyright 2009, Holliston, MA.)

for water supplies high in TOC and aquatic humic matter. Many water supplies are in the range of 0.07 to 0.3 cm⁻¹, which corresponds to TOC concentrations of approximately 2 to 7 mg/L, depending on the SUVA of the NOM in the water. Treated water UV_{254} values depend on the extent of TOC removal and the water treatment process. For GAC and nanofiltration and reverse osmosis membranes, low TOC and thus UV_{254} values are achieved (<0.02 cm⁻¹). Edzwald and Kaminski (2009) have shown that full-scale treatment plants operating with good coagulant dosing for particles (turbidity) and TOC removals achieve UV_{254} of 0.023 to 0.033 cm⁻¹, corresponding to treated water TOC of 1.5 to 2 mg/L.

Finally, it is recommended that treatment plants set treated water UV_{254} goals of 0.02 to 0.035 cm^{-1} . These goals apply prior to oxidant or chlorine addition; oxidants and chlorine reduce UV_{254} without removing TOC.

Specific UV Absorbance

SUVA was first developed by Edzwald et al. (1985) to evaluate whether TOC and DBP precursor concentrations could be correlated with UV_{254} . Further development of the utility of SUVA occurred and guidelines were presented relating raw water SUVA values to the NOM composition of water and the ability of coagulants to remove TOC (Edzwald and Van Benschoten, 1990; Edzwald, 1993). SUVA provides a simple way to characterize the nature of NOM and is calculated from measurements of UV_{254} and DOC—samples are filtered. SUVA values are expressed in units of m^{-1} absorbance per mg/L of DOC.

$$SUVA = \frac{(UV_{254} \text{ in } \text{cm}^{-1}) 100 \frac{\text{m}^{-1}}{\text{cm}^{-1}}}{(\text{DOC in mg/L})} \tag{3-64}$$

As presented above, certain types of NOM absorb UV_{254} light per unit concentration of DOC to a greater degree than other types. Therefore, SUVA is an indicator of the NOM composition of water (Edzwald, 1993; Bose and Reckhow, 1998). SUVA values follow for the following types of NOM: 5 to 7 for humic acid, 3 to 4 for fulvic acid, < 4 for hydrophilic neutrals, about 3 for hydrophilic bases, about 1 for hydrophilic acids, and 1 or less for hydrophobic bases and neutrals. Water supplies contain a mixture of types of NOM, but the SUVA can provide an indication of what types of organic compounds dominate. Guidelines on the composition of NOM for raw waters with respect to three ranges of SUVA are presented in Table 3-22. This table is an updated version of what originally appeared in Edzwald and van Benschoten (1990) and later in Edzwald (1993).

TABLE 3-22 Characterization of NOM and TOC Removals for SUVA Values for Raw Water Supplies

SUVA	Composition	Effects	TOC Removals by coagulation
>4	High fraction of aquatic humic matter High aromatic and hydrophobic character High molecular weight (MW)	High UV absorbance High oxidant and chlorine demand	60–80% Higher end for waters with high TOC
2–4	Mixture of aquatic humic and non-humic matter Mixture of aromatic and aliphatic character Mixture of low to high MW	Medium UV absorbance Medium oxidant and chlorine demand	40–60% Higher end for waters with high TOC
<2	High fraction of non-humic matter High aliphatic and low hydrophobic character low MW	Low UV absorbance Low oxidant and chlorine demand	<20–40% Higher end for waters with high TOC

Water supplies with high SUVA values of 4 or greater indicate that the NOM is composed mainly of aquatic humic matter. Raw waters with SUVA of 2 to 4 contain a mixture of aquatic humic matter and non-humic NOM. Raw waters with $SUVA < 2$ contain mainly non-humic material with properties shown in Table 3-22. Table 3-22 also shows expected TOC removals by coagulation indicating greater removals for higher SUVA waters.

Figure 3-17 shows data over a five-year period for a raw water supply. The TOC of this supply varies from about 2.5 to 13 mg/L. The UV_{254} data follow the variation in TOC and can predict it as previously shown in Fig. 3-16b. The SUVA data are also plotted in Fig. 3-17 and vary from 3.2 to 5.6, with a mean value of 4.3. This water supply has bogs in the watershed yielding NOM with a large fraction of aquatic humic matter and high TOC and UV_{254} following heavy rains that flush the upstream bogs.

In water supplies with high SUVA, the NOM has C=C bonds that contain electrons, and as a result, oxidants and disinfectants will attack and react at these chemical groups. Therefore, water supplies with high SUVA will have greater chlorine demand, greater oxidant demand, and greater DBP formation.

Water treatment processes such as coagulation and adsorption will preferentially remove aquatic humic matter or NOM; consequently, the SUVA of treated waters is much lower than that of raw waters. Treated water SUVA values of 2 or less indicate good removal of NOM.

Measurements of NOM for Water Utilities

Water utilities are required to make monthly measurements of TOC for the USEPA Enhanced Coagulation requirements (see Chaps. 1 and 8). It is highly recommended that water utilities collect monthly data from the same TOC samples for raw and finished water DOC and UV_{254} . From these data, utilities should develop correlations between TOC and UV_{254} so that they can use daily raw water and finished water UV_{254} measurements to predict raw water and finished water TOC concentrations; see Fig. 3-16 and discussion above. Additional correlations between DOC and UV_{254} are useful. Using these data, water utilities can develop finished water UV_{254} goals by making correlations to their TOC goals. As stated earlier, recommended guidelines for treated water UV_{254} are 0.02 to 0.035 cm^{-1} . These goals apply prior to oxidant or chlorine addition; oxidants and chlorine reduce UV_{254} without removing TOC. Treatment plants that use oxidants in pretreatment or in intermediate treatment must collect samples to assess the effect of the oxidant on UV_{254} .

FIGURE 3-17 Raw water TOC, UV_{254} , and SUVA for the Dean's Mill water plant.

Water utilities should also calculate SUVA from their DOC and UV_{254} measurements. Utilities can use raw water SUVA values to determine the fractions of humic matter and non-humic matter in their source water. This was discussed earlier along with the presentation of Table 3-22 and Fig. 3-17. SUVA values also allow utilities to determine expected TOC removals for good coagulation according to the guidelines in Table 3-22. In the previous discussion of SUVA, it was noted that TOC removal processes generally selectively remove aquatic humic fractions, leaving hydrophilic TOC of low molecular weight behind in the finished water. Consequently, the finished water SUVA should be 2 or less and should indicate how well the treatment plant removed the humic matter fraction of TOC. As mentioned above, because oxidants can reduce UV_{254} (without removing DOC), SUVA can be reduced by oxidation. Water utilities should assess the effect of any oxidants on SUVA.

In summary, TOC and DOC should be measured by water utilities on a monthly basis (at minimum) in accordance with the USEPA Enhanced Coagulation requirements. Some utilities may wish to make these measurements more frequently, perhaps weekly basis, in order to capture changes in NOM that may occur in rivers and reservoirs with small watersheds where frequent changes in water quality occur and where seasonal effects and rainfall wash organic matter from the land into supplies. Raw and finished water UV_{254} should be measured on a daily basis and used as a surrogate parameter and predictor of TOC.

There are various other NOM characterization measurements that water utilities can make that provides information on the NOM chemical and physical properties. These are classified as more of a research nature rather than routine water plant operational measures for monitoring and controlling NOM. These include measurements that provide information on the NOM fractions with respect to hydrophobic versus hydrophilic characteristics and acid, base, and neutral fractions (listed earlier in the section, Chemical Properties of NOM Fractions). Other characterization methods are those that give information on molecular weight, charge, elemental composition, and functional groups—the reader is referred to the general references cited at the beginning of the section on NOM and in a new publication by Reckhow (2010) that summarizes various methods. Water utilities can also evaluate the reactivity of NOM to disinfectant dosing and develop models to predict raw water DBP precursors and finished water DBPs from TOC, UV_{254} , and other measurements; see Edzwald et al. (1985) and Chap. 19.

SOURCE WATER SELECTION AND PROTECTION

This section summarizes important principles related to the selection and protection of drinking water sources. Source selection is relevant to development of new sources in areas with increasing water demand. Source protection is important for all sources. The focus is water quality, the topic of this book, not water quantity.

Selection of Source Water

The selection and development of a source of drinking water is often challenging and depends on many factors, including water demand, climate, geography, geology, availability, yield, cost, social and political factors, and water quality. From the perspective of protecting public health and minimizing treatment costs, selection of the best or highest quality source of supply is desirable. This principle of “best available source” was frequently advocated by long-time educator, researcher, and engineer Daniel Okun, as described in an opinion article (Okun, 1991). Okun cited regulatory statements by the U.S. Public Health Service (in 1962) and the USEPA (in 1976) that direct water suppliers to choose the best quality source and to protect that source, subject to economic feasibility constraints.

The best available source concept evolved during the twentieth century from focusing on water quality concerns related to the acute risks to public health from pathogenic microorganisms to focusing on the risks associated with long-term exposure to low levels of chemical contaminants from most, but not all, anthropogenic sources. There is sound logic to avoiding sources with an ever increasing number of measurable contaminants, many of which have unknown health impacts. Selecting well-protected, pristine sources can minimize the types and amounts of possible anthropogenic contaminants and minimize treatment costs along with unknown health impacts.

Along with the best available source concept are the level, density, and location of humans on the watershed. The expanding population increases total amounts of anthropogenic inputs to local, regional, and global hydrologic cycles while decreasing the available land area that could be used to protect surface and groundwaters. In some cases, such as Boston, MA, and New York City, a dense urban population can be provided with drinking water from relatively pristine sources due to favorable climate (available precipitation) and allocation of significant land area for collection, storage, and transmission of the source water, usually from a significant distance. In contrast, large human populations may exist in arid regions and others areas where climate, geography, and human activity make selection of a pristine source technically or economically infeasible. In such cases, the best available source is not pristine, and more extensive treatment technologies must be utilized to provide potable water. Historical treatment process selection reflects water quality impacts of pristine versus non-pristine sources. Protected upland surface waters of pristine quality often require less treatment, i.e., slow sand filtration or conventional coagulation and filtration or in some cases, only disinfection alone. However, treatment for a major downstream run-of-river source may include advanced oxidation and adsorption processes in addition to conventional processes to remove anthropogenic contaminants. More often than not, large, dense urban populations must use non-pristine sources for drinking water due to economic and other factors.

The penultimate non-pristine drinking water source is wastewater generated from human activity, often referred to as water reuse (Chap. 16). In such cases, wastewater is extensively treated prior to being directly or indirectly (via aquifer recharge or discharge to a surface water with non-wastewater derived sources) used as a drinking water source. Examples of near direct reuse of treated wastewater include NEWater in Singapore for industrial uses (as well as for indirect potable uses) and the New Goreangab water reclamation plant in Windhoek, Namibia, which directly augments the potable drinking water supply. An important, long-term example of aquifer recharge with extensively treated wastewater is the Orange County (CA) Water District facility. Discharge of treated wastewaters to surface waters is common such that all “downstream” uses for water supply are indirect reuse. The degree of public concern and attention may be associated with the time between discharge and reuse as well as the relative dilution with more pristine water. Two very different examples include the discharge of treated wastewater from Las Vegas, NV, into Lake Mead from which the city also obtains its raw drinking water source, and the discharge of highly treated low flows of wastewater into the rather pristine upland reservoirs in the supply system for New York City. The major long-term obstacle in the use of wastewater as a drinking water source is the need to remove dissolved constituents, which occur due to use of water to convey waste, from the wastewater. For potable reuse of wastewater, engineers use technology to simulate the natural hydrologic processes of evaporation and condensation of essentially pure water, i.e., desalination. Significant problems are the energy associated with desalination as well as the reject or waste stream containing very high levels of salts.

Not surprisingly, there is growing use of waters of different qualities for different purposes, especially where a sufficient quantity of potable drinking water is not available for all uses. This could be considered a “best suitable source for the purpose” approach. Okun, a proponent of the “best available source,” was also an early and frequent proponent of

dual water distribution systems, with one system for potable water and one for non-potable water suitable for fire fighting, irrigation, toilet flushing, and similar uses (Okun, 1997). Such an approach can be applied on a community level or for a specific recreational, commercial, or industrial facility.

Source Protection—General

Protection of the quality of natural drinking water supplies is an important and significant objective for most water utilities. Most importantly, source water protection serves as a barrier for protection of public health via minimization of health risks associated with water pollution. In addition, source water protection best management practices (BMPs) are implemented to maintain or improve source water quality such that the cost of drinking water treatment is decreased (Pyke et al., 2003).

Point-Source Control. The federal, state, and local laws and regulations governing the point-source discharge of wastewater and, in certain cases, stormwater runoff are significant for source water protection. The Clean Water Act, originally known as the Federal Water Pollution Control Act, requires the USEPA to regulate and monitor point-source discharges of wastewater via the National Pollutant Discharge Elimination System (NPDES) permit system; this is frequently implemented by state agencies. Required levels of wastewater treatment are based on either technology or water quality, depending on the source of the discharge and the type of environment, usually aquatic, being discharged to. Extensive levels of wastewater treatment may be required based on water quality needs for protection of ecosystems and human health. Traditionally, the assimilative capacity of the receiving aquatic environment with respect to nutrients (N, P), oxygen demand, and pathogens and the required quality for the intended use of the receiving water have been considered in establishing water quality based discharge permit requirements. Thus, a wastewater discharge to a protected drinking water supply reservoir has warranted much more extensive treatment than a discharge to a major river that may or may not be used as a drinking water source.

More recently, concerns have increased with respect to the wide range of low-level contaminants in wastewater that have not been regulated or monitored, so-called contaminants of emerging concern, including pharmaceuticals and personal care products (PPCPs) and EDCs. Despite limited knowledge of the potential health impacts of such contaminants (see Chap. 2), significant research is being directed at assessing and controlling sources, assessing treatment efficacy, and monitoring contaminant levels in the environment. Consequently, activities to eliminate or limit discharges of treated wastewater to drinking water sources are a source water quality protection measure, yet such activities may be infeasible or undesirable from a water quantity perspective. In all cases, reasonable control of contaminant inputs to wastewaters is desired (i.e., non-water based disposal and reuse methods).

Nonpoint Source (Diffuse) Pollution. The control of source water pollution from non-point or diffuse sources is often more challenging than the control of point-source inputs. Diffuse contaminants can be input via atmospheric deposition (dry and with precipitation), stormwater runoff and infiltration, subsurface wastewater disposal (i.e., septic systems), and leakage from subsurface storage tanks and pipes. Novotny (2003) provides a comprehensive look at water quality related to diffuse pollution. In contrast to application of treatment technology for point-source discharges (so-called end-of-pipe solutions), control of nonpoint source pollution often involves source control, land use management, and application of ecological engineering principles in order to make sustainable use of natural resources and in turn control contaminant inputs.

Watershed Protection

Watershed protection or management generally refers to activities performed on a topographically and hydrologically defined land area (the watershed) to protect surface water quality. A classic example for drinking water is the topography-based watershed area, or basin, from which surface water runoff can enter a reservoir that was created by impounding a stream or river. Transfer of water between watersheds, or groundwater input and output, can create additional hydrologic-based definitions of a watershed management area. The fact that governmental boundaries (town, county, state, country) often do not coincide with watershed boundaries can present a significant challenge to implementing watershed protection activities. However, this can also present a significant opportunity for citizens to work cooperatively across such boundaries for a common goal. Effective management results when governments create watershed based organizations, such as a water utility, to coordinate watershed activities.

Watershed protection or management plans can take many forms but usually involve identifying possible hazards, identifying hazard mitigation activities, implementing activities, and monitoring the impacts of activities (Novotny, 2003; MA DCR, 2008). Hazards can be identified by routinely conducting a traditional sanitary survey of the watershed to identify locations and sources of contaminants and by careful understanding of watershed geology, topography, vegetation, and land use. Hazards include the potential for natural disaster (hurricanes, flooding) and for pollutant input from human activity. Mitigation activities include land acquisition, control of land use, implementation of best management practices for specific uses (i.e., agricultural), elimination of contaminant sources, and preparation for emergency response. Examples of specific contamination issues include agricultural-based phosphorus inputs (Sharpley et al., 1994) and sources of protozoan pathogens (LeChevallier et al., 1991).

Management and protection of the upland watersheds for the drinking water supplies for New York City (NYC) are very complicated and comprehensive. A National Academy of Sciences (NAS) committee chaired by Dr. Charles R. O'Melia studied the NYC watershed protection plan in light of the potential filtration requirements by the USEPA SWTR (Committee to Review NYC, 2000). NYC is building a coagulation, dissolved air flotation, media filtration, and UV disinfection facility for the Croton watershed source water, while water from the Catskill and Delaware (Cat-Del) sources—the majority of the NYC supply—will be treated via UV and free chlorine disinfection only. Implementation of land acquisition, management of land use (especially agricultural practices), partnership programs with local communities, and extensive treatment of wastewater discharges are utilized by the NYC Department of Environmental Protection (DEP) to maintain the high quality of the Cat-Del source water such that treatment beyond disinfection is not yet required. In order of priority, the NAS report recommended a focus on control of sources of pathogenic microorganisms, NOM precursors to disinfection by-products, phosphorus and turbidity (sediment). The NAS report also recommended that NYC DEP be open to the need for additional treatment and to take a lead role in developing data to document the role of watershed protection activities in reducing public health risk. Specific activities undertaken by NYC to maintain and improve watershed protection are documented in annual reports (e.g., NYC DEP, 2009).

In the United States, watershed-based water quality protection activities have been mandated from a wastewater discharge perspective, for example, under the Section 308 river basin planning portion of the Clean Water Act. Comprehensive consideration of all hydrological activities in a watershed has not typically been undertaken in the United States, although some states have done so (e.g., Massachusetts during approximately 2000 to 2005). In contrast, the United Kingdom has a long history of dividing the country into river basin areas for management of water resources, while the European Union Water Framework Directive of 2000 emphasizes river-basin-based management plans for all member states.

Aquifer Protection

Aquifer protection typically refers to specific activities undertaken to protect the quality and quantity of groundwater sources of drinking water. As described earlier in this chapter, natural groundwater quality is dependent on the geology of the subsurface material from which the water is withdrawn. Specific human activities such as subsurface wastewater disposal, deep-well injection of wastewater, improper underground disposal of wastes, and leaking of wastes from underground tanks and pipes can impact groundwater quality. Natural infiltration of surface water of impaired quality can also impact groundwater quality.

The subsurface water environment is especially challenging to understand and manage, because it is largely unseen and usually spatially non-homogeneous. Understanding the transport and fate of contaminants requires study of groundwater hydrology (Todd and Mays, 2005). Specific activities undertaken to protect and improve groundwater quality include control of risks within the land area near a well (i.e., aquifer protection zones with usage restrictions), treatment to improve the quality of waters infiltrated or pumped into the subsurface, remediation of previously contaminated subsurface material, and hydraulic activities to control the influence of undesirable groundwater quality on water withdrawals (e.g., pumping to prevent saltwater intrusion). Schmoll et al. (2006) cover protection of groundwater from a human health perspective in their book.

ABBREVIATIONS

Acy	acidity
Alk	alkalinity
ANC	acid-neutralizing capacity
BMP	best management practice
DBPs	disinfection by-products
DEP	Department of Environmental Protection
DO	dissolved oxygen
DOC	dissolved organic carbon
EDC	endocrine disrupting compound
EMF	electromotive force
GAC	granular activated carbon
ICR	Information Collection Rule
LT1ESWTR	Long Term 1 Enhanced Surface Water Treatment Rule
LT2ESWTR	Long Term 2 Enhanced Surface Water Treatment Rule
NAS	National Academy of Sciences
NOM	natural organic matter
NPDES	National Pollutant Discharge Elimination System
ntu	nephelometric turbidity units
NYC	New York City
MW	molecular weight
ORP	oxidation reduction potential
PAC	powdered activated carbon
POC	particulate organic carbon
PCCPs	pharmaceuticals and personal care products
PSD	particle size distribution
SUVA	specific ultraviolet absorbance
SWTR	Surface Water Treatment Rule
TDS	total dissolved solids

THM	trihalomethane
TOC	total organic carbon
USEPA	U.S. Environmental Protection Agency
USGS	U.S. Geological Survey
UV ₂₅₄	ultraviolet absorbance at 254 nm
VOC	volatile organic compound
zpc	zero point of charge

NOTATION FOR EQUATIONS

a	activity of the chemical species
A	constant in Davies equation, or gas phase and dissolved gas phase
C	molar or mass concentration
d	diameter
E	electric potential for redox reactions
E^o	standard electric potential for redox reactions
H	Henry's law constant (atm/molar)
H^*	Henry's law constant (molar/atm)
F	Faraday constant (96.485 kJ V ⁻¹ mole ⁻¹)
I	ionic strength
K	equilibrium constant
N	number concentration
P	pressure
Q	reaction quotient for a chemical reaction
R	universal gas constant (8.314 J/mole · K).
S	surface area
T	absolute temperature in K (0°C = 273.15 K)
V	volume
Z or z	charge of the ion
α	fraction of the chemical species
ΔH_r^o	standard enthalpy of the reaction
ϵ	dielectric constant
γ	activity coefficient
κ	conductivity
ρ	density

INTRODUCTION

The treatment processes at the heart of the production of safe drinking water almost always occur in continuous flow reactors. How water flows through those reactors can have a remarkable influence on the treatment efficiency that is achieved. This fact is well understood in the case of disinfection, where it is embedded in the regulations of the Safe Drinking Water Act (SDWA) in the United States. However, the same principles apply for essentially all of the treatment processes in a drinking water treatment plant. In this chapter, we first explain the common descriptions of the hydraulic characteristics of reactors, beginning with ideal flow reactors and proceeding to non-ideal flow reactors; this hydraulic characterization primarily consists of determining the residence time distribution. Subsequently, the ramifications of the different flow characteristics (or different residence time distributions) for some types of chemical reactions are explained, with reference to specific common water treatment objectives.

CONTINUOUS FLOW REACTORS: IDEAL AND NON-IDEAL FLOW

A typical water treatment plant for a surface water pumps water through a pipe from the source (lake, reservoir, river, or stream) to a series of reactors, usually consisting of a rapid mix tank (where chemicals are added to the water for a variety of purposes), flocculation tank(s), sedimentation or flotation tanks, either granular media or membrane filters, and a clearwell that serves both as a disinfection reactor and a flow equalization basin. In most of these cases, all of the water flows into the reactor in a single stream and likewise flows out of the reactor in a single stream. An exception is the sedimentation or flotation unit, which has a single influent stream but two effluent streams, one for the clarified water (which contains most of the water and few particles) and one for the residuals (which contains a small fraction of the water and most of the particles). Because the residuals stream in such reactors is such a small fraction of the water flow, it can often be ignored in the characterization of the overall water flow. Granular media or (dead-end) membrane filters have a periodic backwash that creates a residuals stream, but while treating water, they have only a single effluent. Therefore, for most of the analysis that follows, we consider all reactors to have a single influent and single effluent stream.

Some reactors are designed to promote mixing while others attempt to prevent mixing as much as possible. In this context, mixing is taken to mean the extent to which the water (and any constituents in the water) that comes into the reactor in some small increment of time (say 1 s or 0.001 s) mingles with water that comes into the reactor at any other time (before or after the increment of focus). At one extreme, absolutely no mixing of one entering packet with any other packet occurs, and every packet travels from the influent to the effluent without any exchange of water molecules with any other packet. A reactor with this type of flow pattern is known as a segregated flow reactor; a *plug flow reactor* is a special type of segregated flow reactor in which all packets have the same residence time within the reactor; there is no mixing up of packets in the direction of flow. A plug flow reactor is often thought of as a conveyor belt. Just like boxes on a conveyor belt do not pass one another or exchange material between one another, the packets of water that enter the reactor sequentially stay in the same order and do not exchange water molecules with one another.

At the other extreme, we can imagine complete and instantaneous mixing of every new packet of water entering a reactor with *all* of the water already in the reactor; this type of

reactor is known as a *continuous flow stirred tank reactor* (CFSTR) or as a *continuous flow completely mixed reactor* (CFCMR); although the latter term is perhaps more precise, we follow tradition and refer to such a reactor throughout this book as a CFSTR. Because water is not only entering but also constantly being removed from the reactor, some molecules go essentially directly from the influent to the effluent and spend very little time (and, in the limit, zero time) in the reactor. On the other hand, some molecules of water continually get mixed with new incoming water and escape being in the packets of water leaving the reactor for a very long time, far longer than the theoretical detention time (τ) of the reactor, defined as

$$\tau = \frac{V}{Q} \quad (4-1)$$

Here V is the volume of water in the reactor and Q is the volumetric flow rate of water entering and leaving the reactor. Although the distribution of residence times of different molecules of water in this second type of ideal reactor flow is (probably) not intuitively obvious to the reader, quite clearly it is very different from the plug flow reactor where every water molecule stays in the reactor for the same amount of time. The residence time distribution of a CFSTR is developed subsequently.

Between the two ideal extremes of the plug flow reactor (zero mixing in the direction of flow) and the continuous flow stirred tank reactor (complete and instantaneous mixing of the entire contents of the reactor) is a broad spectrum with some, but incomplete or non-instantaneous, mixing of the influent with the water in the reactor. This spectrum constitutes non-ideal flow. Although the ideal extremes are difficult to accomplish in reality, they are useful concepts and can be approached quite closely in real reactors. Throughout the chapter, the behavior in ideal reactors is used to frame that in non-ideal reactors.

TRACER STUDIES

The primary hydraulic characteristic of interest in most cases is the residence time distribution, that is, a description of how long different molecules of water stay in the reactor. If one could somehow label all of the molecules of water that enter the tank over some small increment of time and then observe the time that each labeled molecule leaves the reactor, the resulting information would yield the desired residence time distribution. One could say, for example, that of all the molecules that came into the reactor in some tiny period of time (say, 1 s in a reactor with a theoretical detention time of 2 h), 5 percent came out of the reactor in less than 6 min, an additional 5 percent came out in the next 8 min, and another 7 percent came out in the following 4 min. The same information could be expressed cumulatively by saying that 5 percent stayed in the reactor less than 6 min, 10 percent stayed in the tank less than 14 min, and 17 percent left the reactor within 18 min. If this description were carried out until 100 percent of the labeled water molecules had been accounted for, we would have the complete residence time distribution.

Because it is not easy to label some water molecules in a way that differentiates them from other water molecules, we add a tracer to the influent water; the tracer must be a measurable and nonreactive soluble constituent that travels through the reactor in exactly the way that water does. By measuring the effluent concentration of this tracer as a function of time, we can learn how water molecules travel through the reactor; in essence, the tracer molecules act like the set of labeled water molecules.

Tracer studies can be performed in two primary ways. In a pulse input tracer test, a known mass of tracer (M) is added to the influent of the reactor all at once; the instant of the addition

is defined as time zero ($t = 0$), and the concentration of the tracer in the effluent ($C_p(t)$) is monitored for a long time thereafter, until all of the tracer is accounted for. Alternatively, in a (standard) step input tracer test, a steady concentration of tracer (C_{in}) is added to the influent beginning at time zero and continuously thereafter, theoretically forever but practically until the effluent concentration matches the influent concentration. The concentration of tracer in the effluent ($C_s(t)$) is monitored throughout the time period of tracer addition.

In both types of tracer tests, the chosen tracer is usually a constituent that is not naturally in the water, so that the baseline concentration of the effluent is zero; however, this condition is not required. A nonzero (but steady) baseline concentration could be subtracted from all of the effluent concentration measurements to obtain the concentration that is caused by the tracer. This idea can be extended to obtain the desired residence time information from the depletion of tracer concentration after a step input tracer test is ended, as explained subsequently. First, it is necessary to present how the tracer information is mathematically transformed to yield residence time distribution information. Although tracer tests in real systems always involve discrete data points (concentrations at discrete times), the explanations are given first as if the data were continuous functions; how discrete data are manipulated to yield the same information is explained subsequently.

The Exit Age and Cumulative Age Distributions

Consider first a pulse input tracer test on some arbitrary (i.e., non-ideal) reactor; the mass M of tracer is put into the influent of the reactor instantaneously at time zero, and the tracer concentration in the effluent is monitored over time. At and before time zero, the concentration in the effluent is zero. After sufficient time, all of the tracer will have exited the reactor and the effluent concentration will again be zero; in the meanwhile, the effluent concentration would be nonzero. Most real reactors yield results for $C_p(t)$ that show a relatively smooth rise followed by a relatively smooth and continuous fall in the concentration, but the shape of the $C_p(t)$ curve could be almost anything depending on the specific design of the reactor. To emphasize the arbitrariness of the possible response of the reactor, a double-humped curve for $C_p(t)$ is shown in Fig. 4-1a. To keep the number of data points relatively small in this example, data are shown for only every 2.5 min, but more frequent data points, especially in the first 25 min or so where the effluent concentration is changing dramatically, would yield better information.

If another pulse input tracer test were performed on the same reactor at the same flow rate but twice the mass of tracer were put into the reactor, we would expect to see the effluent concentration at every time to be twice that of the original test. Since our interest is in the distribution of times that water, not tracer, stays in the reactor, it is useful to eliminate the effect of the mass of tracer used in the test. To do so, we multiply the effluent concentration values by the flow rate Q and divide by the mass M of tracer input to the reactor. The product of the effluent concentration (mass/volume) and the flow rate (volume/time) is the instantaneous rate (at time t) at which the mass of tracer is leaving the reactor (i.e., dimensions of mass/time). The subsequent division by the total input mass then yields the instantaneous fractional rate at which the input mass is leaving the reactor, with dimensions of inverse time. This normalization is so useful that we give it its own symbol, $E(t)$; that is,

$$E(t) = \frac{Q}{M} C_p(t) \quad (4-2)$$

The set of all values of $E(t)$ is called the *exit age distribution*. If the value of Q/M for the experiment under consideration is $0.002 \text{ L/mg-min} = 0.002 \text{ m}^3/\text{g-min}$, the resulting $E(t)$ curve is shown in Fig. 4.1b. (The origin of this value of Q/M is explained subsequently.)

FIGURE 4-1 Pulse input tracer test: (a) effluent concentration profile; (b) exit age distribution; (c) cumulative age distribution.

The exit age distribution describes the distribution of times that *water* stays in the reactor; that is, the fraction of water from any aliquot of influent that stays in the reactor between any time t and $t + dt$ is $E(t)dt$. For example, the value of $E(t)$ in Fig. 4-1b at 15 min is 0.03 min^{-1} , and if we assume that that value is constant for the 1 min from 14.5 to 15.5 min (i.e., $dt \approx \Delta t = 1 \text{ min}$), then $E(t)dt \approx E(t)\Delta t = (0.03 \text{ min}^{-1})(1 \text{ min}) = 0.03$. That is, 3 percent of the water that enters the reactor at one instant will stay in the reactor between 14.5 and 15.5 min. Likewise, if we take a sample of the effluent at some instant, we can say that 3 percent of the water in that sample stayed in the tank between 14.5 and 15.5 min, or in other words, that 3 percent of the water in that sample came into the reactor between 14.5 and 15.5 min earlier. The exit age distribution describes the distribution of residence times that different molecules of water stay in the reactor.

Often, it is more useful to know what fraction of the water stays in the reactor less than a certain accumulated time (say 15 min) than to know how much stays in for some incrementally small time. That information is contained in the dimensionless *cumulative age distribution* $F(t)$, which is found as the integration of $E(t)$ from time zero to time t ; that is,

$$F(t) = \int_0^t E(t) dt \quad (4-3)$$

For the experiment under consideration, the values of $F(t)$ are shown in Fig. 4-1c. As can be seen from the example in the figure, $F(t)$ has the characteristics that it starts at zero and rises continuously toward the ultimate value of 1. At $t = 15 \text{ min}$, the value of $F(t)$ can be seen to be just less than 0.5 (the precise value is 0.483), which means that 48.3 percent of the water that enters this reactor stays in the reactor for less than 15 min.

All of the tracer put into the reactor at time zero in a pulse tracer test eventually exits the reactor; that is, 100 percent of the tracer stays in the reactor for less than infinite time. Mathematically, this fact means that the ultimate value of $F(t)$ is 1 (unity) and that the area under the entire $E(t)$ distribution is also 1. That is,

$$\int_0^{\infty} E(t) dt = F(\infty) = 1 \quad (4-4)$$

In real systems, of course, a practical definition of time infinity might be 4 to 15 times the detention time, with the smaller part of this range being acceptable for reactors that are nearly plug flow. The criterion for stopping the monitoring in a pulse input test is that no appreciable mass of tracer remains in the reactor.

A step input tracer test ultimately yields the same information for the exit age distribution $E(t)$ and the cumulative age distribution $F(t)$, but the raw data, and therefore the analysis, are different from the pulse input case. For the standard step input tracer test (in which the baseline concentration of the tracer in the influent water and throughout the reactor is zero), the effluent concentration ($C_s(t)$) always increases with time because water that came into the reactor prior to the initiation of the test (with no tracer) is replaced with water that entered after the start of the test (with concentration C_{in}). An example of the effluent concentration is shown in Fig. 4-2a using an influent concentration of tracer of 10 mg/L; the reactor is the same as used in the example for the pulse input.

A unit volume of effluent with concentration $C_s(t)$ is a mixture of a fraction of water (i.e., $F(t)$) that came into the reactor less than time t ago with concentration C_{in} and the rest $(1 - F(t))$ that came in earlier with concentration zero. That is, the cumulative age distribution $F(t)$ is found by normalizing the effluent concentration by the influent concentration.

$$F(t) = \frac{C_s(t)}{C_{in}} \quad (4-5)$$

FIGURE 4-2 Step input tracer test: (a) effluent concentration profile; (b) cumulative age distribution; (c) exit age distribution.

The results of this normalization are shown in Fig. 4-2b. As before, $F(t)$ has the characteristics of being zero at time zero, rising continuously over time, and eventually reaching a value of 1.

When the baseline concentration in the influent and throughout the reactor prior to time zero is not zero, a sample of effluent with concentration $C_S(t)$ is a mixture of a fraction ($F(t)$) that came in less than time t ago with concentration C_{in} and the rest ($1 - F(t)$) that came in with concentration $C_{baseline}$. The result is that the baseline concentration must be subtracted from both the numerator and denominator to obtain the cumulative age distribution. That is,

$$F(t) = \frac{C_S(t) - C_{baseline}}{C_{in} - C_{baseline}} \quad (4-6)$$

Equation 4-6 is completely general and can be used for any (properly performed) step input test, including the possibility that $C_{baseline} > C_{in}$. Equation 4-5 is a simplification of Eq. 4-6, where $C_{baseline} = 0$. At the end of a step tracer test with $C_{baseline} = 0$, the reactor has the concentration equal to C_{in} throughout the reactor, so it is possible to perform a second test by continuing the effluent monitoring after the influent concentration has been returned to zero (at a time designated as a new time zero). In that case, the new baseline is the old C_{in} and the new C_{in} is zero. Regardless of how a step input tracer test is performed, the criterion for being able to stop the monitoring is that the difference between the influent and effluent concentrations is minimal or immeasurable.

As noted in Eq. 4-3, the cumulative age distribution is the integral of the exit age distribution; conversely, the exit age distribution is the derivative of the cumulative age distribution at any time t . That is,

$$E(t) = \frac{dF(t)}{dt} \quad (4-7)$$

The data for $F(t)$ for Fig. 4-2b were analyzed according to (a discretized version of) Eq. 4-7 to find the $E(t)$ values for this reactor, and the resulting values are plotted in Fig. 4-2c. As noted above, this step input tracer study was performed on the same reactor as the pulse input test shown earlier; as a result, the exit age distributions and cumulative age distributions for the two tests shown in Figs. 4-1 and 4-2 are identical. Both types of tests ultimately yield the identical information, and therefore, the type test that is performed is a matter of choice (perhaps influenced by issues of measurement and precision, discussed subsequently).

Discrete Data in Tracer Tests

The conceptual understanding of the exit age and cumulative age distributions presented above presupposes that these distributions are continuous functions and that the tracer data are likewise continuous. However, the data in real tracer tests are always obtained at discrete times, and the figures given above indicate that samples were taken at discrete times. In this section, we explain how to analyze discrete data from both pulse and step input tracer tests to obtain the desired age distributions. The data for a pulse test used to generate Fig. 4-1 are shown as a spreadsheet in Fig. 4-3. The raw data from the test—the times that samples were taken and the corresponding values of $C_p(t)$ —are given in columns A and B, respectively.

In column C, the average concentration in the time interval between adjacent samples is shown in the row corresponding to the end of the time period and is calculated as

$$C_{ave,i} = \frac{C_{i-1} + C_i}{2} \quad (4-8)$$

	A	B	C	D	E	F	G

FIGURE 4-3 Spreadsheet for handling pulse input tracer test data.

So, for example, the value of 9.5 mg/L shown in cell C5 is the average of 5 and 14 mg/L shown in cells B4 and B5, respectively. In the subsequent column (col. D), the average concentrations are multiplied by the associated time interval ($\Delta t = t_i - t_{i-1}$); in this example, all of the time intervals are 2.5 min, although the time intervals are often varied to obtain more data when the changes are rapid. The value of 23.75 mg-min/L in cell D5 is obtained as 9.5 mg/L \times 2.5 min. The sum of all of the values in column D from the entire test is given in cell D23. This value is found because, when multiplied by the volumetric flow rate, the product is the mass of tracer accounted for in the effluent throughout the tracer test; that is,

$$M_{\text{out}} = Q \sum_{\text{all } i} C_{\text{ave},i} \Delta t_i \quad (4-9)$$

This calculation constitutes a quality control on the entire tracer test, because the resulting value can be checked against the known value of the mass input to the reactor. If M_{in} and M_{out} are not in close agreement, the cause should be determined before using the tracer data to calculate the age distributions and ultimately to make treatment decisions. In some cases, one might decide that using M_{out} rather than M_{in} in normalizing from $C_p(t)$ to $E(t)$ is a more accurate approach. In the generation of the exit age distribution in this spreadsheet and in Fig. 4-1, it was assumed that $M_{\text{in}} = M_{\text{out}}$, so that

$$\frac{Q}{M} = \frac{Q}{Q \sum_{\text{all } i} C_{p,\text{ave},i} \Delta t_i} = \frac{1}{\sum_{\text{all } i} C_{p,\text{ave},i} \Delta t_i} = \frac{1}{500 \text{ mg-min/L}} = 0.002 \frac{\text{L}}{\text{mg-min}}$$

The values for $E(t)$ shown in column E in Fig. 4-3 are the product of this value and the values of $C_p(t)$ in column B; the resulting units for $E(t)$ are min^{-1} .

The values for $E_{ave,i}$ shown in column F are calculated from the values in column E in the same way that the $C_{ave,i}$ values in column C are calculated from column B. Finally, after recognizing that the value of $F(0) = 0$, we calculate the subsequent values of $F(t)$ in column G as

$$F_i = F_{i-1} + (E_{ave,i})(t_i - t_{i-1}) \quad (4-10)$$

So, for example, the value in cell G5 is found as $0.013 + (0.019)(2.5) = 0.060$; the value of 0.013 shown in cell G4 is rounded from the precise 0.0125, and the spreadsheet uses this more precise value.

The analysis of discrete data for a step input tracer test is shown in Fig. 4-4, with the raw data of time and measured effluent concentration shown in columns A and B. As indicated by Eq. 4-5 (or Eq. 4-6 with $C_{baseline} = 0$), the values of $F(t)$ in column C are calculated by dividing the values of $C_S(t)$ in column B by C_{in} , which is 10 mg/L in this case.

Next, the estimate of the derivative of $F(t)$ over a time interval is calculated in column D as follows:

$$\left(\frac{dF}{dt}\right)_i \approx \left(\frac{\Delta F}{\Delta t}\right)_i = \frac{F_i - F_{i-1}}{t_i - t_{i-1}} \quad (4-11)$$

So, for example, the value of 0.019 in cell D5 is calculated as $(0.060 - 0.013)/(5.0 - 2.5) \text{ min}^{-1}$. In reality, the values in column D are average values of $E(t)$ over the interval from t_{i-1} to t_i and are shown in the spreadsheet associated with the end of the interval. After recognizing that the initial value of $E(t)$ equals zero, the remaining values of $E(t)$ for the specific values of t are calculated in column E as

$$E(t_i) = 2E_{ave,i} - E_{i-1} \quad (4-12)$$

	A	B	C	D	E
1	Time	$C_S(t)$	$F(t)$	dF/dt	$E(t)$

FIGURE 4-4 Spreadsheet for handling step input tracer test data.

For example, the value of 0.028 in cell E5 is calculated from the values in cells D5 and E4 as $2(0.019) - 0.010$. The values in columns B, C, and E for $C_S(t)$, $F(t)$, and $E(t)$, respectively, were plotted against the time values in column A to make the plots shown in Fig. 4-2.

Choosing a Step or Pulse Input Tracer Test

As shown above, both types of tracer tests ultimately yield the same information, so the question of which type of test to perform is a matter of choice. The monitoring of the effluent is essentially the same in both cases, although a step input test has the advantage that it usually requires measurements over a much narrower range of concentrations. The ability to put tracer into the influent either as a pulse or as a step often dictates the choice. For a pulse test, a substantial mass of tracer must be entered in a very short period of time (theoretically, instantly) into the influent in the same way that water enters the reactor; the design of a reactor and its influent structure often makes this impossible. For a step test, the tracer is added continuously to the influent in a small flow rate (relative to the influent flow); it is often easier to accomplish this type of addition with either the existing facility or a slight modification. Many tracer tests in water treatment plants in the United States are undertaken in response to current disinfection regulations that require determining the time (usually designated as T_{10}) at which $F(t) = 0.10$; although this information is available from either type of test, it is far simpler in terms of data handling to find it from a step input test. In some cases, it is convenient to simply turn off the feed of a chemical, such as fluoride which is added continually and is nonreactive,¹ to perform a test in which the concentration decreases from the normal (post addition) value to the natural baseline value; when normal operation is resumed, the effluent concentration will rise and can continue to be monitored as a second tracer test. For all of these reasons, step input tracer tests are performed more often than pulse input tests, although site specific considerations might dictate the opposite choice in some cases. Teefy (1996) delineated many of the issues involved in choosing both the tracer material and the type of tracer test to perform.

Ideal Plug Flow

From the description of a plug flow reactor above, the results of tracer studies on these ideal reactors can be predicted intuitively. In a pulse test, all of the mass that is put into the reactor at time zero travels together from one end to the other, and it all leaves together at the time equal to the theoretical detention time τ . No tracer comes out of the reactor prior to $t = \tau$, nor does any come out afterward; the entire spike of tracer exits the reactor at exactly $t = \tau$. Because M_{in} is not mixed with surrounding fluid, it is difficult to convert to concentration units, but the fact that all of the water that comes in at one time comes out of the reactor at a time τ later leads directly to the exit age distribution shown in Fig. 4-5 (with an assumed theoretical detention time τ of 20 min). The function shown is known as the Dirac delta function and has the following properties: a value of zero everywhere except one time, the value of infinity at that time, and an area under the curve (from time zero to infinity, and therefore under the spike) of 1. In terms of the water age distribution, we can interpret this function in three ways. First, all of the water that enters at one time exits exactly τ later. Second, all of the water that is in a sample of the effluent came into the reactor τ earlier.

¹Fluoride is reactive with aluminum, so plants that use aluminum-based coagulants cannot use fluoride as a tracer until after filtration. Other commonly considered choices for the tracer include lithium, sodium, and chloride.

FIGURE 4-5 Exit age distribution for a plug flow reactor with theoretical detention time of 20 min.

Third, the probability that a molecule of water will stay in the tank for a time equal to τ is 1, and the probability that it will stay in the reactor for a time less than or greater than τ is 0.

Translating the exit age distribution to the cumulative age distribution means integrating $E(t)$ from 0 to time t , as indicated in Eq. 4-3. For the plug flow reactor under consideration, the value of $F(t)$ is 0 for all $t < \tau$ and 1 for all $t \geq \tau$. Using the same 20-min detention time indicated in Fig. 4-5, the cumulative age distribution $F(t)$ for the plug flow reactor is shown in Fig. 4-6.

The interpretations of the cumulative age distribution are similar to those of the exit age distribution. First, all of the molecules of water in a sample of the influent will stay in

FIGURE 4-6 Cumulative age distribution for a plug flow reactor with theoretical detention time of 20 min. (The function jumps from 0 to 1 at $t = \tau$; the vertical dashed line is simply to aid the visual effect, but the function does not take on any value between zero and one.)

the reactor for exactly τ . Second, all of the molecules of water in a sample of the effluent came into the reactor exactly τ earlier. Finally, the cumulative probability that a molecule of water will stay in the reactor for a time less than τ is 0, and the cumulative probability that a molecule of water will stay in the reactor for a time equal to or greater than τ is 1.

Continuous Flow Stirred Tank Reactor

A drawing depicting a pulse input tracer test being performed on a continuous flow stirred tank reactor (CFSTR) is shown in Fig. 4-7. The flow rate Q must be steady throughout the test, and except for the instant at time zero when the mass M_{in} of tracer is input into the reactor, the influent flow has no tracer in it. Because the contents of the reactor are completely mixed at any instant, the concentration in the effluent at any time is the same as that anywhere in the reactor at that time; that concentration is designated as $C_p(t)$.

FIGURE 4-7 Schematic diagram for a pulse input tracer test on a CFSTR.

At the initiation of the pulse input test (i.e., at $t = 0^+$), the mass M_{in} is instantaneously mixed throughout the entire volume of the reactor, leading to a concentration throughout the reactor of

$$C_p(0) = C_0 = \frac{M_{in}}{V} \tag{4-13}$$

Because the concentration is the same throughout the reactor at any time (by the definition of a CFSTR), the control volume for a mass balance for the tracer is the entire (water) volume of the reactor. No transfer of mass occurs by dispersion or diffusion across these boundaries, so the mass balance valid for any time after time zero is

$$\left[\begin{array}{c} \text{Rate of change} \\ \text{of mass of} \\ \text{tracer in the} \\ \text{reactor} \end{array} \right] = \left[\begin{array}{c} \text{Rate of advective} \\ \text{input of mass} \\ \text{of tracer} \\ \text{into the reactor} \end{array} \right] - \left[\begin{array}{c} \text{Rate of advective} \\ \text{output of mass} \\ \text{of tracer} \\ \text{from the reactor} \end{array} \right] + \left[\begin{array}{c} \text{Rate of change} \\ \text{of mass of tracer} \\ \text{in the reactor} \\ \text{due to reactions} \end{array} \right] \tag{4-14}$$

The first term on the right side is 0 because no tracer is put into the reactor after time zero. Since the tracer is nonreactive, the final term on the right side can be omitted, and the remaining word equation can be translated into symbols as follows:

$$\frac{d(V C_p(t))}{dt} = -Q C_p(t) \tag{4-15}$$

Because the volume is constant, it can be taken out of the differential, and both sides of the equation can be divided by V to obtain

$$\frac{dC_p(t)}{dt} = -\frac{Q}{V} C_p(t) = -\frac{1}{\tau} C_p(t) \tag{4-16}$$

When integrated with the initial condition shown in Eq. 4-13, the response of a CFSTR to a pulse input tracer test is found to be

$$C_{p,CFSTR}(t) = C_0 \exp\left(-\frac{t}{\tau}\right) \tag{4-17}$$

FIGURE 4-8 Pulse input tracer test on a CFSTR: (a) effluent concentration profile; (b) exit age distribution; (c) cumulative age distribution. [Arbitrary choices for this example include a 20 min theoretical detention time (both affects the abscissa of all three plots) and a value of C_0 equal to 50 mg/L (both affects Fig. 4-8a only)]

As indicated in Eq. 4-2, the exit age distribution can then be found as

$$E(t)_{CFSTR} = \frac{Q}{M_{in}} C_{p,CFSTR}(t) = \frac{Q}{M_{in}} C_0 \exp\left(-\frac{t}{\tau}\right) = \frac{Q}{M_{in}} \frac{M_{in}}{V} \exp\left(-\frac{t}{\tau}\right) \quad (4-18)$$

or

$$E(t)_{CFSTR} = \frac{1}{\tau} \exp\left(-\frac{t}{\tau}\right) \quad (4-19)$$

The cumulative age distribution $F(t)$ is then found by integration of $E(t)$ to be

$$F(t)_{CFSTR} = \int_0^t E(t) dt = \frac{1}{\tau} \int_0^t \exp\left(-\frac{t}{\tau}\right) dt = \frac{1}{\tau} (-\tau) \exp\left(-\frac{t}{\tau}\right) \Big|_0^t \quad (4-20)$$

$$F(t)_{CFSTR} = 1 - \exp\left(-\frac{t}{\tau}\right) \quad (4-21)$$

Graphs of $C_p(t)$, $E(t)$, and $F(t)$ for a CFSTR with a 20-min detention time are shown in Fig. 4-8; the value of $C_0 = 50$ mg/L and the detention time were chosen arbitrarily for this example. Since all three functions are mathematically related, all yield essentially the same information. The shape of the $C_p(t)$ and $E(t)$ curves indicate that some tracer or water stays in the reactor for a very short time—the highest point of these functions is at $t = 0$; on the other hand, the exponential decay indicates that some water (or tracer) stays in the tank for extremely long times. The data for $F(t)$ indicate that 10 percent of the water that enters the reactor at one moment exits the reactor within approximately one-tenth of the detention time (i.e., $F(t) = 0.10$ at $t = 0.109\tau$, or just over 2 min in the example shown). Alternatively, we can say that approximately 10 percent of the water in any sample of effluent entered the reactor less than one-tenth of the detention time earlier. At 1 detention time, $F(t) = 0.632$; this means that 63.2 percent of the water stays in the reactor for less than one detention time. On the other hand, some water stays in the tank for a long time; it takes 3 detention times for 95 percent of the water that comes in at one time to leave the reactor, and it takes 4.5 detention times for 99 percent of the water to have left. As shown subsequently, the fact that a fraction of the water escapes after spending little time in the reactor has some significant negative consequences on the extent of reaction (treatment) for most reactive substances, and these consequences are not fully offset by the fact that some water stays in the reactor for a long time.

In a step input tracer test, the tracer is put into the influent of the reactor starting at $t = 0$ and continuing forever, as indicated above. A schematic of such a test being performed on a CFSTR is shown in Fig. 4-9; the picture is the same as that for a pulse test except for the continuous input. The word equation for the mass balance is identical to that for the pulse input, but the translation into symbols now must account for the steady input, as follows:

FIGURE 4-9 Schematic diagram for a step input tracer test on a CFSTR.

$$\frac{d(VC_s(t))}{dt} = QC_{in} - QC_s(t) \quad (4-22)$$

As before, recognizing that the volume V is constant and can be taken out of the differential, then dividing by that volume and substituting the definition of the theoretical detention time, we obtain

$$\frac{d(C_s(t))}{dt} = \frac{1}{\tau} C_{in} - \frac{1}{\tau} C_s(t) \quad (4-23)$$

The initial condition for this step input situation is that $C_s(0) = C_{baseline}$; we assume again that this value is zero, the most common case. This initial condition is quite different from that for the pulse input because the amount of tracer put into the reactor in the instant surrounding time zero is different. In a small time period (Δt) after initiating the step input, the small mass of tracer that has been put into the reactor ($QC_{in}\Delta t$) is diluted into the entire reactor volume. As Δt approaches zero, the concentration in the reactor (and therefore in the effluent) approaches zero (or more generally, $C_{baseline}$). In the limit, $C_s(0) = 0$.

Integration of Eq. 4-23 with the stated initial condition leads to

$$C_s(t) = C_{in} \left[1 - \exp\left(-\frac{t}{\tau}\right) \right] \quad (4-24)$$

Invoking Eq. 4-5, we find the cumulative age distribution $F(t)$ as follows:

$$F(t) = \frac{C_s(t)}{C_{in}} = 1 - \exp\left(-\frac{t}{\tau}\right) \quad (4-25)$$

Finally, taking the derivative of $F(t)$ yields the exit age distribution.

$$E(t) = \frac{dF(t)}{dt} = \frac{1}{\tau} \exp\left(-\frac{t}{\tau}\right) \quad (4-26)$$

The exit age and cumulative age distributions determined from a step input test are identical to those determined from the pulse test. This result is inevitable, since these functions describe how water flows through the tank and that is independent of what kind of tracer test is performed. Hence, the $E(t)$ and $F(t)$ curves shown in Fig. 4-8b and c are valid for the step input tracer test. A graph of $C_s(t)$ for the CFSTR (not shown) would have the same shape as the $F(t)$ curve, except the asymptote would be C_{in} instead of 1.

MATHEMATICAL MODELS FOR NON-IDEAL FLOW

Most real reactors do not meet the ideals of either a plug flow reactor (PFR) (no mixing in the direction of flow) or a CFSTR (complete and instantaneous mixing). Water enters most reactors from a pipe or open channel or directly from a previous reactor through a shared wall. In most cases, the influent structure is designed to distribute that flow across a broad area, either horizontally or vertically or both. That distribution of the flow is accomplished by baffles, multiple small entry ports, or a combination of the two. Similarly, the effluent end of most reactors is designed to remove water from a broad area through submerged or overflow weirs, or again by multiple small holes through a wall or, in the case of granular media filters, the floor. Within the main body of the reactor, that is, between the influent and effluent structures, some reactors (rapid mix tanks, flocculators) have mechanical mixers whereas others (sedimentation tanks or filters) have no intentional mixing.

The efforts to distribute the flow over a broad area at the influent end and withdraw water over a broad area at the effluent end are almost inevitably imperfect. The velocity through an

entry or exit port of, say, a concrete wall, will not be evenly distributed across that port because friction at the surface will impose a zero velocity there (the “no-slip” condition) while the velocity at the center of the port will be necessarily greater than the average. Just inside the reactor, the velocity variation will be dissipated to some degree at the influent end by the viscosity of the water, and turbulent eddies will likewise dissipate as they are broken into smaller and smaller sizes. Similarly at the effluent end, some variation in the velocity will occur as the water approaches the effluent weir. In exposed reactors, the wind can cause a higher depth of water above the weir at one end (and therefore more flow) in comparison to the other end of the weir. Excellent design can result in these variations only affecting the flow a short distance into the reactor at both the influent and effluent, but nonideal flow is nevertheless expected.

Although the experimentally determined exit age distribution and the cumulative age distribution are the most accurate descriptors of the flow patterns in a reactor, they require a lot of data in the case of non-ideal flow. It is often more convenient to characterize the flow pattern using a mathematical model with a small number of parameters, especially if one uses the model of the hydraulic characteristics in conjunction with reaction kinetics to predict (or describe) treatment performance. Common models that are useful in water treatment practice are explained below; these models, as well as some other possible models, are also discussed in Levenspiel (1999), Clark (1996), and MWH (2005).

CFSTRs-in-Series Model

A single reactor might be physically or conceptually divided into several reactors in series. Baffles, for example, provide a physical division of a single reactor into somewhat separated compartments. But any reactor might behave, even without baffles, as if the water flowed from one part of the reactor to another with some mixing in each part. If we consider a single reactor with a (total) theoretical detention time τ as if it were divided into N equal compartments and assume that each of those compartments is completely mixed (i.e., acts as a CFSTR), the exit age and cumulative age distributions can be developed mathematically with the following results:

$$E(t) = \frac{1}{\tau} \frac{N^N}{(N-1)!} \left(\frac{t}{\tau} \right)^{N-1} \exp \left(-\frac{Nt}{\tau} \right) \quad (4-27)$$

$$F(t) = 1 - \exp \left(-\frac{Nt}{\tau} \right) \sum_{i=1}^N \frac{1}{(i-1)!} \left(\frac{Nt}{\tau} \right)^{i-1} \quad (4-28)$$

Graphs showing these distributions for a few selected values of N are shown in Fig. 4-10. For the exit age distribution in Fig. 4-10a, the plot is a dimensionless version of the exit age distribution, obtained by multiplying both sides of Eq. 4-27 by τ . The area under each of these curves is 1, as it is for the usual (dimensional) $E(t)$ curve. When $N = 1$, the reactor is a true CFSTR, and the lines in both parts of Fig. 4-10 are the same as those shown in Fig. 4-8. As N increases from 1 to 10, the distributions gradually become narrower ($E(t)$) or sharper in their rise ($F(t)$). In this model, a value of $N = \infty$ is equivalent to a plug flow reactor, which would be the Dirac delta function on the $E(t)$ curve and the step function on the $F(t)$ curve, as shown in Figs. 4-5 and 4-6, respectively. Focusing on the cumulative age distribution, it is clear that, for values of $F(t) < 0.5$, the time to reach that value increases with increasing value of N , or in other words, with increasing baffling in the reactor. Similarly, for values of $F(t) > 0.7$, the time to reach that value decreases with increasing value of N . That is, a sample of effluent taken from a reactor with a high degree of baffling (i.e., a high value of N) will have a relatively narrow distribution of residence times, meaning that a high fraction of the water stayed in the reactor for a small range of times surrounding the theoretical detention time.

FIGURE 4-10 Age distributions for the CFSTRs in series model (N is the number of equal compartments or CFSTRs that a single real reactor is divided into).

Of particular interest with respect to current regulations are the times associated with $F(t) = 0.10$, that is, the values of T_{10} or T_{10}/τ . For the N values of 1, 2, 3, and 10 shown in Fig. 4-10, the corresponding values of T_{10}/τ (often referred to as the baffling factor) are 0.105, 0.266, 0.367, and 0.622. An open reactor without ostensible mixing or baffling but with inlet and outlet structures that spread the flow over a wide area (e.g., a sedimentation tank) is likely to behave as two or three CFSTRs in series. Rapid mix tanks are likely to come close to behaving as a single ideal CFSTR. Packed bed reactors, such as filters or adsorption columns, act nearly like plug flow reactors; their N value, if modeled with this CFSTRs-in-series model, is likely to be 20 or higher.

Fitting the CFSTRs-in-Series Model to Tracer Data. The equations for the CFSTRs-in-series model have only two parameters: the (total) detention time and the number N of reactors in series. The advantage of mathematical modeling is encapsulated in that fact; instead of having all of the data obtained in a tracer test, one can describe the hydraulic behavior with only two parameters. The model is never (or at least extremely rarely) a perfect fit to the data but, if the fit is good, the slight loss of information by the lack of a perfect fit is

often more than made up for by the simplicity of two parameters. We address here a method to find the values of those two parameters to fit the exit age distribution in a way that gives the same average spread. Depending on the task, other methods (such as finding the best fit to the eye or the one that gives the lowest sum of squared residuals) may often be best. But the task of finding equal spread (variance) is a relatively straightforward method that can be achieved in a spreadsheet.

Although the theoretical development of the model uses the theoretical detention time τ , the model should be fit by using the average detention time as determined from the tracer data. After finding the exit age distribution from the tracer test data (as explained above), the average hydraulic detention time \bar{t} can be found as follows:

$$\bar{t} = \frac{\sum_{\text{all } i} t_{i,\text{ave}} E_{i,\text{ave}} \Delta t_{i,\text{int}}}{\sum_{\text{all } i} E_{i,\text{ave}} \Delta t_{i,\text{int}}} \quad (4-29)$$

Here, the subscript *ave* means the average over an interval (int) between adjacent sampling times, as illustrated in Eq. 4-8; to make this calculation requires adding a few columns to the spreadsheet shown in Fig. 4-3. Theoretically, the value of the denominator on the right side of Eq. 4-29 is equal to 1, so the equation would be simplified if that theoretical value were achieved in the tracer test.

The variance of the experimentally determined $E(t)$ distribution must also be calculated, as follows:

$$\sigma_E^2 = \frac{\sum_{\text{all } i} (t_{i,\text{ave}})^2 E_{i,\text{ave}} \Delta t_{i,\text{int}}}{\sum_{\text{all } i} E_{i,\text{ave}} \Delta t_{i,\text{int}}} - (\bar{t})^2 \quad (4-30)$$

Finally, the value of N , the number of CFSTRs in series, is found as

$$N = \frac{(\bar{t})^2}{\sigma^2} \quad (4-31)$$

For the data in the spreadsheet shown in Fig. 4-4, the following values were found using Eqs. 4-29, 4-30, and 4-31:

$$\begin{aligned} \bar{t} &= 16.63 \text{ min} \\ \sigma_E^2 &= 74.26 \text{ min}^2 \\ N &= 3.72 \end{aligned}$$

Although it is mathematically possible to have a noninteger value of N in the model (with some minor changes to Eqs. 4-27 and 4-28), it is usually sufficient, at least when the calculated value of $N \geq 3$, to use only integer values. In this case, the experimentally determined $E(t)$ is compared to the model using both $N = 3$ and $N = 4$ in Fig. 4-11. The model necessarily has only a single peak in the values of $E(t)$ and therefore cannot fit the experimental double-humped curve perfectly. Nevertheless, the fit of the model to the data for either value of N is quite good, especially when viewed as the cumulative age distribution, as shown in Fig. 4-11. In this case, the model with $N = 3$ fits the data for times less than 15 min better than the model with $N = 4$, whereas the reverse is true for the later times. As shown subsequently, the early part of these distributions is far more important than the later parts, at least when concerned with the effectiveness of the reactors in accomplishing a desired removal efficiency or degree of disinfection, so we should choose the value of $N = 3$ as the best fit to these data.

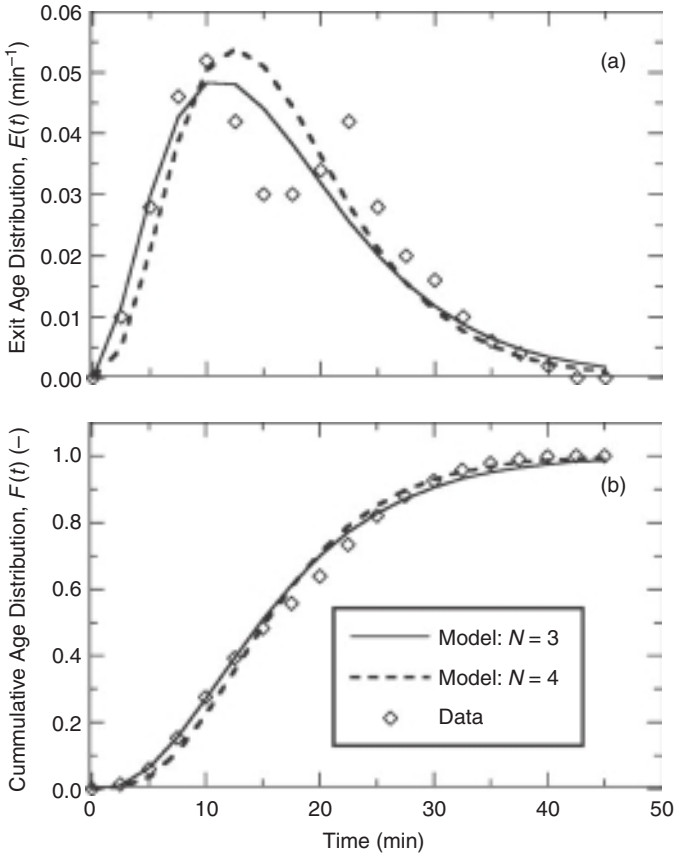

FIGURE 4-11 Fitting the CFSTRs in series model to the data in Fig. 4-1.

Dispersion Model

A second model in common use, especially when the hydraulic behavior of the reactor in question is nearly plug flow, is the dispersion model. Dispersion occurs when small variations in flow velocity occur in the direction of flow; this condition often occurs in turbulent pipe flow and in packed bed reactors. As described above, plug flow occurs when every packet of water stays in the reactor for exactly the same time because every packet has the identical axial flow velocity; when a small and random variation from the average velocity occurs in these one-dimensional situations, a tracer curve shows small variations from the plug flow conditions shown in Figs. 4-5 and 4-6.

In the development of the mathematical model, one develops a mass balance on the tracer in a pulse test over a small differential element of the reactor; water (and tracer) can penetrate the influent and effluent surfaces of that differential element not only by advection (the primary flow), but also by dispersion. Dispersion is mathematically identical to diffusion, although the cause of the dispersion is spatial variation in the flow velocity rather than the molecular motion due to concentration differences that causes diffusion. To solve

FIGURE 4-12 Sensitivity of the dispersion model to variations in D_n (Figure drawn with theoretical detention time of 20 min).

the differential equation, one needs to describe the boundary conditions at the influent and effluent of the reactor. In this case, one can describe either *open boundaries*, where dispersion can occur across the boundaries, or *closed boundaries*, where no dispersion can occur across the boundaries. Most real reactors in water treatment plants have closed boundaries; that is, the influent and effluent structures (e.g., holes in a wall, weirs of any type, pipe flow into a reactor) do not allow any significant amount of water to disperse back across the boundary against the main flow. Unfortunately, an analytical solution to the differential equation of the mass balance is only available for open boundaries. However, the difference between the numerical solution with closed boundaries and the analytical solution for open boundaries is quite small as long as the dispersion number, the one parameter of this model besides the mean detention time, is low. That fact allows us to use the analytical solution for real reactors when the dispersion is small, that is, when the flow is nearly plug flow.

The model is expressed for the exit age distribution as follows:

$$E(t) = \frac{1}{\tau \sqrt{4\pi D_n \frac{t}{\tau}}} \exp \left(-\frac{\left(1 - \frac{t}{\tau}\right)^2}{4D_n \frac{t}{\tau}} \right) \quad (4-32)$$

Here, D_n is the dimensionless dispersion number.²

The sensitivity of this model to the dispersion number D_n is shown in Fig. 4-12. The maximum value of D_n in the figure (0.10) should be considered the maximum value for this model as shown here, because the error of using the open boundary solution for the closed boundary situation becomes significant at higher values. The fitting of this model to experimental data is similar to the process used for the CFSTRs-in-series model. One finds

²In the development of the model, D_n is defined as the ratio of the dispersion coefficient (with dimensions of length² per time) to the product of the flow velocity (length per time) and the reactor length. Many texts show this ratio explicitly in the equation of the model, but since the ratio is used as a single number, we have chosen to use a single symbol here.

the experimental average detention time \bar{t} and the variance σ^2 of the Exit Age Distribution. The value of D_n is then found, by trial and error (including solver routines built into most spreadsheets), as the value that best fits the following equation:

$$\frac{\sigma^2}{\bar{t}^2} = \frac{2D_n + 8D_n^2}{(1 + 2D_n)^2} \quad (4-33)$$

For the low values of D_n under consideration, the denominator of Eq. 4-33 is close to 1.0 and can often be ignored. In that case, the value of D_n can be found using the quadratic equation. The model was not fit to the experimental exit age distribution shown earlier because the best-fit value of D_n would be greater than 0.1, where this model (as shown here) is not valid.

Other Models

A wide variety of other mathematical models have been developed to describe the hydraulic characteristics of a single reactor or a larger portion of a water treatment plant. An infinite number of models can be developed by considering various combinations of ideal reactors either in series or parallel or a combination of the two. No single model can be expected to fit the hydraulic characteristics of all reactors, so one often needs to try several models to find one that fits the data well for a particular reactor, at least over the range of $E(t)$ or $F(t)$ that is of primary interest. A conceptually simple model composed of a small number of reactors in series and/or parallel that gives a reasonable fit to the data is generally of greater value than a far more complex model with a somewhat better fit; good judgment is often required to choose a point in the trade-off between complexity and fit. The value of a model is often to determine what characteristics of a reactor might be changed to make the reactor behave better for its intended purpose; usually, the challenge is to make a reactor more like a plug flow reactor, in delaying the early rise of the $F(t)$ distribution. A simple conceptual model is often easier to understand and interpret than a more complex one, and therefore better in visualizing the physical changes that could or should be made to the reactor.

One example of this type of conceptual model was presented by Rebhun and Argaman (1965) and by Levenspiel (1999). A single reactor with a total volume V is considered to have a dead-space fraction m (in which the water is essentially stagnant so that no exchange of the flowing water with the stagnant water takes place) and an active fraction $1 - m$; within the active fraction, the reactor is assumed to behave as two ideal reactors in series: a PFR (with a fraction of the active volume (p) followed by a CFSTR ($1 - p$). At a flow rate Q , the theoretical detention time of the entire reactor is $\tau = V/Q$, but the detention time in the PFR portion is $p(1 - m)\tau$ and in the CFSTR portion is $(1 - p)(1 - m)\tau$. The cumulative age distribution of a reactor with this description can be derived to yield

$$F(t) = 1 - \exp \left\{ -\frac{1}{(1-p)(1-m)} \left[\frac{t}{\tau} - p(1-m) \right] \right\} \quad (4-34)$$

To use this model with data for $F(t)$, a plot of $\ln(1 - F(t))$ versus t/τ is made; a perfect fit of this model would be a horizontal line at the ordinate value of 0 for low values of t/τ , followed by a straight line with a negative slope. The breakpoint (value of t/τ) between these two line segments occurs when $t/\tau = p(1 - m)$, and the slope of latter portion is $-1/[(1 - p) \times (1 - m)]$. From that point and slope, the values of the parameters p and m can be determined. Real reactors are unlikely to have the abrupt change from a PFR to a CFSTR, so data from tracer tests plotted this way tend to have some curvature between the two straight-line

portions. Although this model has been recommended by the USEPA (1991) as a means of finding the value of T_{10} for compliance with the disinfection regulations, one should ensure that this model is a reasonable fit to the data before applying it for this purpose. If one does the analysis for this model with the data presented in Fig. 4-1c for $F(t)$, for example, the result does not fit the model well at all, as the data past the mean detention time is continuously curved, rather than the straight line proposed by this model.

The double-humped $E(t)$ curve shown in Fig. 4-1b does not fit any simple model well, but a combination of models can be put together to approximate that curve. The most reasonable hypothesis for a double-humped curve is that the flow is divided into two parallel paths through different parts of the reactor, each receiving some fraction of the flow. The curve in Fig. 4-1b can be thought of as the sum of two curves like those shown in Fig. 4-10a for various numbers of CFSTRs in series; that is, we hypothesize that the single reactor with the double-humped exit age distribution is acting like two reactors in parallel, and each of those two is behaving as N -CFSTRs in series described by Eq. 4-27. Each of the two imaginary reactors in parallel has its own flow, detention time, and value of N , but the two fractions of the flow have to add to 1. This conceptual model is depicted in the top part of Fig. 4-13, and the mathematical model can be written as the sum of two fractional exit age distributions.

$$E(t) = f_A \left[\frac{1}{\tau_A} \frac{N_A^{N_A}}{(N_A - 1)!} \left(\frac{t}{\tau_A} \right)^{N_A - 1} \exp \left(-\frac{N_A t}{\tau_A} \right) \right] + (1 - f_A) \left[\frac{1}{\tau_B} \frac{N_B^{N_B}}{(N_B - 1)!} \left(\frac{t}{\tau_B} \right)^{N_B - 1} \exp \left(-\frac{N_B t}{\tau_B} \right) \right]$$

The five parameters of the model are the detention times (τ_A and τ_B) in each of the two subreactors (A and B) of the overall reactor, the number of CFSTRs in series (N_A and N_B) for each subreactor, and the fraction of flow into Reactor A (f_A). The fraction of the flow that goes into Reactor B (f_B) is shown as $(1 - f_A)$ because the two fractions have to add to 1. The terms inside the brackets on the right side are the exit age distribution of the CFSTRs-in-series model (Eq. 4-27); multiplying each by its respective flow fraction ensures that that the area under the entire $E(t)$ curve will equal 1.

To fit the model, a spreadsheet was used with a graph that showed both the experimentally determined $E(t)$ curve and the model results; the best fit (determined by eye) is shown in the graph in Fig. 4-13. The model matches the experimental curve very well through the first 12.5 min and adequately thereafter. The modeling process (i.e., the determination of the parameter values) was guided by a few facts. First, a characteristic of the curves for the CFSTRs-in-series model is that the peak of the distribution occurs at time, $t = [(N - 1)/N]\tau$; this fact suggested that the values of τ_A and τ_B be slightly greater than the times of the two peaks in the experimental curve (10 and 22.5 min). Second, the earlier consideration of the reactor as a single reactor divided into N CFSTRs in series showed that $N = 3$ or $N = 4$ gave a reasonable fit to the early part of the curve. That result suggested that a slightly higher value of N would be useful for reactor A, which was to primarily fit the early part of the overall curve. Reactor B would then require a high value of N so as to give a very small contribution to the overall $E(t)$ value at values of t less than approximately 15 min (see Fig. 4-10). Finally, because both the peak and the spread from Reactor A would be greater than those from Reactor B, the fraction of the flow in Reactor A (i.e., the fraction of the total area of the $E(t)$ curve due to Reactor A) would be greater than that in Reactor B. These facts guided the original selection of values for the five parameters, and these values were then adjusted in small increments to find the final values shown on Fig. 4-13.

It should be noted that more sophisticated methods for finding the parameter values for this model could be used. Also, other models, such as considering the overall reactor to behave like several PFRs in parallel (resulting in a stair-step $F(t)$) could also be fit to the data.

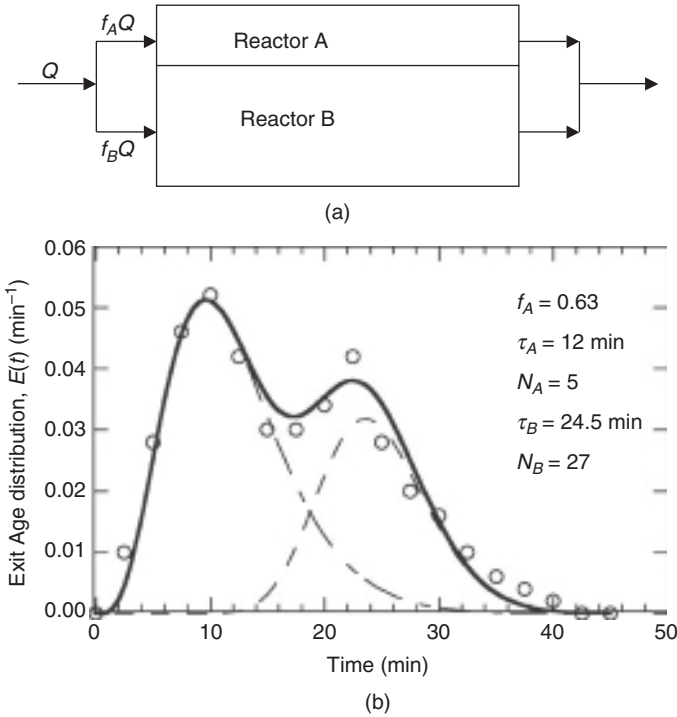

FIGURE 4-13 Fitting the exit age distribution of Fig. 4-1 to a more complex model (a) schematic of two sub-reactors in parallel, each behaving as N-CFSTRs in series; (b) model fitting.

COMPUTATIONAL FLUID DYNAMICS

In recent years, the field of computational fluid dynamics (CFD) has been developed and used increasingly for evaluating the hydraulic behavior of reactors for water treatment. The fundamental equations of fluid mechanics express the conservation of mass, momentum, and energy; collectively, they are known as the Navier-Stokes equations. Theoretically, these differential equations could be solved numerically for any flow situation, but practically, the computational intensity would be too great to use the full equations due to the short time and small length scales of turbulent motion. For incompressible fluids (such as water), this problem is avoided by using so-called Reynolds averaging, which dramatically reduces the computational needs by solving for mean quantities of the flow and developing models that try to simulate the effects of small-scale fluctuations of turbulence in a small number of averaged parameters. A wide variety of models for these small-scale turbulent effects have been developed, with varying degrees of complexity; many are explained in Garg (1998) and Chen and Jaw (1998). The most commonly used (and simplest) models are those describing the turbulent kinetic energy (k) and the turbulent energy dissipation (ϵ) and are usually referred to as eddy viscosity, two-equation, or k - ϵ turbulence models. These k - ϵ models are semi-empirical models that were validated under specific conditions to simulate the behavior of turbulent structures in the flow. The formulation of these eddy

viscosity models includes a number of empirical constants, and various investigators have proposed specific values for these coefficients that have proven useful in a wide variety of situations. When the eddy viscosity models are not able to simulate the flows adequately, more complex models become necessary.

In many variants of the k - ϵ model described in the literature, the model assumes that turbulence is isotropic. Therefore, the primary shear stresses are well predicted but secondary shear stresses from secondary flow structures and normal stresses are not well predicted. As a result, the simpler k - ϵ models often have difficulty describing certain 3D flows. Some of these errors are minimized in so-called anisotropic eddy viscosity models, which incorporate additional terms within the two-equation model structure to capture the strong 3D effect flow. A comparison of various turbulence models for the same application is provided by Liu et al. (2007).

Several commercial software packages for performing CFD calculations are available. These products include a menu of the turbulence models from which the user chooses, depending on the problem. These CFD software packages also have user-friendly interfaces to import or re-create the reactor geometry and to set the finite element grid spacing for the discretization of the flow domain. As a result, they have become a versatile tool to analyze a wide variety of problems relevant in drinking water treatment. The algebraic equations expressing the differential versions of the fluid mechanics equations are solved for all of the grid elements in the reactor. Often, it is reasonable to formulate the flow pattern in two dimensions rather than three, at great reduction in the computational complexity (and time). For example, in many disinfection reactors, the length of the flow path from inlet to outlet is far greater than the depth, so that the variation of flow with depth becomes relatively unimportant in comparison to the use of the surface area; in such cases, formulating the CFD problem in the two horizontal dimensions and ignoring the depth yields sufficiently accurate information.

For use in water treatment plants, a CFD model can be used to find the steady-flow velocity vectors at all locations (grid points) within a tank, and then the response to a tracer at the influent can be followed throughout the reactor. Unlike in a real tracer test, the concentrations at all locations of the tank at any time can be calculated, so that graphical software can be used to visualize the flow pattern. In this way, the CFD model produces far more information than a tracer test in identifying specific areas of the reactor that are barely participating in the flow pattern (Templeton et al., 2006).

For an existing plant, the combination of a single tracer test and CFD can be used to determine the effects of variables that had only a certain value in the tracer experiment. For example, any tracer test is run at particular values of flow rate and water temperature, but the plant runs at different flow rates and different temperatures at other times. The user first fits a CFD model to a limited set of experimental results; that is, a set of grid spacing, boundary conditions, and turbulent model in the CFD software is found that yields results in close agreement with the experimental results. Then, the model can be run at different conditions to predict how the reactor would respond. In this way, the CFD model can be used to predict whether the reactor is likely to perform poorly (for example, have an unacceptably low value of T_{10}/τ) under flow conditions that are different than those used in the tracer test.

A common and powerful use of CFD is to aid in design of retrofits (for existing plants) or new facilities. In an existing plant, for example, many designs of new baffles in a clearwell can be tested to arrive at a design that improves the compliance with $C \times T$ regulations for disinfection under various conditions (flow and current storage); examples are shown in Grayman et al. (1996), Hannoun et al. (1998), and Crozes et al. (1998). Grayman et al., for example, showed a dramatic improvement in the T_{10} that could be achieved by the installation of baffling in a circular clearwell that had been originally designed prior to the current disinfection regulations and that had the influent and effluent pipes adjacent

to one another. Similarly, Mahmood et al. (2005) showed through CFD modeling that mixing in a distribution system elevated reservoir could be improved by orienting the entrance port vertically rather than horizontally and reducing its diameter to increase the exit velocity; subsequent construction verified these findings. For water quality purposes, mixing is more important than residence time in that situation; the focus in the CFD model in this case was on equalizing the temperature of the water throughout the tank to avoid stratification that would allow warmer water to sit on top of colder water and stagnate for long times.

In the design of new plants, the model cannot be calibrated against tracer results, but the same concept of testing various designs to see the effect on the predicted hydraulic behavior can be undertaken. The results might not be as accurate as a calibrated model in an existing facility would give, but the differences caused by different designs are likely to be well characterized, particularly if a model that has been tested in similar plant conditions (elsewhere) is used.

The use of CFD software is not limited to simulating tracer studies under steady-flow conditions; rather, one can directly calculate the behavior of reactive substances in the flow pattern or study the transient behavior of a reactor under a changed influent flow condition. Several investigators, for example, have applied CFD modeling to UV disinfection modeling; examples include Blatchley and coworkers (Naunovic et al., 2008; Blatchley et al., 2008), Ducoste and coworkers (Zhao et al., 2009; Ducoste et al., 2005), and Munoz et al. (2007). CFD modeling has proven particularly valuable in this situation because the validation of UV reactors has been a difficult experimental (and regulatory) problem (see Chap. 18 for additional information). CFD modeling has also been used for reactive substances including ozone disinfection, including gas transfer and ozone decay (Zhang et al., 2004), and chloramine (Liu and Ducoste, 2006). Finally, CFD has also been applied to modeling particle processes such as flocculation (Prat and Ducoste, 2007) and sedimentation (e.g., Goula et al., 2008); these models are somewhat more complicated inasmuch as particles do not simply follow the fluid flow because of their different density and the effects of Brownian motion and fluid drag.

REACTION RATE EXPRESSIONS

Chemical reactions occur in a wide variety of ways in water treatment, and the rates of those reactions also vary widely. The study of reaction rates is strictly empirical, as the reaction pathways and, particularly, the rate at which those pathways are traversed cannot be determined on purely theoretical grounds. Reaction rate expressions are derived from those experimental investigations and are mathematical formulas that describe the observed kinetics. Once they are developed (usually from batch experiments), these rate expressions can be inserted into appropriate mass balances for reactors with continuous flow and used to predict the behavior of chemical species under various treatment conditions.

Reactions whose kinetics are often of interest in water treatment plants include disinfection, oxidation and reduction reactions, precipitation reactions, and flocculation of particles. Some investigators have also expressed particle removal processes such as granular media filtration, sedimentation, and dissolved air flotation (DAF) in terms of reaction rate expressions. The kinetics of most of these reactions, and the underlying reasons for the form of the kinetic expressions, are discussed in the appropriate later chapters. Here, we present a generic approach for considering the combination of reaction kinetics and reactor hydraulic characteristics that is useful background for those subsequent chapters. The reader may find additional coverage of reaction rates and reactor hydraulics in Weber and DiGiano (1996).

The simplest reaction rate expressions for irreversible reactions (those in which the products cannot be reformed into the reactants) are those of the following form:

$$r_A = -k_n C_A^n \quad (4-35)$$

where C_A is the concentration of species A, k_n is the rate constant, and n is an exponent and is known as the *order* of the reaction. The most common use of this equation is with $n = 1$, a first-order reaction, but it is also used for zero or second or fractional orders (values of n). The original model for disinfection kinetics (see Chap. 17), Chick's law, is an example of such first-order kinetics (Chick, 1908); the expression is

$$r_I = -k C_I \quad (4-36)$$

where C_I is the concentration of viable microorganisms of a particular genus or species (e.g., coliforms) and k is the rate constant.

A slightly more complicated version of this type of rate expression occurs when the concentrations of two species (say, A and B) are known to affect the reaction rate, but each to some power of their respective concentrations. In that case, the form is

$$r_A = -k_n C_A^\alpha C_B^\beta \quad (4-37)$$

In this case, we say that the reaction is α -order with respect to A, β -order with respect to B, and $(\alpha + \beta)$ -order overall. An example in common use in the drinking water field is the Chick-Watson law of disinfection (Watson, 1908), which is written as follows:

$$r_I = -k C_I C_D^n \quad (4-38)$$

where C_D is the concentration of disinfectant present in the water. This reaction is considered first order with respect to the microorganism concentration (C_I) but some fractional order with respect to the disinfectant concentration (n , usually in the range 0.85 to 0.90, although often taken to be 1 for mathematical simplicity). The degradation of many specific organic compounds in the presence of ozone is also commonly reported to be a second-order reaction (see Chap. 7), first order with respect to ozone and first order with respect to the particular organic chemical (von Gunten, 2003a, 2003b).

Other reactions of interest in water treatment engineering have more complex reaction rate expressions. For example, biological treatment of certain contaminants is becoming routine in some areas, and the most common rate expression used in that case is the Monod kinetics:

$$r_S = -\frac{kXS}{K_S + S} \quad (4-39)$$

where S is the contaminant of interest, designated S for substrate; X is the microorganism concentration (considered somewhat differently for suspended versus attached growth systems); and k and K_S are constants for a given system. This rate expression is generally coupled with a second one expressing the net rate of growth of the microorganism population (not shown here), leading to a more complex situation mathematically. Other more complex rate expressions are required for biological systems when competing substrates are available, when toxicity at higher concentrations is possible or when the contaminant degradation occurs by co-metabolism (in which the microorganism gains no advantage by the degradation of the substrate of interest, but performs the degradation fortuitously while oxidizing some other compound).

A final rate expression of great importance in water treatment engineering is the flocculation rate (see Chap. 8). *Flocculation* is the collision and attachment of two particles to

form a single particle (a *floc*). When considering a large number of particles of many different sizes as in a water treatment plant, the size distribution is subdivided into a discrete number (N) of size classes with all particles in each class considered to be the same size. Particles of size class k can be formed when two smaller particles (say i and j) attach to each other, with the provision that the volumes of the two smaller particles add to be in the size range of k -size particles. Particles of size class k can also be lost when one such particle collides with and attaches to any size particle and thereby form yet larger particles. To describe flocculation kinetics (i.e., to describe the changes in the particle size distribution), a set of N equations of the following form must be written:

$$r_k = \frac{1}{2} \alpha_{\text{emp}} \sum_{\text{vol}_i + \text{vol}_j = \text{vol}_k} \gamma(i, j) n_i n_j - \alpha_{\text{emp}} n_k \sum_{i=1}^N \gamma(i, k) n_i \quad (4-40)$$

where n_i is the number concentration of particles of size i , $\gamma(i, j)$ is the (theoretical) kinetic coefficient (rate constant) for the collisions between particles of sizes i and j , and α_{emp} is an empirical fitting factor, reflecting the fact that the state of the art of flocculation still requires a fitting factor (between 0 and 1) to match experimental results. The major point to raise in the context of this chapter is that flocculation is a second-order reaction; that is, the rate of gain (first term on the right side) is dependent on both the concentrations of i and j particles (each at first order), and the rate of loss (second term on the right) is dependent on both the concentrations of i and k particles. Because N linked equations must be solved simultaneously, an analytical solution is impossible, and the set of equations resulting from inserting the rate equation into an appropriate mass balance is solved numerically.

Reactions in Batch Reactors

The rate expressions for the various types of reactions described above form one part of a mass balance for a constituent. The overall mass balance for a species i in most situations of interest (those that do not have diffusion or dispersion across the boundary of a control volume) can be expressed by the following word equation:

$$\left[\begin{array}{c} \text{Rate of change} \\ \text{of mass of} \\ \text{species } i \text{ in the} \\ \text{control volume} \end{array} \right] = \left[\begin{array}{c} \text{Rate of advective} \\ \text{input of mass of} \\ \text{species } i \text{ into the} \\ \text{control volume} \end{array} \right] - \left[\begin{array}{c} \text{Rate of advective} \\ \text{output of mass of} \\ \text{species } i \text{ from the} \\ \text{control volume} \end{array} \right] + \left[\begin{array}{c} \text{Rate of change of} \\ \text{mass of species in} \\ \text{the control volume} \\ \text{due to reactions} \end{array} \right] \quad (4-41)$$

The dimensions of such a mass balance are mass per time. To translate this word equation into a mathematical equation, one must specify the control volume and the species under consideration. Usually, the species of concern is easily identified as a particular contaminant, reactant, or reaction product. However, in cases of closely related species (e.g., soluble and solid forms of a metal, the different species in a weak acid system such as carbonate, related species with different oxidation states such as arsenic), the choice of species or group of species must be carefully made. The choice of control volume is usually either a differential element with a specified geometry or the entire reactor volume, depending on whether there are spatial variations of concentration in the system of interest.

The most common way to study reaction kinetics is in a well-mixed batch reactor; for that case, the control volume is simply the entire liquid volume in the reactor, because the mixing eliminates spatial variations in the concentration. The defining characteristic of a

batch reactor is the absence of any advection (flow) into or out of the reactor, and therefore the first two terms on the right side of the word equation are eliminated. In that case, the equation simplifies to

$$\left[\begin{array}{l} \text{Rate of change} \\ \text{of mass of} \\ \text{species } i \text{ in the} \\ \text{control volume} \end{array} \right] = \left[\begin{array}{l} \text{Rate of change of} \\ \text{mass of species } i \text{ in} \\ \text{the control volume} \\ \text{due to reactions} \end{array} \right] \quad (4-42)$$

Translating to symbols yields

$$\frac{VdC_i}{dt} = Vr_i \quad (4-43)$$

or, more simply (and with a change of dimensions to mass/(volume-time)),

$$\frac{dC_i}{dt} = r_i \quad (4-44)$$

Equation 4-44 is the (volume-normalized) mass balance for any constituent i in a batch reactor. Those who study kinetics typically perform batch experiments in which they measure C_i as a function of time, and then find an expression for r_i that agrees with the data. For most reactions of interest in water treatment, the rate expressions are known, and the objective is to recognize how that knowledge is best translated into successful design and operation. In most (but not all) situations of interest, the reaction is one in which the constituent is an undesired contaminant, and the reaction rate expression is negative, that is, one in which the constituent is destroyed.

Generally, r_i is a function of the concentration of i , and so Eq. 4-44 is rearranged to separate the variables (concentration and time) for the integration as follows:

$$\int_{C(0)}^{C(t)} \frac{dC_i}{r_i} = \int_0^t dt = t \quad (4-45)$$

The simplest rate expression is that for an irreversible, first-order reaction: $r_i = -k_1C_i$. Inserting that expression into Eq. 4-45 yields

$$\int_{C_0}^{C(t)} \frac{dC_i}{C_i} = -k_1 \int_0^t dt \quad (4-46)$$

$$\ln \frac{C(t)}{C_0} = -k_1 t \quad (4-47)$$

or

$$C(t) = C_0 \exp(-k_1 t) \quad (4-48)$$

Graphical representations of Eqs. 4-47 and 4-48 are shown in Fig. 4-14. In an experiment, the raw data for $C(t)$ would be like that shown in Fig. 4-14a, and an analysis of the data to check for first order behavior would be done like the plot shown in Fig. 4-14b.

FIGURE 4-14 Graphical representation of first order kinetics in a batch reactor.

Similar analyses for zero-order ($r_i = -k_0$) and second-order ($r_i = -k_2 C_i^2$) reactions are performed by inserting these kinetic expressions into Eq. 4-45, with the following results. For zero order,

$$C(t) = C_0 - k_0 t \quad (4-49)$$

For second order,

$$C(t) = \frac{C_0}{1 + k_2 C_0 t} \quad (4-50)$$

or

$$\frac{1}{C(t)} = \frac{1}{C_0} + k_2 t \quad (4-51)$$

For zero-order reactions, Eq. 4-49 indicates that the raw data (concentration versus time) will yield a straight line with intercept equal to the initial concentration C_0 and a

negative slope equal to the rate constant k_0 . For second-order reactions, a graph of $1/C(t)$ versus time will have an intercept of $1/C_0$ and a positive slope equal to k_2 .

The critical fact is that, for first- and second-order reactions, the rate of reaction is dependent on concentration, so that the higher the concentration, the faster the reaction. Unfortunately, our desire in water treatment is to have a low concentration of contaminants where these reaction rates are relatively slow. Engineering a system to account for the kinetics of reaction properly is a critical part of water treatment plant design.

After inserting some of the more complex rate expressions noted in the previous section into Eq. 4-45, integration by analytical methods is possible under some circumstances but not all. For example, we can consider a reaction that is first order with respect to each of two constituents and second order overall (i.e., $\alpha = \beta = 1$ in Eq. 4-37) and further that C_A and C_B are directly linked by stoichiometry, so that the loss of a B molecule is accompanied by the loss of m A molecules (i.e., $mA + B \rightarrow \text{product}$). In that case, the concentration of one chemical at any time can be expressed in terms of the concentration of the other (and the initial concentrations); that is, $C_A = C_{A_0} - m(C_{B_0} - C_B)$, where the subscript 0 represents the initial condition. If the two constituents are present originally at their stoichiometric ratio (i.e., $C_{A_0} = mC_{B_0}$), then this ratio of concentrations is maintained at all times (i.e., $C_A(t) = mC_B(t)$) and the mathematical solution is the same as Eq. 4-50 except that k_2 in the integrated expression is replaced by mk . That is,

$$C_B(t) = \frac{C_{B_0}}{1 + mkC_{B_0}t} \quad (4-52)$$

When the two constituents are not present originally at their stoichiometric ratio (i.e., $C_{A_0} \neq mC_{B_0}$), the mass balance for the batch reactor yields

$$\frac{dC_B}{(C_{A_0} - mC_{B_0} + mC_B)C_B} = -k dt \quad (4-53)$$

where C_B is a function of time but is written in this shorthand form for convenience. The solution to this differential equation is

$$\frac{C_B}{C_{A_0} - mC_{B_0} + mC_B} = \frac{C_{B_0}}{C_{A_0}} \exp[-(C_{A_0} - mC_{B_0})kt] \quad (4-54)$$

This expression can be rearranged to yield an explicit expression for C_B as a function of time.

$$C_B(t) = \frac{mC_{B_0} - C_{A_0}}{\left[m - \frac{C_{A_0}}{C_{B_0}} \exp[(C_{A_0} - mC_{B_0})kt] \right]} \quad (4-55)$$

An example of the difference between the two situations described by Eqs. 4-52 and 4-55 is shown in Fig. 4-15 (with $m = 2$). In the case where excess A is present originally (and therefore at all times), the degradation of B is faster because the reaction rate is proportional to C_A . The faster kinetics in this case can be used to advantage in water treatment engineering, as long as A itself is not an undesirable contaminant.

Another reaction of major interest is the Chick-Watson law of disinfection (see Chap. 17) expressed in Eq. 4-38; the rate of disinfection is dependent on both the disinfectant concentration and the concentration of viable microorganisms. In that expression, it is often found that the exponent n on the disinfectant concentration is nearly 1, and for simplicity of the

FIGURE 4-15 Progression of a second order bi-molecular reaction: effect of concentration. (In the case shown, $m = 2$; for $C_{A_0} = 80 \mu\text{mol/L}$, the two constituents are present in their stoichiometric ratio at all times; for $C_{A_0} = 100 \mu\text{mol/L}$, constituent A is always in excess of that ratio.)

mathematics, it is often taken to be 1. For chlorine, for example, the most commonly reported value for n is 0.86 (Berg, 1964), and the error associated with considering that value to be 1.0 is relatively small. The USEPA, in its CT tables for compliance with the Surface Water Treatment Rule, considers $n = 1$ for several disinfectants and target microorganisms but not for chlorine disinfecting *Giardia* cysts (which is why those tables have separate entries for different chlorine concentrations; see USEPA 1991, guidance documents and tables). With the assumption that $n = 1$, the rate expression is essentially identical to that of the second-order reaction of two constituents (i.e., first order with respect to each). However, the consumption of disinfectant in natural waters is rarely, if ever, linked directly to the degree of disinfection. Two possible scenarios for the concentration of the disinfectant C_D are often considered. In the simpler case, the disinfectant is not considered to decay at all, in which case the disinfection reaction is a first-order reaction with the rate constant being $k_I C_{D_0}$; the solution is similar to that shown in Eq. 4-48.

$$C_I(t) = C_{I_0} \exp(-k_I C_{D_0} t) \quad (4-56)$$

More realistically, the disinfectant or oxidant is consumed by many reactions, and the consumption by disinfection is small in comparison to that from other reactions. As a result, the decay of the disinfectant is considered independent of the disinfection reaction; if that decay is (or is assumed to be) first order (Lawler and Singer, 1993), then the disinfectant concentration varies with time.

$$C_D(t) = C_{D_0} \exp(-k_D t) \quad (4-57)$$

The Chick-Watson law with these assumptions can then be expressed as

$$r_I = -k_I [C_{D_0} \exp(-k_D t)] C_I \quad (4-58)$$

FIGURE 4-16 Disinfection achieved: effect of disinfectant decay during disinfection. (Conditions: $C_{i0} = 10^6/100$ ml; $C_{D0} = 2.5$ mg_D/L; $k_D = 0.005$ /min; $k_I = 0.06$ L/(mg_D·min); disinfectant decayed to 1.85 mg/L in 60 min)

Substituting this expression into Eq. 4-45 and integrating yields

$$C_t(t) = C_{i0} \exp \left\{ -C_{D0} \frac{k_I}{k_D} [1 - \exp(-k_D t)] \right\} \quad (4-59)$$

The effect of disinfectant decay is illustrated in Fig. 4-16 for conditions that could be considered representative of water treatment conditions; the figure uses Eq. 4-56 for the conditions without disinfectant decay and Eq. 4-59 for conditions with disinfectant decay. With no decay of the disinfectant, the results plot as a straight line on this semilogarithmic plot; base 10 logarithms are used so that the results can be shown (on the right axis) as the (commonly used) log inactivation achieved, defined as $\log_{10} \frac{C_{i0}}{C_t(t)}$. The slope of that line is $-\frac{C_{D0} k_I}{2.30}$, where 2.30 stems from the conversion from base e to base 10 (i.e., $\ln 10 = 2.30$). Disinfectant decay increases the time required to achieve a specified degree of inactivation; in the example shown, the time to achieve 3-log inactivation increases from 46 min with no disinfectant decay to 52 min with decay (from 2.50 to 1.93 mg/L).

REACTIONS IN CONTINUOUS FLOW SYSTEMS AT STEADY STATE: COMBINING HYDRAULICS AND REACTION KINETICS

In virtually all cases, water treatment plants operate as a series of continuous flow reactors, and so it is critical to understand the interaction of the flow characteristics of a reactor and the kinetics of reactions of interest. In this section, we address that concern by considering reactors that are operating at steady state, that is, reactors in which nothing is changing with time, and we progress from ideal reactors (PFRs and CFSTRs) to non-ideal reactors.

Plug Flow Reactors

As described earlier, a plug flow reactor is one in which water that comes into the reactor at one instant travels from the inlet to the outlet without any mixing with water that came in at any other time. This condition means that all of the water stays in the reactor for exactly the same amount of time, the theoretical detention time τ . To consider the behavior of a reactive substance in a plug flow reactor, we can choose a small differential element as the control volume in the mass balance, as indicated in Fig. 4-17.

FIGURE 4-17 Schematic of a plug flow reactor, with differential element for the mass balance. (A is the cross-sectional area; x is the distance from the reactor entrance, and L is the length of the reactor.)

Translating the word equation in Eq. 4-41 for the mass balance on the differential element shown on the right side of Fig. 4-17 into symbols yields

$$\frac{\partial(AC\Delta x)}{\partial t} = QC - Q(C + \Delta C) + (A\Delta x)r \quad (4-60)$$

where r is the reaction rate. The stipulation that we are considering steady state conditions means that the left side is zero. Combining the first two terms on the right side and dividing by the cross-sectional area A yields

$$0 = -\frac{Q}{A}\Delta C + r\Delta x \quad (4-61)$$

In the limit as the differential element shrinks in length toward zero, further rearrangement leaves us with

$$\frac{dC}{r} = \frac{A}{Q} dx \quad (4-62)$$

Since r is generally a function of concentration, the integration of the left side must include that functionality, whereas the integration of the right side is straightforward.

$$\int_{C_{in}}^{C_{out}} \frac{dC}{r} = \frac{A}{Q} \int_0^L dx = \frac{AL}{Q} = \frac{V_{pfr}}{Q} = \tau_{pfr} \quad (4-63)$$

Comparing Eq. 4-63 with Eq. 4-45 for batch reactors reveals that they are nearly identical; that is, the amount of reaction that occurs between the influent and effluent of a plug flow reactor with detention time τ is identical to the amount that occurs in a batch reactor in the time $t = \tau$. This identity should perhaps not be surprising: all of the water that comes in to a PFR at one instant travels through the reactor without interacting with water that comes in earlier or later. In essence, a PFR is a moving batch reactor. This result means that all of the expressions from the batch system described above can be directly translated to the PFR case. That translation to the PFR for most of the results shown above for reactions in batch reactors is shown in Table 4-1.

TABLE 4-1 Performance in Plug Flow Reactors

Description	Rate expression	Effluent concentration, C_{out}	Required detention time to achieve C_{out} , τ_{pfr}
Zero order	$r = -k_0$	$C_{in} - k_0 \tau_{pfr}$	$\frac{1}{k_0} (C_{in} - C_{out})$
First order	$r = -k_1 C$	$C_{in} \exp(-k_1 \tau_{pfr})$	$\frac{1}{k_1} \ln \frac{C_{in}}{C_{out}}$
Second order	$r = -k_2 C^2$	$\frac{C_{in}}{1 + C_{in} k_2 \tau_{pfr}}$	$\frac{1}{k_2} \left(\frac{1}{C_{out}} - \frac{1}{C_{in}} \right) = \frac{1}{k_2 C_{in}} \left(\frac{C_{in}}{C_{out}} - 1 \right)$
First order in each of two constituents related by stoichiometry	$r_A = -k C_A C_B$ with $\Delta C_A = m \Delta C_B$	$C_{B,out} =$ $\frac{m C_{B,in} - C_{A,in}}{\left\{ m - \frac{C_{A,in}}{C_{B,in}} \exp[(C_{A,in} - m C_{B,in}) k \tau_{pfr}] \right\}}$	$\frac{1}{k(C_{A,in} - m C_{B,in})} \ln \left[\left(\frac{C_{B,in}}{C_{A,in}} \right) \frac{C_{B,out}}{C_{A,in} - m m C_{B,in} + m C_{B,out}} \right]$
Disinfection Chick-Watson with constant disinfectant concentration $C_{D,out}$	$r_I = -k_I C_{D,out} C_I$	$C_{I,out} = C_{I,in} \exp(-k_I C_{D,out} \tau_{pfr})$	$\frac{1}{k_I C_{D,out}} \ln \frac{C_{I,in}}{C_{I,out}}$
Disinfection Chick-Watson with decaying disinfectant concentration	$r_D = -k_D C_D$ $r_I = -k_I C_D C_I$	$C_{D,out} = C_{D,in} \exp(-k_D \tau_{pfr})$ $C_{I,out} = C_{I,in} \exp\left(-C_{D,in} \frac{k_I}{k_D} (1 - \exp(-k_D \tau_{pfr}))\right)$	$-\frac{1}{k_D} \ln \left(1 + \frac{k_D}{k_I C_{D,in}} \ln \frac{C_{I,out}}{C_{I,in}} \right)$

Continuous Flow Stirred Tank Reactors

FIGURE 4-18 Schematic diagram of a CFSTR with a reactive substance.

We next consider the extent of reaction that occurs in CFSTRs at steady state. As with the tracer studies considered earlier, the control volume for the mass balance is taken as the entire water volume of the reactors, as depicted in Fig. 4-18. Because the concentration is identical everywhere in the reactor, the concentration of the effluent C_{out} is the same as that in the reactor (or vice versa).

In this case, the translation of the mass balance expressed in words in Eq. 4-41 results in

$$0 = QC_{in} - QC_{out} + Vr_{C_{out}} \quad (4-64)$$

where the zero on the left side reflects that, at steady state, nothing changes with time. Since the concentration is C_{out} everywhere in the reactor, the relevant reaction rate is that associated with this concentration, as indicated by $r_{C_{out}}$. Dividing by V and recognizing that $V/Q = \tau$ leads to

$$C_{out} = C_{in} + r_{C_{out}} \tau_{cfstr} \quad (4-65)$$

or

$$\tau_{cfstr} = -\frac{C_{in} - C_{out}}{r_{C_{out}}} \quad (4-66)$$

The various reaction rate expressions can be substituted into Eqs. 4-65 and 4-66 to predict the performance in CFSTRs. The results of this algebra are collected in Table 4-2 for the same reaction rate expressions considered earlier. For the Chick-Watson law, only the decaying disinfectant equation is shown; the constant disinfectant case would be the same, except that $C_{D,out} = C_{D,in}$.

Comparison of CFSTRs and PFRs

The equations for the performance of the two types of ideal reactors shown in Tables 4-1 and 4-2 are different, and it is worthwhile to explore the meaning of those differences. We limit the discussion to zero-, first-, and second-order reactions. The disinfection expression is similar to a first-order reaction (with the differences from first order being in the direction of second order). Also, the behavior for the reaction that is first order in each of two constituents is essentially identical to the second-order reaction. The differences are most easily explored by determining the ratio of the detention times required for a CFSTR and a PFR to accomplish the same degree of removal (assuming the same influent conditions for both types of reactors). The expressions for these ratios, along with calculated values for a few specific desired removal efficiencies, are different for each reaction order and are collected in Table 4-3.

For zero-order reactions, the flow pattern makes no difference in what is accomplished in a reactor; the extent of reaction that occurs depends only on the time provided and not on the concentration at any point in the reactor. For first- and second-order reactions, however, the results in Table 4-3 are dramatic in showing that the required detention times (or reactor volumes) are much higher for a CFSTR than a PFR. For example, to achieve 99 percent removal of a chemical undergoing a first-order reaction in the two types of reactors, the volume of the CFSTR would have to be 21.5 times that of the PFR. The ratios of required detention times increase with reaction order and also with desired removal efficiency. Plug

TABLE 4-2 Performance in Continuous Flow Stirred Tank Reactors (CFSTRs)

Description	Rate expression	Effluent concentration C_{out}	Required detention time to achieve C_{out} τ_{cfstr}
Zero order	$r = -k_0$	$C_{in} - k_0 \tau_{cfstr}$	$\frac{1}{k_0}(C_{in} - C_{out})$
First order	$r = -k_1 C$	$\frac{C_{in}}{1 + k_1 \tau_{cfstr}}$	$\frac{1}{k_1} \left(\frac{C_{in}}{C_{out}} - 1 \right)$
Second order	$r = -k_2 C^2$	$\frac{C_{in}}{1 + C_{out} k_2 \tau_{cfstr}}$ or $\frac{-1 + \sqrt{1 + 4k_2 \tau_{cfstr} C_{in}}}{2k_2 \tau_{cfstr}}$	$\frac{1}{k_2 C_{out}} \left(\frac{C_{in}}{C_{out}} - 1 \right)$
First order in each of two constituents related by stoichiometry	$r_A = -k C_A C_B$ with $\Delta C_A = m \Delta C_B$	$C_{B,out} = C_{B,in} (1 + mk\tau) - k C_{A,in} \tau - mk C_{B,out}^2 \tau$ $= \frac{-1 + \sqrt{1 + 4mk\tau_{cfstr} a}}{2mk\tau_{cfstr}}$ where $a = C_{B,in} (1 + mk\tau_{cfstr}) + k C_{A,in} \tau_{cfstr}$	$\frac{1}{k C_{A,out} C_{B,out}} \left(\frac{C_{B,in}}{C_{B,out}} - 1 \right)$ where $C_{A,out} = C_{A,in} - m C_{B,in} + m C_{B,out}$
Disinfection Chick-Watson with decaying disinfectant concentration	$r_D = -k_D C_D$ $r_I = -k_I C_D C_I$	$C_{D,out} = \frac{C_{D,in}}{1 + k_D \tau_{cfstr}}$ $C_{I,out} = \frac{C_{I,in}}{1 + k_I C_{D,out} \tau_{cfstr}}$	$\frac{1}{k_I C_{D,out}} \left(\frac{C_{I,in}}{C_{I,out}} - 1 \right)$

TABLE 4-3 Comparison of Required Detention Times in CFSTRs versus PFRs

Reaction order and rate expression	Expression for $\frac{\tau_{CFSTR}}{\tau_{PFR}}$	Value of $\frac{\tau_{CFSTR}}{\tau_{PFR}}$ for 90% removal	Value of $\frac{\tau_{CFSTR}}{\tau_{PFR}}$ for 99% removal
Zero: $r = -k_0$	1	1	1
First: $r = -k_1 C$	$\frac{\frac{C_{in}}{C_{out}} - 1}{\ln \frac{C_{in}}{C_{out}}}$	$\frac{9}{\ln(10)} = 3.91$	$\frac{99}{\ln(100)} = 21.5$
Second: $r = -k_2 C^2$	$\frac{C_{in}}{C_{out}}$	10	100

flow reactors are simply far more efficient than CFSTRs in their use of space to accomplish constituent removal by many types of reaction. The design of water treatment plant reactors should always account for these differences.

Non-ideal Reactors with Common Flow Models

Most reactors do not exhibit the ideal flow of either a plug flow reactor or a continuous flow stirred tank reactor. As noted earlier in the chapter, several models are in common use to describe the flow characteristics, and some of them can be used in conjunction with reaction kinetic expressions to model the expected conversion accomplished in these reactors under steady state conditions.

The first model to be considered is the CFSTRs-in-series model. If the hydraulic behavior of a single reactor with theoretical detention time τ is adequately modeled as N CFSTRs in series, each with a detention time τ/N , the expressions for the steady state effluent concentration in Table 4-2 can be used successively N times to predict the effluent concentration, as the output concentration of each (imaginary) reactor (or compartment) is the influent concentration of the next one in series. The ease of predicting the performance for reactive species is a major advantage of the CFSTRs-in-series model. For a first-order reaction, the result is particularly straightforward.

$$\frac{C_{out}}{C_{in}} = \frac{1}{\left(1 + \frac{k_1 \tau}{N}\right)^N} \quad (4-67)$$

The sensitivity of the steady state removal accomplished for a constituent undergoing a first-order reaction in reactors whose hydraulic characteristics are described by the CFSTRs-in-series model is shown in Fig. 4-19. The abscissa represents the size (detention time) of the reactor, in dimensionless terms, as the product of the first-order rate constant (with dimensions of inverse time) and the actual detention time. The left ordinate shows the fraction remaining on a logarithmic basis; the value of -2 , for example, means that $\frac{C_{out}}{C_{in}} = 10^{-2} = 0.01$; the labeling on the right ordinate expresses the same information in terms of the percent removal, $\left(1 - \frac{C_{out}}{C_{in}}\right) \times 100\%$. For any value of N , the removal improves with increasing detention time, as would be expected. The ideal CFSTR ($N = 1$) is seen not to be very efficient; to achieve high removal efficiencies requires a high value of the dimensionless detention time. Manipulation of Eq. 4-67 with $N = 1$ shows that the required value of the

FIGURE 4-19 Steady state performance of a first order reaction according to the CFSTRs-in-series model.

parameter $k_1\tau$ equals the percent removal desired, so a 99 percent removal would require that $k_1\tau = 99$. For a given value of $k_1\tau$, the removal efficiency improves with increasing values of N , that is, as the hydraulic behavior becomes more plug flow-like. The reason why disinfection reactors are built with many baffles to increase the value of N is clear from Fig. 4-19. For the same 99 percent removal that requires $k_1\tau = 99$ for $N = 1$, the values of $k_1\tau$ drop to 18, 11, and 6 for $N = 2, 3$, and 10, respectively. Although not shown, the effect of increasing N on the removal achieved for second-order reactions is even more dramatic than for first-order reactions.

The plug flow with dispersion model can also be solved analytically to predict the steady state performance of a reactor with a first-order reaction. The result is expressed as

$$\frac{C_{out}}{C_{in}} = \frac{4a \exp\left(\frac{1}{2D_n}\right)}{(1+a)^2 \exp\left(\frac{a}{2D_n}\right) - (1-a)^2 \exp\left(-\frac{a}{2D_n}\right)} \tag{4-68a}$$

where D_n is the dimensionless dispersion number (the parameter of the dispersion flow model) and the dimensionless group a is defined as

$$a = (1 + 4k_1\tau D_n)^{1/2} \tag{4-68b}$$

The steady state performance of a first-order reaction according to the plug flow with dispersion model is shown in Fig. 4-20; the axes are identical to those used in Fig. 4-19, and the variation with the dispersion number D_n is indicated. The ideal PFR ($D_n = 0$) is the most efficient reactor possible, and increasing dispersion number reduces the efficiency of removal for the same value of the dimensionless detention time $k_1\tau$. The expected performance is strongly influenced by the dispersion; for example, a reactor designed with a value of $k_1\tau = 10$ will achieve 99.99 percent removal at $D_n = 0.01$ but approximately 99.8 percent removal at $D_n = 0.1$.

FIGURE 4-20 Steady state performance of a first order reaction according to the PFR with dispersion model.

Using the Exit Age Distribution Directly to Estimate Removal

In discussing the exit age distribution earlier in the chapter, we noted that a value of $E(t)\Delta t$ represented the fraction of the effluent that came into the reactor in an interval of time between $t - [(1/2)\Delta t]$ and $t + [(1/2)\Delta t]$ earlier. The example we used was that, if $E(t)\Delta t$ was 0.03 with $t = 15$ min and $\Delta t = 1$ min, we could say that 3 percent of a sample of effluent came into the reactor between 14.5 and 15.5 min earlier. If we now further hypothesize that this 3 percent of the water traveled together throughout the reactor from influent to effluent (i.e., that this packet was segregated from other parts of the flow), we can calculate the concentration of a reactive constituent in that packet as the concentration in a batch reactor with an initial concentration equal to the influent concentration and a reaction time of 15 min (or, more generally, t). The entire effluent under steady state conditions, then, is a weighted average of the concentrations in all the packets, with the weighting factor being the fraction of the total water in that packet.

$$C_{\text{out}} = \frac{\sum_{\text{all } i} C(t_i)E(t_i)\Delta t_i}{\sum_{\text{all } i} E(t_i)\Delta t_i} = \sum_{\text{all } i} C(t_i)E(t_i)\Delta t_i \quad (4-69)$$

The second equality recognizes that the denominator has a value of 1 (i.e., the sum of all the fractional aliquots of water is 1). If $E(t)$ can be expressed as a continuous function, then the equation can be written in integral form as

$$C_{\text{out}} = \int_0^{\infty} C(t)E(t) dt \quad (4-70)$$

It is important to realize that these expressions are valid for steady state conditions, despite the variable t in the equations; this time is simply the distribution of times for different packets of water under steady flow. The values of, or expressions for, $C(t)$ to be used in these equations are those for batch reactions (with the substitution of C_{in} for C_0): Eq. 4-48 for a first-order reaction, Eq. 4-49 for zero order, 4-51 for second order, and others shown earlier for more specialized reaction rate expressions.

As indicated, the analysis above assumes that the flow is segregated, and such flow probably never happens in a non-ideal reactor. However, the assumption turns out to be irrelevant for both first-order and zero-order reactions. For such reactions, the value of $C(t)/C_{in}$ is independent of C_{in} , and that means that mixing of one packet with another along the flow path does not change the fractional removal in the next segment of the reactor. Therefore, the analysis for zero- or first-order reactions does not really rely on the assumption of segregated flow and is accurate under all conditions.³ For a zero-order reaction, the flow pattern makes no difference in the fractional removal achieved; the only influence in the fraction removed is the average detention time.⁴ While an analysis of the type described in Eqs. 4-69 and 4-70 can be used for zero-order reactions, a much simpler analysis based on τ alone leads to the same result. For any other reaction rate expression besides zero or first order, this analysis provides only an estimate (and the most optimistic one possible) of the removal achieved in a reactor; nevertheless, it is a tool that can be used as an estimate of what could occur in a continuous flow reactor under steady state conditions.

We now consider an example of the various equations and methods of estimating the removal achieved in real reactors. For the non-ideal reactor that we have considered throughout the chapter (with the tracer information in Fig. 4-1), the detention time was found to be 16.63 min. If the reactor were a plug flow reactor with that detention time, we would obtain 99 percent removal via a first-order reaction (say, disinfection according to Chick's law) if the reaction rate constant were 0.277 min^{-1} . That is, in a plug flow reactor,

$$\left(\frac{C_{out}}{C_{in}}\right)_{PFR} = \exp(-k_1 \tau_{PFR}) = \exp[(-0.277 \text{ min}^{-1})(6.63 \text{ min})] = 0.01$$

If this same reaction occurred in a CFSTR with the same detention time, the fraction remaining would be

$$\left(\frac{C_{out}}{C_{in}}\right)_{CFSTR} = \frac{1}{1 + k_1 \tau_{CFSTR}} = \frac{1}{1 + (0.277 \text{ min}^{-1})(16.63 \text{ min})} = 0.178$$

or, the fractional removal would be $\eta = (1 - 0.178) = 0.822$ or 82.2 percent.

For the non-ideal reactor, we have developed three hydraulic models, and for each, we can calculate an expected fraction remaining. Those three models are the N -CFSTRs-in-series model with values of $N = 3$ and $N = 4$ (both with the detention time of 16.63 min) and the two reactors in parallel model depicted in Fig. 4-13. For the CFSTRs-in-series model, we use Eq. 4-67.

For $N = 3$,

$$\left(\frac{C_{out}}{C_{in}}\right)_{N=3} = \frac{1}{\left(1 + \frac{k_1 \tau}{3}\right)^3} = \frac{1}{\left[1 + \frac{(0.277 \text{ min}^{-1})(16.63 \text{ min})}{3}\right]^3} = 0.061$$

or $\eta = 1 - 0.061 = 0.939$.

³The reader can show, for example, that a two-reactor system consisting of a PFR with τ_{PFR} and a CFSTR with τ_{CFSTR} in series will give the same fraction remaining regardless of which reactor is first in the series for a first-order reaction but not for a second-order reaction.

⁴Recall that the removal for a zero order reaction is the same in a CFSTR and PFR of identical size, a clear indication that flow pattern makes no difference in the removal for zero order reactions.

For $N = 4$,

$$\left(\frac{C_{\text{out}}}{C_{\text{in}}}\right)_{N=4} = \frac{1}{\left(1 + \frac{k_1 \tau}{4}\right)^4} = \frac{1}{\left[1 + \frac{(0.277 \text{ min}^{-1})(6.63 \text{ min})}{4}\right]^4} = 0.047$$

or $\eta = 1 - 0.047 = 0.953$.

For the two non-ideal reactors in parallel, each behaving as N -CFSTRs-in-series,

$$\begin{aligned} \left(\frac{C_{\text{out}}}{C_{\text{in}}}\right) &= \frac{f_A}{\left(1 + \frac{k_1 \tau_A}{N_A}\right)^{N_A}} + \frac{f_B}{\left(1 + \frac{k_1 \tau_B}{N_B}\right)^{N_B}} \\ &= \frac{0.63}{\left[1 + \frac{(0.277 \text{ min}^{-1})(12 \text{ min})}{5}\right]^5} + \frac{0.37}{\left[1 + \frac{(0.277 \text{ min}^{-1})(24.5 \text{ min})}{27}\right]^{27}} = 0.0501 \end{aligned}$$

or $\eta = 1 - 0.050 = 0.950$.

Finally, we use the direct combination of the exit age distribution ($E(t)$) and the integrated reaction rate expression ($\exp(-k_1 t)$) as explained above. A spreadsheet with the appropriate calculations is shown in Fig. 4-21; columns A and C are repeated from the spreadsheet shown in Fig. 4-3 and columns B and D are the average of successive values in

	A	B	C	D	E	F

FIGURE 4-21 Spreadsheet for estimating the conversion in non-ideal flow.

columns A and C, respectively. For the analysis, Eq. 4-69 is rearranged and made explicit for the intervals as follows:

$$\frac{C_{\text{out}}}{C_{\text{in}}} = \sum_{\text{all intervals } i} \exp(-k_1 t_{\text{ave},i}) E_{\text{ave},i} \Delta t_i \quad (4-71)$$

In the spreadsheet, the values of $\exp(-k_1 t_{\text{ave},i})$ are calculated in column E; for example, the value in row 4 is calculated as

$$\exp[(-0.277 \text{ min}^{-1})(1.25 \text{ min})] = 0.7073$$

The values in column F represent the unconverted material that is coming out of the effluent in the fraction of the fluid that stayed in the tank for each time interval. These values are calculated as the product of the values in columns D and E and also Δt_i ; in this example, all of the values of Δt_i equal 2.5 min. So, for example, the value in row 4 is calculated as

$$\exp(-k_1 t_{\text{ave},i}) E_{\text{ave},i} \Delta t_i = (0.7073)(0.005 \text{ min}^{-1})(2.5 \text{ min}) = 0.0088$$

Finally, the overall fraction remaining is shown as the sum of the values in column F, as 0.0618; that is,

$$\frac{C_{\text{out}}}{C_{\text{in}}} = \sum_{\text{all intervals } i} \exp(-k_1 t_{\text{ave},i}) E_{\text{ave},i} \Delta t_i = 0.0618$$

or $\eta = 1 - 0.0618 = 0.9382$.

This last estimate uses the tracer information directly and completely, and so it is the best estimate of the removal that is achieved in the reactor. The other methods use models that encapsulate the tracer information in a small number of parameters, but those models do not fit the original data perfectly and therefore are not quite as reliable as this spreadsheet method in estimating the conversion. Coincidentally, the value calculated for the $N = 3$ CFSTRs in series is essentially identical; this agreement stems primarily from the fact that the model agrees very well with the tracer-derived $E(t)$ curve over the first few time periods, as discussed below.

The calculations in the spreadsheet illustrate a critical point about conversion in continuous flow reactors: the portion of the flow that only stays in the reactor for a few min is primarily responsible for the unreacted material that gets into the effluent. Note, for example, that the sum of the first four values in column F of the spreadsheet in Fig. 4-21 is 0.0529, while the sum of the entire column, as indicated above, is 0.0618; that is, the fraction of the water that stayed in the tank for 10 min or less was responsible for 0.0529/0.0618, or 85.6 percent, of the unreacted material. The $F(t)$ value at $t = 10$ min was reported in Fig. 4-3 as 0.275; that is, the 27.5 percent of the effluent water that stayed in the tank for 10 min or less contained 85.6 percent of the unreacted material. This fact illustrates why baffling to prevent water from going quickly from the influent to the effluent is so critical to obtaining excellent removal in most reactors.

REACTORS IN WATER TREATMENT AND THEIR HYDRAULICS CHARACTERISTICS

Surface water treatment systems are a series of reactors, each designed with a specific purpose (or, in some cases, multiple purposes). Throughout this chapter, we have discussed the possible hydraulic characteristics of reactors and the consequences of those characteristics

on the achievement of reaction goals. However, that discussion has been generic in elucidating the principles of exit age distributions and the effects on reactions. In this section, the application of those principles in specific reactors of a water treatment plant is presented. The discussion that follows is summarized in Table 4-4.

A conventional surface water treatment plant has a pipeline from a water source to the plant. This supply pipeline can be, and often is, used as an oxidation or disinfection reactor with the addition of a chemical oxidant at or near a pump near the water source; less frequently, it is used as a particle destabilization reactor by the addition of metal coagulants or polymers. Pipelines leaving the plant are also often used as disinfectant reactors. Pipelines are usually modeled as plug flow reactors, although it would be more accurate

TABLE 4-4 Hydraulic Characteristics of Water Treatment Plant Reactors

Reactor	Assumed hydraulic characteristics in design or process models	Actual hydraulic characteristics in common designs	Possible improvements to common designs
Pipelines	Plug flow	Plug flow with small amount of dispersion so plug flow is good assumption	Improved mixing at point of chemical addition
Rapid mix tanks	CFSTR	CFSTR* or small number of CFSTRs in series	Series of true CFSTRs if order of chemical addition is critical
Flocculation tanks	PFR	2 or 3 CFSTRs in series	Serpentine flow through all but last reactor
Sedimentation	PFR	2 or 3 CFSTRs in series	Baffling to improve plug-flow like conditions
Dissolved air flotation	PFR	Near PFR in contact zone and 2 or 3 CFSTRs in series in separation zone	Addition of tubes or plates in the separation zone to improve hydraulics and performance
Granular media filtration	PFR	Very close to PFR [†]	None
Membrane filtration	PFR	Very close to PFR	None
Clearwells (traditional)	---	Large dead zones; active area behaves like few CFSTRs in series	Baffling to improve plug-flow-like conditions and eliminate dead zones
Clearwells (designed for disinfection credit)	PFR	Multiple CFSTRs in series	Further baffling if necessary
Elevated storage tanks	---	Susceptible to temperature stratification, leading to large dead zones	Vertical influent nozzles to provide high velocity and induce thorough mixing

* Continuous flow stirred tank reactor.

† Plug flow reactor.

to describe them as plug flow with a small amount of dispersion. Flow in pipelines is usually turbulent, and turbulent flow in a pipe flowing full is characterized by nearly uniform velocity throughout most of the cross section (and a sharply diminishing velocity in a laminar boundary layer as one approaches the pipe's wall). Because of the nearly plug flow characteristics, pipelines are excellent reactors, and should probably be used more often than they traditionally have been as oxidation and/or particle destabilization reactors. The point of addition should be near the pump or other point of hydraulic change (bend, expansion, or reduction in the pipe) to ensure rapid integration of the added chemical into the entire water flow.

The first reactor in most plants is the rapid-mix tank, where one or several chemicals are added for various purposes. Possibilities include any of the oxidants/disinfectants, the particle destabilization chemicals (synthetic polymers, metal coagulants), pH adjustment chemicals (lime and/or soda ash as bases or sulfuric or hydrochloric acid), and precipitation chemicals (lime for softening). Several of these chemicals might need to be added in the same reactor, and the order of addition of some combinations is also critical. The hydraulic design must be performed carefully because of the somewhat conflicting goals of complete and instantaneous mixing required to mix the chemicals with the water and the desire for plug flow conditions for the initiation of the reactions for which those chemicals are added. Many plants include a single completely mixed reactor (CFSTR) for this part of the plant, but the needs for several additions and the importance of the order of addition in several cases mean that a multiple part reactor (i.e., a real set of CFSTRs in series, not just a single reactor modeled that way) is better; a multiple-reactor design is becoming more common. The exit age distribution ($E(t)$) of a single CFSTR suggests that much of the material that enters at any instant leaves the reactor in a small fraction of the detention time; if the reaction required for the added chemical requires contact with other constituents, that rapid exit of material might not be favorable. A growing trend in treatment plant design is to use the pipeline as all or most of the rapid-mix tank, because it combines the benefits of mixing (via the turbulence) with the benefits of plug flow. Klute and Amirtharajah (1991) noted that a major benefit of the intimate mixing of particles and metal coagulants in turbulent pipe flow was to reduce the amount of coagulant required to obtain excellent particle destabilization; apparently, the achievement of particle-coagulant mixing more rapidly than the time required for the coagulant's hydrolysis reactions resulted in a substantial improvement in the efficiency of destabilization.

Flocculation is a second-order reaction in particle number; as indicated earlier in this chapter, achieving conditions that are as close to plug flow as possible is particularly valuable for second-order reactions. On the other hand, maintaining sufficient mixing that the particles stay in suspension so that they can contact one another and not settle to the bottom is also critical. Traditionally, many flocculators have been built as three CFSTRs in series, often with increasing volume and decreasing mixing intensity from the first to the third, so as to avoid breakup of flocs. This design could be improved further by imposing a serpentine flow (much like many disinfection reactors) through the first two compartments to make each act like three or four CFSTRs in series, assuming floc breakup could still be avoided. Adding baffling to existing flocculators to make the hydraulic pattern more plug flow-like would likely improve the flocculation achieved, perhaps substantially. Han and Lawler (1992) suggested that the intensity of mixing (as measured by the velocity gradient G) is less important as a means of bringing particles together than had been previously thought; modern flocculators in sedimentation plants are designed with lower G values (in the range of 15 to 25 s^{-1} and some even lower) than was common in earlier times.

Because flocculation is a second-order reaction (i.e., because high particle concentrations increase the rate of reaction), many designs of flocculators incorporate means of maintaining high particle concentrations. The use of metal coagulants to precipitate new solids is the first way in which this goal is commonly accomplished; especially when the

turbidity of the raw water is low, this benefit of metal coagulants is essential. The other means of maintaining high particle concentrations are to either recycle solids from the settled (or floated) residuals in the subsequent gravity separation device or to make it more difficult for particles than for water to leave the flocculator. This latter means is often accomplished in reactors that combine flocculation and sedimentation by maintaining a high concentration of particles in the central section of a circular reactor where flocculation is the dominant process occurring.

Traditional sedimentation tanks are large open reactors with no baffling between the influent structure and the effluent weirs. Both the influent structure and the weirs are designed to spread the flow over the entire surface area, since the surface area (for a given flow rate) is the primary design feature. The traditional (and still widely used) analysis of sedimentation tanks developed by Hazen (1904) assumes plug flow conditions. However, the lack of baffling and the exposure to wind at the surface means that a substantial amount of mixing generally occurs; tracer studies indicate that they behave like a small number (two to four) of CFSTRs in series. Adding baffling can be difficult because of the requirement for mechanisms to remove residuals, but manufacturers now have designs that improve the traditional designs with respect to baffling and hydraulic behavior. While sedimentation is not a reaction in the same sense as those noted earlier in the chapter, the value of nearly plug flow conditions follows the same trend. Sedimentation in water treatment plants is actually “floculent sedimentation”; that is, flocculation continues simultaneously with sedimentation in these reactors. Improvements in baffling in the sedimentation tanks in a treatment plant in Austin, Texas, for example, reduced the particle load on the subsequent gravity filters so much that the filter runs were increased from 24 to 72 h. Tube or plate settlers not only provide a great increase in the surface area available for settling but also exhibit hydraulic behavior that is much closer to plug flow conditions than traditional sedimentation tanks; retrofitting an existing, traditional open sedimentation tank with tubes or plates can have a dramatic effect on the removal achieved.

Dissolved air flotation units consist of a contact zone and a separation zone. In the contact zone, where the bubbles form and move upward by the balance of gravity and buoyancy (and contact and stick to particles), the hydraulic characteristics are best described as plug flow with dispersion. The drag on the rising bubbles causes water to also flow upward in this part of the reactor; this water flow produces the nearly plug flow conditions. In the separation zone, plug flow is desirable (as in sedimentation), but the flow is often mixed for low-rate DAF systems and the high-rate systems have a complicated flow regime (see Chap. 9).

Granular media filters (either pressure filters or gravity filters) are packed bed reactors with an unbaffled water layer above. As noted earlier in the chapter, packed beds have nearly plug flow hydraulic characteristics. The water layer above the media is mixed to a substantial degree by the momentum of the influent flow which usually comes into the reactor horizontally through a pipe opening; this part of the reactor behaves as one or two CFSTRs in series. Since no reactions are expected to be occurring in that part of a treatment plant and the detention time is low in that water layer, changing the hydraulics of that part of most plants would have little value. Membrane filters also have very good hydraulic characteristics in achieving nearly plug flow conditions, because the head loss is spread evenly over the membrane surface area.

Clearwells are the final reactor in a water treatment plant. In earlier times, clearwells (and elevated storage tanks within distribution systems) were thought of only as storage devices; they were sized to allow for the plant to operate at nearly steady-flow conditions while meeting the fluctuating demand in the distribution system. Now, clearwells are a critical part of the disinfection that is achieved in water plants. As in all disinfection reactors, the importance of avoiding short circuiting (where some of the flow proceeds from the influent to the effluent in a tiny fraction of the detention time) must be emphasized.

Proper baffling to lengthen T_{10} to at least 0.4τ should be a goal in every treatment plant. The prevention of short circuiting usually also prevents the creation of *dead space*, a portion of the reactor where water sits for very long periods of time without participating in the flow pattern. Dead space not only decreases the average residence time of the remaining water but can also directly lead to the deterioration of water quality in the *dead water* (e.g., loss of disinfectant residual), and so it too must be avoided. As in any disinfection reactor (or other reactor in which a high removal efficiency is desired), providing sufficient baffling so that water must take a highly circuitous path from the influent to the effluent creates the best-quality effluent by preventing both short circuiting and dead space.

SUMMARY

The hydraulic characteristics of reactors in existing water treatment plants can be determined by tracer studies. For plants under design, computational fluid dynamics can be a useful tool for modeling the effects of different design details on the expected hydraulic behavior. The results of tracer studies can be converted to the exit age distribution or the cumulative age distribution of a reactor (or series of reactors). These distributions then can be either used directly to predict the effluent quality for known reactions or fit to relatively simple mathematical models of the hydraulic behavior. For most reactions of interest, achieving hydraulic conditions that approach plug flow behavior is of great value in achieving excellent water quality; these conditions are accomplished through careful design of influent and effluent structures, long length to width ratios, and adequate baffling.

ABBREVIATIONS

CFD	computational fluid dynamics
CFCMR	continuous flow completely mixed reactor
CFSTR	continuous flow stirred tank reactor
DAF	dissolved air flotation
PFR	plug flow reactor
SDWA	Safe Drinking Water Act
USEPA	U.S. Environmental Protection Agency
UV	ultraviolet light

NOTATION FOR EQUATIONS

A	cross-sectional area
a	dimensionless group in equation for first-order reaction in a reactor described by the plug flow with dispersion model
$C_{ave,i}$	average concentration in the time interval between t_{i-1} and t_i
$C_{baseline}$	concentration throughout a reactor and in the influent prior to initiation of a step input tracer test

C_{in}	influent concentration to a continuous flow reactor (generally constant)
C_0	initial concentration in (or exiting) a reactor
$C_p(t)$	effluent concentration at time t in pulse input tracer test
$C_S(t)$	effluent concentration at time t in step input tracer test
D_n	dispersion number, parameter of the plug flow with dispersion model (—)
$E(t)$	exit age distribution (time^{-1})
$E_{ave,i}$	average value of the exit age distribution in the time interval between t_{i-1} and t_i
$F(t)$	cumulative age distribution (—)
f_A	fraction of flow in compartment A in non-ideal flow modeled as reactors in parallel
G	velocity gradient in flocculation (s^{-1})
k	rate constant (various dimensions) or
k	turbulent kinetic energy
K_S	half-velocity constant in Monod kinetic expression
L	total length
M or M_{in}	mass of tracer input in pulse test
m	parameter in the PFR-CFSTR dead-space model, the fraction of the reactor that is dead space
m	stoichiometric ratio (one molecule of B reacts with m molecules of A)
M_{out}	mass of tracer accounted for by the effluent in pulse test
N	number of size classes in a discrete particle size distribution
N	parameter of the CFSTRs-in-series model for non-ideal flow; the number of equal CFSTRs that the single reactor is (conceptually) composed of
n	reaction order
n_i	number concentration of particles in size class i
p	parameter in the PFR-CFSTR dead-space model, the fraction of the active volume that is plug flow
Q	volumetric flow rate (L^3t^{-1})
r	reaction rate expression ($\text{ML}^{-3}\text{t}^{-1}$)
S	substrate concentration
t	time
$t_{ave,i}$	average time in the time interval between t_{i-1} and t_i
\bar{t}	average hydraulic detention time calculated from tracer or exit age distribution data
T_{10}	time at which $F(t) = 0.10$
V	volume of water in a reactor
X	microorganism concentration
x	length dimension
α_{emp}	empirical collision efficiency factor in flocculation
ε	turbulent energy dissipation rate

$\gamma(i, j)$	rate constant for collisions between particles of sizes i and j
σ^2	variance of a distribution
τ	theoretical detention time

INTRODUCTION

Selection of appropriate unit processes and integration of the processes into an overall water treatment plant when assessing site-specific treatment needs is a complex task. Factors that are typically considered during treatment process evaluation and selection include (1) source water quality, (2) regulatory compliance and contaminant removal requirements, (3) process reliability and flexibility, (4) initial construction and annual operating and maintenance costs, (5) environmental impacts, (6) utility preferences and capabilities, (7) available site space, and (8) residuals handling requirements and site constraints.

The purpose of this chapter is to provide a general description of the various unit processes included in the design of water treatment facilities and their effectiveness and applicability for achieving broad treatment objectives. It is intended to serve as a guide and to direct the reader to more detailed information in the chapters that follow.

SOURCE WATER QUALITY CONSIDERATIONS (CHAP. 3)

Foremost among the considerations for selecting sources of supply for a water system is provision of adequate quantity to meet system demands over a wide range of conditions. Other factors that must be considered are the amount of effort and cost to withdraw and convey the water to the point of use and the water quality characteristics that affect treatment needs and the ultimate acceptability of the potential source. The complexity of these issues varies with location. In some locations, adequate supplies of high-quality water are available in reasonable proximity to the area to be served, whereas others involve vast conveyance systems and multiple jurisdictions.

In recent years, communities with limited available freshwater supplies have begun to look for new types of sources, including brackish and saline waters that can be treated by technologies such as desalination. The potential for reuse of wastewater for either nonpotable or potable applications is another consideration. In the case of potable applications, a distinction is made between indirect potable reuse, where the effluent is returned to a source of supply and subsequently conveyed to a water treatment process, and direct potable reuse, where highly treated effluent is conveyed to a water distribution system for direct consumption (see Chap. 16).

Water sources traditionally have been categorized as either surface or groundwater supplies, both of which have several general characteristics, as discussed below. Details on the compositions of these types of supplies are presented in Chap. 3.

Surface Water

Surface water is open to the atmosphere, which brings it into contact with oxygen, a key regulator of oxidizing conditions in natural waters. Much of the chemistry of surface water is dominated by the presence of oxidized constituents. An exception occurs in the case of impoundments that undergo stratification, with the accompanying oxygen deficit in the lower levels, where the presence of biodegradable substances leads to microbial decay of oxygen residuals. In such impoundments, the level of withdrawal and the time of year dictate the extent to which reducing conditions develop. Strategies such as mixing to limit stratification and various methods of in-lake aeration can be considered to alleviate such conditions.

Potential for exposure to microbial pathogens in surface supplies leads to the use of disinfection as a treatment step in these supplies. In addition, particle-removal processes

such as filtration typically are applied as a component of a multiple-barrier approach to provide high levels of safety.

Runoff that enters surface supplies contains natural organic matter (NOM) that reacts with disinfectants to form by-products, some of which are currently regulated. Production of NOM also can result from the activity of algae and other biota within water bodies. The concentration of NOM and the associated potential formation of disinfection by-products (DBPs) depend on the nature of the watershed and can vary seasonally as well. The extent of this variation should be considered when developing treatment strategies.

Point-source waste discharges and non-point-source surface runoff can directly influence the presence of contaminants in surface supplies. Although the volume of flow available in most surface supplies often reduces contaminant concentrations to relatively low levels, concerns have been raised even at extremely low concentrations for new categories of contaminants such as endocrine-disrupting compounds (EDCs) and pharmaceutical and personal care products (PPCPs). While the detrimental impacts of some of these contaminants on aquatic life and wildlife have been documented, the importance of low-level human exposure to EDCs and PPCPs has not yet been determined (see Chap. 2).

Trophic status of impounded supplies can be an important consideration because algal activity can lead to treatment problems that challenge a number of processes. Problems with tastes and odors and with soluble iron and manganese that increase in oxygen-depleted lower strata of impoundments also accompany algal activity. Problems that stem from excess discharges of nutrients often can be resolved by watershed management measures that are also applicable for limiting exposure to a broader range of contaminants.

Storm events can be detrimental to the quality of some surface supplies by increasing turbidity and NOM concentrations, as well as by increasing nutrient loadings and the concentration of microbial contaminants. Facility design and operating concepts should incorporate provisions for dealing with these and other causes of extreme water quality conditions.

Groundwater

Groundwater supplies are confined to substrata, thereby limiting the availability of oxygen, which can lead to the need for different treatment methods than those used with surface supplies. These conditions often lead to treatment to deal with reduced substances such as iron, manganese, hydrogen sulfide, ammonia, and reduced arsenic.

The substrata also can protect the water against contamination by microbial pathogens, resulting in treatment approaches for this category of contaminant that differ from those applied for surface-water supplies. Multiple-barrier approaches that combine disinfection with particle-removal processes are not needed for some groundwater supplies. However, not all groundwater supplies are the same, and some are subject to direct surface-water influence, requiring the use of treatment barriers for pathogens in such cases.

Quality of groundwater varies widely depending on the nature of the geology through which it flows (see Chap. 3). Variations can be regional or across the aquifer layers within a region, resulting in wide differences in required treatment sequences that depend on general characteristics such as hardness and total dissolved solids and the presence of specific natural contaminants such as radon and radionuclides. While total organic carbon (TOC) concentrations in most groundwater supplies are generally low (<2 mg/L), some groundwater supplies contain elevated concentrations of TOC that require treatment strategies to limit the formation of regulated disinfection by-products.

The confinement of groundwater can restrict flow, which can affect the rate of withdrawal from an aquifer and the corresponding yield for a given well. Often a system is supplied from multiple wells, each of which may have its own water quality characteristics and susceptibility to contamination that affects blended quality, thereby requiring management and operating decisions to make best use of these resources.

Groundwater aquifers have long residence times and thus are renewed with less frequency than surface water systems. Therefore, should aquifers become contaminated, the contaminants can occur at much higher concentrations than surface supplies, which places consumers at greater risk of extended exposure to contaminants unless effective treatment measures are provided.

Water Quality

Several general water quality variables must be considered when selecting and configuring the treatment sequence for a given water source regardless of whether it is a surface-water or groundwater supply, including the following:

1. *pH*. This variable has major effects on the chemistry of constituents in water and on treatment-process performance. It is therefore imperative that the pH of the source water is monitored routinely and that the pH profile through the treatment process is controlled. pH also affects corrosion and water quality in the distribution system and thus must be controlled to minimize water quality impacts.
2. *Alkalinity*. Alkalinity is the measure of the acid-neutralizing capacity of a solution. It is defined by the amount of acid required to reduce the pH to a defined end point. For the pH conditions of most supplies, alkalinity is due mainly to the bicarbonate concentration. Alkalinity is an important factor in coagulation and in selecting the corrosion-control methodology to be implemented. Acidity, a related parameter, is a measure of the base-neutralizing capacity. Principles pertaining to alkalinity and acidity are discussed in Chap. 3.
3. *Hardness*. The level of hardness can dictate treatment concepts that should be applied. A high level of hardness tends to favor softening over clarification only and can affect a range of treatment processes. Like alkalinity, it also can affect the choice of corrosion-control methods.
4. *Turbidity*. Turbidity is a measure of the particulate matter in the water. It affects the choice of clarification methods and can dictate whether or not there is a need for pretreatment upstream of some other processes.
5. *Natural organic matter*. NOM presents a concern for disinfection by-product formation, increases coagulant and oxidant demand, and can affect a number of treatment processes. It can be characterized by several surrogate measurements, including TOC concentration and ultraviolet (UV) absorbance (see Chap. 3).
6. *Total dissolved solids (TDS)*. This measure of salt and mineral content can affect treatment needs as well as the acceptability of a source of supply.
7. *Dissolved oxygen*. Dissolved oxygen is an important regulator of oxidation-reduction conditions that determine the chemical speciation of a number of constituents in water (see Chap. 3). Oxidizing conditions are produced even when oxygen is present at low concentrations.

In addition to these general parameters, water sources can have unique quality concerns that must be addressed.

CHARACTERISTICS AND GENERAL CAPABILITIES OF UNIT PROCESSES

This section provides an introduction to the treatment processes discussed in the chapters that follow. The objectives are to present a broad overview of the various process components and their typical applications and capabilities and to serve as a “road map” to the

contents of the remainder of the book. A more detailed discussion of each unit process is presented in the referenced chapters.

Aeration and Air Stripping (Gas-Liquid Processes; Chap. 6)

Air stripping and aeration are gas-transfer processes that have played important roles in water treatment for many years, including transfer of oxygen for oxidation of constituents such as iron and manganese, removal of certain tastes and odors, and removal of dissolved gases such as hydrogen sulfide and carbon dioxide. Air stripping typically is used to remove volatile organic compounds (VOCs) from contaminated groundwaters that became a concern in the 1980s and newer contaminants such as methyl-*tert*-butyl-ether (MTBE) and radon. Air stripping to remove trihalomethanes (specifically, chloroform) has been used in some facilities, but this approach has proven somewhat limited in scope because most disinfection by-products are not amenable to removal by air stripping.

Aeration is not appropriate for treatment of groundwater containing reduced arsenic and iron because iron is oxidized more quickly than arsenic by oxygen. For effective removal of arsenic, both arsenic and iron need to be oxidized at the same time by a strong oxidant such as free chlorine.

Gas transfer processes are most applicable when there is an imbalance in the activity of the constituent in the gaseous and liquid phases, where activity in the gas phase is generally characterized by the partial pressure, and activity in the liquid phase is characterized by concentration. This imbalance causes constituents to flow from the condition of higher activity in the direction of lower activity to balance the conditions in the two phases. The rate of transfer depends on the extent of the imbalance, the surface area available for transfer, the degree of mixing and turbulence, temperature, and intrinsic diffusion rates of the target constituent. Constituents such as VOCs are readily removed by air stripping. For constituents that can react in solution, the rate and extent of the transfer are also affected by factors such as pH and other reactive constituents in solution, such as chlorine, carbon dioxide, hydrogen sulfide, ammonia, and oxygen. Constituents that have little or no tendency for reaction in solution, such as radon and VOCs, recently have become targets for treatment by air stripping.

The susceptibility of a target constituent to gas transfer depends on its solubility in water relative to its corresponding partial pressure or concentration in the gas phase. Gases that are poorly soluble in water relative to their concentrations in the gas phase can be readily removed. The most common measure of these relationships is *Henry's constant*, which is the ratio of the activity of a constituent in gas to the activity in solution at equilibrium. The higher the Henry's constant of the constituent, the more readily removable it is by gas transfer.

Equipment for bringing gas and water together to produce gas transfer generally is configured to produce a large surface area at the boundary between the two phases and, in some cases, a degree of turbulence, both of which are necessary for accelerating the rate of transfer. This equipment includes spray nozzles, diffusers that control the size of the bubbles for the gaseous phase, and tray aerators and packed-bed towers that spread the surface of the interface across specially designed media. In some cases, treatment of aerator/stripper off-gas may be required to remove contaminants in order meet air quality criteria.

Chemical Oxidation (Chap. 7)

The basic purpose of chemical oxidation is to change the oxidation state of the constituents involved. In the context of water treatment, the intent is to produce changes that improve water quality, but there is also the potential for the formation of undesired reaction products

(such as halogenated disinfection by-products when chlorine is used as the oxidant), an outcome that can require wise decision making.

Two different types of chemical oxidation are used commonly in water treatment. The more direct method consists of applying the chemical oxidant to produce the desired treatment outcome in a single step, such as in the oxidation of taste- and odor-causing compounds by ozone. With the second method, chemical oxidation is a component of a multistep sequence whereby the oxidant is used to alter the oxidation state of the target constituent to a form that is more readily removable by subsequent treatment steps. Oxidation of reduced forms of iron and manganese to higher oxidation states that will readily precipitate is one example of this method. Removal of sulfides and arsenic in multistep sequences is another example. Since all chemical disinfectants are oxidants, oxidation will occur to some degree even when the objective is inactivation of microbial contaminants.

Chemical oxidants used most commonly in water treatment include

1. *Chlorine.* Chlorine is used widely in water treatment as a disinfectant. It can oxidize iron and manganese, color, and some taste- and odor-causing compounds. It is especially effective in manganese removal when applied ahead of filtration to maintain an oxidized coating on the granular media. This method of manganese removal, while often inadvertent, is an important consideration if points of chlorine addition are modified to meet other treatment objectives. Chlorine is available commercially in several forms: as a compressed gas, in aqueous liquid form (sodium hypochlorite), and in solid form (calcium hypochlorite). Another alternative that has received increased attention in recent years is on-site electrolytic generation of sodium hypochlorite from salt (see Chap. 17).
2. *Permanganate.* Permanganate can be used for oxidation of iron and manganese and for removal of some taste and odors. Traditionally, it has been available as potassium permanganate, which is delivered as a solid that requires handling and dissolution prior to application. Recently, liquid sodium permanganate has become available and can be applied directly as delivered.
3. *Ozone.* Ozone is a strong oxidant that is effective for reduction of color, control of a broad range of taste- and odor-causing compounds, and conversion of NOM to forms more readily removed by biological filtration. It sometimes can improve coagulation and filtration and reduce the formation of some disinfection by-products, notably trihalomethanes and haloacetic acids. While also effective for oxidation of iron and manganese, use of ozone for control of manganese has proved complex and problematic in some cases because of the formation of colloidal manganese oxide particles. Overdosing of ozone also can result in the formation of permanganate, which can pass through filters and later precipitate manganese oxides in the distribution system. Because ozone is highly reactive and not sufficiently stable for storage, it is produced on site using generation equipment that applies a controlled electrical discharge to interact with oxygen to form ozone. Sources of oxygen for this process include ambient air that has been treated to remove moisture and impurities, commercially manufactured liquid oxygen, and application of equipment to produce a concentrated oxygen stream on site. While use of ambient air was the predominant approach in early ozone-generation systems, newer designs typically use more concentrated oxygen streams that yield improved generation efficiencies and higher ozone concentrations in the feed gas.
4. *Chlorine dioxide.* Chlorine dioxide can oxidize iron and manganese and some taste- and odor-causing compounds, reduce color, and in some cases reduce trihalomethane and haloacetic acid formation potential. It is an alternative to chlorine that reduces production of chlorinated organic by-products, but care must be exercised to manage application rates such that excessive amounts of chlorine dioxide and its inorganic degradation

products (i.e., chlorite and chlorate) are not present in the finished water. Being highly reactive, chlorine dioxide cannot be manufactured off site for delivery to the point of use. It is therefore generated on site by reactions between (1) gaseous chlorine and sodium chlorite, (2) hydrochloric acid, sodium hypochlorite, and sodium chlorite, or (3) sulfuric acid and proprietary blended sodium chlorate–hydrogen peroxide products.

5. *Advanced oxidation.* Advanced oxidation processes produce highly reactive free radicals, most notably the hydroxyl radical. Much of the interest in these processes has been directed toward removal of specific organic contaminants, such as taste- and odor-causing compounds that are resistant to treatment using other oxidants. Interest in removal of a range of other organic contaminants also has emerged. Technologies used to generate these radicals include (a) ozone and hydrogen peroxide, (b) UV radiation and hydrogen peroxide, (c) UV radiation and ozone, and (d) various approaches involving catalysts.
6. *Mixed oxidants.* Mixed oxidants are generated on site from salt solutions and carefully controlled operational settings to produce a hypochlorite-based solution with disinfection and oxidation properties different from hypochlorite alone. Mixed oxidants offer an alternative to traditional forms of chlorination and chloramination for secondary disinfection and residual maintenance in the distribution system.

Treatment results from use of these oxidants are influenced by pH, temperature, oxidant dose, reaction time, and the presence of interfering substances. Characteristics of an oxidant in solution can be affected particularly by pH, whereas increased temperature almost universally increases the rate of reaction. Reaction time and dose are fundamental considerations for providing conditions that affect the extent to which a target constituent will be removed, whereas pretreatment processes and process sequencing may be important considerations for limiting the adverse effects of interfering substances. The susceptibility of various chemical bonds to oxidative attack are also critical considerations and therefore influence selection of chemical oxidants. Each oxidant can lead to different treatment outcomes and effectiveness for a given application.

While chemical oxidants are most commonly used for oxidation of specific constituents, they also can take part in other types of reactions where oxidation is not necessarily the only outcome, such as substitution reactions between chlorine and ammonia to form chloramines. This is a desirable outcome because chlorine is substituting into the structure of ammonia without a change in oxidation state, thereby retaining the capability for disinfection. Other substitution reactions include the formation of halogenated disinfection by-products, an undesired outcome of reactions between oxidants and precursor components of NOM.

Coagulation and Flocculation (Chap. 8)

Coagulation is a fundamental process used at water treatment plants worldwide as a pre-treatment step not only for traditional rapid-rate filtration technologies that comprise much of the water treatment infrastructure that still exists but also for many of the newer technologies. In rapid-rate filtration plants it serves as the mechanism for building particles to a size that can be readily removed in the clarification step, as well as for conditioning particles to adhere to the filter media to ensure maximum process efficiency. Its importance to filtration was underscored by the results of a survey by Cleasby et al. (1989) that found coagulation to be more important than physical filter characteristics and loading rates for meeting filtration goals at many of the sites surveyed.

The traditional view of coagulation is that it facilitates agglomeration of small colloidal particles into larger particles of a size that can be physically removed. The mechanisms for achieving this are discussed in detail in Chap. 8. The role of coagulation in removing

TOC has emerged in the last 20 years, and for many surface-water supplies, TOC controls coagulant dosing rather than raw-water turbidity.

Ferric and aluminum salts are the most common primary coagulants. Aluminum salts include alum and various commercial products such as polyaluminum chlorides. Ferric salts include ferric chloride and ferric sulfate and less commonly used formulations.

High-charge-density cationic polymers are sometimes used alone in direct filtration applications or as a dual coagulant with alum or ferric coagulants. High-molecular-weight, long-chained nonionic polymers or anionic polymers of very low charge are used as flocculant aids and filter aids. As flocculant aids, they are capable of bridging particles together to increase floc size and strength, thereby increasing floc settling velocities. As filter aids, they improve attachment of particles to filter grains and previously retained floc particles. Typical points of application of flocculant aids are downstream from the rapid mix or near the midpoint or the end of a conventional flocculation basin. Filter-aid polymers are typically added immediately upstream of the filters.

Discussions of coagulation chemistry emphasize the importance of pH as a critical process condition for coagulation with the common metal salts, which can be especially sensitive to changes in this parameter (see Chap. 8). This is because pH affects the chemical speciation of the dissolved coagulant in rapid mixing and the precipitation of aluminum or ferric hydroxide.

Polyaluminum chlorides, aluminum chlorohydrates, and some other commercial formulations differ from the common metal coagulant salts in that their composition is adjusted during the manufacturing process to maximize the presence of the most effective dissolved aluminum species in rapid mixing. These prehydrolyzed coagulants, which are effective at neutralizing the negative charge of particles, are less acidic than alum and ferric coagulant, so their use in low- to medium-alkalinity waters without the need for addition of supplemental base to control pH may be feasible. In addition to pH, coagulation is strongly affected by a number of other factors, including particle characteristics, concentration and nature of NOM, presence of anions that interact with the metal coagulants, and temperature. There is no single “preferred” coagulant—the selection varies with the treatment conditions and goals.

In addition to these and other direct chemical influences, decisions regarding coagulant application are affected by a number of other secondary effects that can result, such as the production of residual solids, the introduction of contaminants such as manganese that occur as impurities in the coagulant, and changes in pH that affect other aspects of treatment. A more recent concern has emerged regarding the effects that coagulant chemicals have on the finished water chloride-to-sulfate ratio, which may lead to increased lead corrosion in some water systems (see Chap. 20). Corrosion of metal components within a water treatment facility prior to final adjustment of finished water pH can also be affected by the pH during coagulation.

Rapid mixing and flocculation provide the physical mechanisms for dispersion of chemicals and particle contacting following coagulation. Although the physical characteristics of the equipment used in the coagulant dispersion and flocculation processes are similar, the process goals are very different. The objective of mixing is rapid dispersion of the coagulant chemical to achieve relatively uniform distribution. Long detention times are not needed to achieve this goal and actually can be detrimental because dispersion tends to be most effective when it occurs rapidly within a confined space. Older rapid-mix basin configurations based on detention-time criteria are no longer regarded as the best approach. Dispersion-oriented configurations include basins in which mixing is confined to the smallest possible volume as flow passes the mixer blade and a variety of in-pipe configurations that include mechanical mixers, static mixers, and hydraulic-jet dispersion concepts. Other approaches can involve distributed dispersion across weirs and hydraulic jumps. Even simple in-pipe addition can provide better results than some of the older conventional rapid-mix basins (Clark et al., 1994).

Mixing of the coagulant is followed by flocculation to aggregate the chemically conditioned particles into floc that can be removed by downstream processes. The objective of this process step is controlled introduction of mixing energy to induce contact between particles that leads to a progressive increase in floc size. Ideally, this process will result in a uniform floc size with particles in the optimal size range for removal by clarification or filtration. Unlike coagulant dispersion/mixing processes, detention time is important in the flocculation process for developing floc of the desired size. The most common types of equipment for this process are vertical turbines and paddle-type flocculators. Hydraulic flocculators, which rely on the turbulence created as flow is redirected around baffles installed in the floc basin, are another alternative. In some cases, gates that can be adjusted to vary the energy imparted to the process stream are provided to optimize the hydraulic flocculation process. Turbulence within a pipeline or at the entrances to a series of unmixed chambers is also applied in some cases. However, these hydraulic flocculation systems generally offer less operational flexibility and process-control capability over a range of flow rates than conventional mechanically mixed systems.

The design of the flocculation step is generally based on the floc characteristics desired for downstream clarification and filtration. As an example, dissolved air flotation targets smaller floc sizes than conventional sedimentation because the floc particles attach to air bubbles to be floated; excessively large floc size would be detrimental to this process. Other downstream processes are also optimized by using different floc size distributions. For direct filtration, filterable floc size is the target; floc that is too large can cause filter “blinding.” Even for conventional settling, there is usually a maximum desirable floc size owing to the lower floc densities and susceptibility to shear that is often encountered with large floc. Therefore, it is essential that particle size be considered in configuring and operating the flocculation process.

The performance of most unit processes within a water treatment plant is highly dependent on effective coagulation, mixing, and flocculation. The pretreatment benefits of coagulation can significantly influence the performance of other unit processes discussed in this book, including chemical oxidation, ion exchange, adsorption of organic compounds, chemical disinfection, and UV irradiation.

Sedimentation and Flotation (Chap. 9)

Sedimentation and flotation processes achieve the objective of separating particles from the process stream. While these processes can be used alone in pretreatment or other applications, they usually follow coagulation or precipitation. In a larger context, these processes fall into the category of clarification technologies. Both processes are gravity processes; in the case of settling, since the density of the particles exceeds the density of water, settling occurs, whereas in flotation, because the density of the bubble-floc aggregate is less than the density of water, the aggregate rises. Principles of settling and rise velocity are similar, and both processes are sized based on hydraulic loading rates—often referred to as the *overflow rate*.

Central to an understanding of sedimentation processes is the concept of surface loading rate or overflow rate (OR), which was developed by Hazen (1904). Its importance was further developed with regard to process effectiveness by Camp (1936). Calculated by dividing the process flow rate by the unit process steeling area, OR corresponds to a vertical particle settling velocity and therefore is commonly expressed in units of m/h (gpm/ft² or gpd/ft²).

Under the OR concept, settling basins with greater settling or surface areas perform better. Recognition of this relationship led to the development of tray, tube, and inclined-plate settling concepts to increase sedimentation rates by incorporating additional settling

surfaces within a given volume. The OR concept is commonly applied to all the sedimentation processes and is used as a fundamental basis for characterizing and evaluating these processes.

A number of sedimentation processes are available, including a variety of proprietary configurations. In general, they are divided into the following categories:

1. *Conventional horizontal-flow sedimentation.* This is a traditional approach that consists of simple gravity settling in a basin or tank with no enhancements to accelerate settling. It is simple to operate but requires a larger plan area than other clarification processes.
2. *High-rate gravity settling.* This process involves the use of additional configurations or devices that increase the available effective surface area in the basin. Commercially available inclined-plate and tube settler equipment is the most widely used equipment of this type. Tray sedimentation basins that employ multiple “floors” within a given sedimentation basin area to maximize flow path lengths are another example—these were used in the past but are not used now in new plants.
3. *Solids contact clarifiers.* These basins generally contain mixing and flocculation equipment within a common reaction zone, with settling occurring in another zone of the same basin. Solids are recycled to maintain a high solids inventory in the reaction zone and to provide increased opportunities for contact between particles, thereby increasing the size and settling rates of flocs or precipitates and allowing the use of higher surface loading rates than in conventional gravity settling. One modification of this approach is the IDI Densadeg process, which separates the mixing and settling compartments between different basins; the solids inventory within the reaction zone is maintained through collection and return of settled solids from the settling tank to the mixing/reaction stage. Withdrawal of solids (termed *blowdown*) from the sludge blanket within the solids contact clarifier is necessary to avoid loss of solids from the clarifier into the process stream. Appropriate blowdown rates and duration are critical to maintaining a properly balanced system; excessive rates will remove too many solids from the blanket, whereas an inadequate rate will allow solids to overflow to the process stream.
4. *Floc blanket clarifiers.* Flow into these clarifiers is introduced at the bottom and withdrawn from the surface. The process relies on a solids blanket that is developed at the bottom of the basin to entrain incoming particles. These clarifiers are available in several configurations, but all are equipped with a submerged weir over which the blanket will overflow to be removed by a blowdown process. The appropriate blowdown rate is also critical for this process because excess blowdown will result in larger than necessary waste streams, and inadequate blowdown will result in overflow of solids into the process stream. One application of this approach is the SuperPulsator clarifier, in which a pulsing action is applied to the floc blanket to keep it homogeneous.
5. *Ballasted flocculation.* This process accelerates settling by using polymer to attach floc particles to a concentrated mass of fine sand (microsand). The density of the resulting floc is increased by the sand, thereby allowing use of high overflow rates. Settled solids are collected from the bottom of the settling compartment and pumped to hydrocyclones, where the sand is separated from the lighter floc and returned to the process stream, and the waste solids are directed to the disposal process. The accelerated particle settling features of this process allow use of high loading rates in the settling zone, with corresponding reductions in the system footprint.

Dissolved air flotation (DAF) is an alternative to sedimentation. Available in several configurations, DAF employs a pressurized recycle stream that is saturated with air. The recycle stream discharges at the inlet to the flotation basin, and large quantities of fine bubbles are released. Floc particles from the upstream coagulation/flocculation process

attach to the bubbles and are floated to the surface. Conventional DAF systems operate at hydraulic loading rates similar to filter rates. High-rate systems have been introduced in the last 10 years (see Chap. 9).

The sedimentation and DAF processes have site-specific advantages that require recognition of respective benefits and limitations for proper process selection. For example, dissolved air flotation is most effective in treating reservoir supplies, which are low in mineral turbidity (turbidity attributable to silts/clays). In addition, it can have application to supplies with moderate to high color or TOC.

Polymer is used with some of the sedimentation processes, and possible effects of polymer residual on downstream processes are a potential concern depending on the nature and quantity of polymer applied. Ballasted flocculation processes require the application of polymer to attach floc to microsand; polymer usage cannot be avoided for this process, and excessive carryover of polymer has been shown to be detrimental to downstream granular media filter performance if dosing is not regulated properly. Other processes can also benefit from the application of polymer for improved settling. This can be an important consideration for both solids blanket and floc blanket clarifiers, where settling properties within the floc blankets can be critical to effective performance. Gravity settling (both conventional and high rate) can benefit from polymer addition as well, but application generally is less critical for these processes. Dissolved air flotation generally functions well without polymer, although there can be isolated situations where polymer can be beneficial.

Granular Media Filtration (Chap. 10)

Conventional media filtration systems include granular bed, precoat, and slow sand filters. Granular bed filtration, the most commonly used of these processes, consists of a filter box that contains a bed of granular media placed on a support layer with an underdrain below it. Sand, anthracite, granular activated carbon (GAC), and high-density garnet and ilmenite represent common media options, and other commercially produced media have been developed. The dual-media arrangement (typically anthracite over fine sand) is the most common configuration. Efficient removal of particles requires an upstream coagulation step because attachment of flocs to filter grains and previously retained flocs are the mechanisms of floc particle removal within the pores of the filter bed.

Water flows through the filters in the downward direction; filtered water is collected by the underdrain system at the bottom of the filter and conveyed through filter effluent piping. Flow and filter level are usually controlled by valves in the filter effluent piping; however, some types of granular bed filters allow flow to diminish as head loss accumulates to produce a declining-rate mode of operation.

Granular bed filters require periodic backwashing to displace particles that accumulate on the media over the course of a filter run. Older backwashing methods relied on hydraulic scour to clean the filter media during backwash, but newer air-scouring approaches offer significant advantages, including improved media cleaning and reductions in the amount of water required for backwashing.

Precoat filtration consists of applying a fine filter medium to a filter leaf assembly, where it is restrained by a fine-mesh septum. The media are applied initially to build up a cake on the surface of the septum in a precoat step. Naturally occurring diatomaceous earth and commercially produced perlite are the typical sources of this media. Feed water is applied following completion of the precoat step, and it is common to provide a supplemental body feed of the filter material as the run progresses. Precoat filtration differs from granular bed filtration in two respects: (1) particles are removed by straining, and therefore, the process does not require the upstream addition of coagulant for particle conditioning, and (2) the media are disposed of at the end of each filter run. Since coagulant is not added,

removal of TOC is not achieved, which limits the process to treating high-quality waters with low TOC.

Slow sand filtration is similar to granular media filtration in that the water passes through a bed of sand, but the process differs mechanistically. Hydraulic loading rates are much lower [typically 0.1–0.3 m/h (0.04–0.12 gpm/ft²)], and much finer media are used. As with precoat filtration, coagulation is not required because much of the removal takes place through a gelatinous layer that develops on the top of the filter; this layer is commonly referred to as the *schmutzdecke*. Biological activity that plays a role in the filtration process can develop in this layer and in the upper portion of the sand bed. The filter is cleaned periodically by scraping the *schmutzdecke* and the top layer of sand when head loss becomes excessive. Required cleaning frequencies can range from several weeks to up to one year, depending on media design and applied water quality. GAC also has been incorporated into slow sand filters to improve removal of organic contaminants, typically with an overlying layer of sand media.

While filtration is important for producing high-clarity water for customers, its primary function is to remove particles that may include microbial pathogens. This is a role that has evolved in the last 20 years following promulgation of the U.S. Environmental Protection Agency's (USEPA's) Surface Water Treatment Rule in 1989. Prior to that time, the regulated limit for filtered water turbidity was 1 nephelometric turbidity unit (ntu). Heightened awareness of the importance of filtration for controlling waterborne pathogens in a multiple-barrier approach in conjunction with disinfection processes emerged in the 1980s with the discovery of pathogens that were resistant to chemical disinfectants. Initially, the focus was on *Giardia*, and the turbidity limit was lowered to 0.5 ntu for granular bed filters to address this concern. Recognition of *Cryptosporidium* as an even more chlorine-resistant waterborne pathogen led to further reduction in the turbidity limit for plants employing coagulation and granular media filtration to 0.3 ntu level or less, and voluntary guidance under the criteria developed for the Partnership for Safe Water set a turbidity goal of less than 0.1 ntu.

These more restrictive requirements have profoundly altered the approach to granular bed filtration in recent years. The need to view it as a component of a larger process sequence has increased, particularly with recognition of the importance of effective coagulation for producing conditioned particles that can be removed efficiently by attachment to filter media. Older, shallow-depth, single-media sand filters that were once common have been displaced by more efficient dual-media filters. Deep-bed monomedia filters are being used in higher-rate filters. Whereas older single-media filters had a smaller sand size and operated at lower hydraulic loading rates, these configurations ignored the importance of attachment rather than straining mechanisms for achieving efficient filter performance. These older configurations were more prone to surface blinding and accompanying turbidity breakthrough that results from shearing of floc even at lower filtration rates.

Hydraulic loading rates, or filter rates, for granular media filters have increased substantially in recent years with the application of newer and more efficient media configurations. While rates as low as 5 m/h (2 gpm/ft²) were once common, filter rates of 10–15 m/h (4–6 gpm/ft²) are now routine, and rates of 20 m/h (8 gpm/ft²) and higher have proved acceptable in some circumstances. Media size and configuration affect the acceptable filter rate because some configurations are more tolerant of higher rates than others. In most cases, larger media applied in deeper beds are more accommodating to higher filter rates than smaller, shallower media.

While granular bed filtration until recently has been the most common approach to media-based filtration, precoat filters and slow sand filters may be preferable in some situations, and membrane filters (discussed in Chap. 11) offer a new option that is increasingly being used in new treatment facilities. These processes differ from granular bed filters in terms of the mechanism of particle removal; precoat and membrane filters remove particles

based on exclusion at pore openings. These distinctions in mechanism translate into different criteria for acceptable effluent turbidity. In the case of precoat and slow sand filters, allowable turbidity levels under current regulations are increased from the 0.3-ntu criterion that applies for granular bed filtration to 1 ntu.

Specialized adaptations of granular bed filters are an important consideration in many water treatment systems. One of the most widespread and significant of these is the removal of manganese by adsorption to an oxidized coating that develops at the media surface in the presence of a free chlorine residual; other oxidants are not effective in producing this effect, and changes in chlorine addition procedures or application of an alternative disinfectant or oxidant can alter this mechanism, resulting in manganese breakthrough if appropriate adjustments are not made. Similar issues also may arise when prechlorinated granular bed filters are replaced with other filtration approaches.

Another adaptation of granular bed filters is biological filtration that removes biodegradable organics. Biological activity will develop within any granular media filter when a disinfectant residual is not present at the influent to any granular filter media and particularly when intermediate application of ozone just prior to filtration is practiced. GAC is a common media choice for this application owing to its large surface area, although other media also can work well in this capacity. GAC also can be applied as a filtering layer that can remove taste- and odor-causing compounds.

Granular bed filtration is sometimes practiced without an upstream clarification step. This approach, commonly referred to as direct filtration, follows rapid mixing and flocculation, as required for conditioning the particles and development of a filterable floc. In some cases, the flocculation step is eliminated in a variation referred to as in-line filtration. Use of these approaches is generally restricted to water with low turbidity. Water with low color is also necessary because applicable coagulant dosages for direct and in-line filtration generally are not sufficient to result in significant coagulation and removal of color when high levels are present. While direct filtration was commonly applied in the treatment of low-turbidity source waters during the 1960s and 1970s, it is rarely used in new treatment facilities today due to the desire to provide multiple barriers to contaminants. In addition, direct filtration does not readily accommodate the higher coagulant dosages that may be required to provide for TOC removal to meet regulatory requirements for disinfection by-products control.

Membranes (Chap. 11)

A membrane is a semipermeable barrier that allows certain materials to pass while preventing the passage of others. The two main groups of membrane processes used in water treatment are (1) microfiltration and ultrafiltration (MF/UF) that remove particles and (2) reverse osmosis and nanofiltration (RO/NF) that remove dissolved materials. A generalized comparison of these processes based on the sizes of materials that are removed is presented in Fig. 5-1.

MF/UF, the filtration processes, can be used instead of granular media filtration for treatment of potable water. The use of MF/UF for municipal water treatment is relatively new. The first major water treatment plant in North America to apply MF/UF was placed in service in 1994 in San Jose, California. The success of that facility and others has led to wide acceptance, and MF/UF is now considered commonplace. By 2006, hundreds of North American utilities were using MF/UF plants with a combined capacity exceeding 5678 ML/day (1500 mgd), or about 44 percent of the worldwide installed capacity of such plants (Furukawa, 2008).

The widespread use of MF/UF is attributable to consistent production of low-turbidity filtered water and high microbial pathogen removal rates. Unlike conventional granular

Size, Microns	Ionic Range		Molecular Range		Macro Molecular Range	Micro Particle Range	Macro Particle Range
	0.001	0.01	0.1	1.0	10	100	1,000

	Nano Filtration						

FIGURE 5-1 Membrane removal size ranges.

media filters, MF/UF produces these results without chemical preconditioning of the feed water because the removal mechanism is physical sieving. Speth et al. (2005) summarized a literature review of 122 studies as follows: “MF and UF membranes produce extremely high-quality water regardless of influent turbidity, and there is no apparent difference in turbidity removal between membrane type, manufacturer, or whether a coagulant was used.” Mean filtrate turbidity values had a median of 0.06 ntu, and maximum turbidity values had a median of 0.08 ntu. Studies by Jacangelo et al. (1991), Coffey (1993), and others have shown that MF/UF consistently remove *Giardia* cysts and *Cryptosporidium* oocysts at least to the 4-log level, and in some cases removals as high as 6 log to 7 log have been demonstrated. While there is no observed difference between removals of 2- to 15- μ m-sized protozoan cysts achieved by MF and UF, UF provides greater removal of viruses, which are one to two orders of magnitude smaller than *Giardia* cysts and *Cryptosporidium* oocysts. Generally, virus removal credits of up to 0.5 log are granted for MF and 2 to 4 log for UF depending on the specific membrane, level of testing sensitivity, and regulatory agency.

MF membranes used for water treatment have pore sizes of 0.1–0.5 μ m, and UF membranes have pore sizes of 0.01–0.1 μ m. To approximately quantify the removal of dissolved organic material, UF membranes are also rated on the basis of molecular weight cutoff (MWCO); nominal MWCO values of 100,000 to 200,000 Daltons are typical. MF and UF membranes are particle-removal processes that generally do not remove dissolved contaminants unless additional process steps (i.e., coagulation and flocculation) are included. To augment removal of dissolved contaminants, MF/UF is integrated with processes that convert the dissolved constituent into a form that can be removed by the membranes, such as the addition of coagulant or powered activated carbon to adsorb dissolved organics, taste- and odor-causing compounds, and DBP precursors, or the addition of an oxidant to precipitate iron and manganese.

Typical transmembrane pressures for MF/UF are 27.6–242 kPa (4–35 psi). The most common membrane configuration is hollow fibers of polymeric materials arranged in bundles that are mounted inside pressure vessels (typically referred to as *encased membranes*)

or directly into atmospheric tanks (typically referred to as *submerged, immersed, or vacuum membranes*). The most commonly used membrane materials are polyvinylidene difluoride (PVDF), polysulfone (PS), or polyether sulfone (PES); a few facilities use ceramic or other materials.

Operating cycles for MF/UF membranes consist of filtration, backwashing, maintenance washing or chemically enhanced backwashing, chemical cleaning, and direct integrity testing. Filtration and backwashing (BW) cycles are analogous to those used in granular media filtration, but MF/UF backwash cycles occur more frequently, with backwashing generally conducted two or three times per hour. In some installations, a brief chemical cleaning, sometimes called a *maintenance wash*, is conducted daily or weekly, and a longer, more intensive chemical cleaning may need to be conducted every four to six weeks to remove accumulated material that impedes flow through the membrane. A direct integrity test (typically an air-based test) is conducted at least daily, as required by the Long-Term 2 Enhanced Surface Water Treatment Rule (USEPA, 2006a), to verify that the membranes are intact and achieving the required microbial pathogen log removals. Because of the complexity of the various operating cycles, essentially all MF/UF facilities are automatically controlled.

RO/NF membranes are pressure-driven processes that remove dissolved materials from water. There are a wide range of uses, with the most frequent being desalination of brackish supplies and seawater. Brackish or lower-pressure RO typically is used to control one or more of the following constituents: TDS, chloride, sodium, hardness, nitrate, arsenic, sulfate, and radium, as well as other ions and dissolved organic carbon (DOC), including true color, DBP precursors, and agricultural chemicals. A key difference between RO and NF, which is actually a subclass of RO, is that removal percentages (rejection) for NF are generally lower; NF exhibits more selectivity based on ion charge. For example, for a typical RO membrane, the rejection of divalent sulfate might be about 99 percent (i.e., the sulfate concentration in the permeate flow would be only about 1 percent of the RO feed-water concentration), whereas monovalent chloride rejection might be about 98 percent. In a similar example, a typical NF membrane might yield 85 percent rejection of sulfate but only 40–50 percent rejection of chloride. Both types of membranes would typically yield a rejection of DOC (molecular weight greater than 200 Daltons) of at least 95 percent. Exact values would depend on many variables, including membrane type, temperature, concentration, and ionic strength, but this example illustrates a typical case. The use of NF tends to be limited to controlling color and/or softening and thus is sometimes referred to as *membrane softening*, whereas RO is applied to a wider range of desalination or single-solute applications such as nitrate removal. Neither RO nor NF is effective for removing dissolved gases such as radon and carbon dioxide.

RO/NF also can be used to remove particulate material, for example, to lower turbidity, because RO/NF product water (also known as *permeate*) generally has a turbidity of less than 0.05 ntu; however, this would be a misapplication of the process. To avoid fouling or plugging of RO/NF membranes, the feed water has to be clear, generally with turbidity of less than 0.1 ntu and with a 15-minute silt density index (SDI) of less than 5 and preferably less than 3.

In the past, NF was considered less costly to operate than RO because it operated at lower pressure; however, improvements in RO membranes have reduced the difference in operating pressures when treating comparable feed waters. For a typical low-salinity feed water, operating pressures for an NF system are 620–1040 kPa (90–150 psi), whereas lower-pressure (sometimes mistakenly referred to as *high flux*) RO membrane systems operate at 620–1725 kPa (90–250 psi). Required operating pressures increase as feed-water dissolved solids concentrations increase because the resistance to flow through the membrane (osmotic pressure) increases with TDS concentration. For example, seawater RO plants operate at 5500–6900 kPa (800–1000 psi) while desalinating 32,000–45,000 mg/L of TDS feed water.

The typical configuration of membranes used in municipal-scale RO/NF plants is spiral wound, with flat-sheet membrane, spacer materials, and glues wrapped around a central product water tube into cylindrical elements. These spiral elements are usually 200 mm (8 inches) in diameter by 1000–1525 mm (40–60 inches) long (nominal dimensions). Larger 400- and 460-mm-diameter (16- and 18-inch-diameter) elements are now available and may become more commonplace. At least one manufacturer provides hollow-fiber RO modules. The most common membrane material is polyamide thin-film composite.

Membrane elements are mounted in pressure vessels arranged in stages, banks, or arrays to meet design goals, such as suitable overall TDS/contaminant rejection, pressure drop, and velocity across the membrane surface. RO/NF is a cross-flow filtration method in which only a portion of the feed water becomes permeate. The remainder leaves the system as concentrate (sometimes called *brine*) that carries away the concentrated material before it precipitates to form scale on the membrane surface. For lower-salinity applications, such as desalination, softening, or removal of color from groundwater, system recovery (the ratio of permeate flow to feed flow) typically is 80–85 percent, whereas for seawater desalination it is typically 45–55 percent.

There are two other types of desalination processes: distillation and electro dialysis, including the related electro dialysis reversal (ED/EDR). While there are a number of distillation methods, distillation is essentially never the low-cost alternative at feed-water concentrations below that of seawater (32,000 mg/L). About half the seawater desalination plants in operation today use RO, and the relative percentage has been increasing in recent years as operating costs for seawater RO systems continue to decline. On the other end of the spectrum, ED/EDR is only cost competitive with RO/NF at low TDS concentrations. It is generally accepted that there is no reason to consider ED/EDR when feed TDS concentrations exceed 1500–2000 mg/L, and at lower TDS concentrations, ED/EDR is typically considered only under special circumstances, such as when achievable recovery for RO/NF would be limited by silica scaling. Even in cases where distillation or ED/EDR might be competitive with RO/NF, a detailed site-specific evaluation is required before an informed decision can be made with respect to the optimal treatment approach.

Ion Exchange and Adsorption of Inorganic Contaminants (Chap. 12)

Ion exchange (IX) has an established place in water treatment practice and has been used for more than 100 years as a means of softening water. Inorganic adsorption media also have been developed recently for removal of certain inorganic constituents. Interest in application of both types of media for removal of a broader range of constituents is emerging, including applications for removal of NOM that can lead to formation of disinfection by-products. Equipment for these processes can include both fixed- and fluidized-bed configurations in columns that provide contact with the process stream. Suspensions of ion exchange media in mixed contact tanks are also used in some specialized applications.

While IX and adsorption processes share similarities in the physical characteristics of the contacting equipment, differences do exist, most notably with the underlying mechanisms that are involved. IX is based on the attraction of ions in solution to oppositely charged sites at the surface of the media. Competition for sites occurs between ions of like charge, an attribute that can be used to achieve regeneration through the application of concentrated salt solutions to displace constituents removed during the in-service cycle; the exchange process is reversed, and the constituents that have been removed are concentrated in a smaller stream for disposal. Many IX media are manufactured as organic resins, but some inorganic IX media also exist, notably natural zeolites that are in widespread use for softening applications.

Inorganic adsorption processes rely on chemical bonding of the constituent to be removed to active sites at the surface of the media. While regeneration is possible for some of these processes through the application of regenerant streams that contain high concentrations of a competing reactant to displace constituents removed during the in-service cycle, regeneration is not always conducted, and the media are often disposed of after only one use.

Applicability of the respective processes depends on the characteristics of the constituent targeted for removal. IX works for charged constituents, but there is a hierarchy of preference that needs to be considered because ions with multiple charges are more favorably attracted to exchange sites than singly charged ions. Other characteristics, such as size of the ions to be removed and chemical affinities for exchange sites, also must be considered during evaluation of alternative IX resins.

Chemical affinity for sites is a key aspect of inorganic adsorption media application because it confines the range of candidate contaminants to those with chemical characteristics that allow bonding to active surface groups. While this limits the range of candidate contaminants, it offers the potential advantage of selectivity for contaminants where this process can be applied.

An illustration of the effect of contaminant characteristic in selecting an applicable approach is provided by comparing the removal of nitrate and arsenate. While arsenate [As(V)] can be removed by IX, it also exhibits an affinity for aluminum and ferric ions that also facilitates removal by inorganic adsorbents such as activated alumina and some ferric media. However, nitrate is not removable by these adsorbents. IX is more effective for nitrate removal. Another illustration of the effect of chemical reactivity on process application is provided by the reduced arsenite [As(III)] form of arsenic, which is much less reactive with metal ions than the more oxidized arsenate ion. Arsenic in the As(III) form must be oxidized to As(V) to facilitate removal by adsorption, thereby demonstrating the effect of chemical speciation on process sequencing.

Softening (removal of calcium and magnesium) is the most widespread and established use of IX. Other potential target constituents for IX and inorganic adsorption include barium, strontium, radium, uranium, manganese, fluoride, nitrate, arsenate, selenate, chromate, sulfate, sulfide, and perchlorate.

Recent advances in IX/adsorbent technologies include specialized inorganic adsorbents for the removal of arsenate and the use of anion-exchange resin with magnetized properties in a mixed suspension (MIEX process) to facilitate its recovery and reuse for NOM removal (see Chap. 12). Also receiving increased attention is the role played by oxidized media coatings on granular media filters as inorganic adsorptive surfaces for the removal of manganese. Since this approach relies on the presence of free chlorine to sustain the process, the coatings can be lost following modifications such as conversion to biofiltration or relocation of points of chlorine addition.

Factors to consider in the application of IX and inorganic adsorption include (1) the potential for fouling of media by suspended solids, precipitates, and biological growth and associated pretreatment requirements to limit fouling, (2) special materials of construction to handle corrosive brine and regenerant solutions, and (3) requirements for disposal of spent regeneration solutions and media. The extraction of contaminants into smaller volumes can require special consideration in some circumstances because the higher concentrations that result may lead to categorization of the resulting waste streams or spent media as hazardous wastes.

Chemical Precipitation (Chap. 13)

Chemical precipitation is commonly used in water treatment facilities to remove hardness and heavy metals such as iron and manganese, as well as regulated contaminants such as radium, uranium, fluoride and, to a lesser extent, natural organic matter. Coagulation with

metal salts such as aluminum sulfate or ferric compounds is typically more effective than lime softening for removing natural organic matter. Chemical precipitation also can be used as pretreatment or intermediate treatment in membrane desalination systems to reduce the potential for scaling of the membranes by mineral salts (e.g., strontium, barium, and silica) at high raw-to-product conversion rates, thereby increasing achievable membrane conversion rates and reducing the amount of residual concentrate generated.

Lime softening is by far the most common application of chemical precipitation, with more than 1,000 potable water softening facilities operating throughout the United States (primarily in Florida and the Midwest). A typical softening process train includes either conventional flocculation and sedimentation basins, similar to those used for coagulation and clarification, or, more commonly, upflow solids contact clarifiers, which are more efficient and occupy smaller footprint areas than conventional basins. The precipitation process is followed by pH adjustment (recarbonation) and filtration. Treatment of groundwater supplies with high concentrations of carbon dioxide, which increases required lime or caustic dosages and associated production of chemical solids, will typically also include forced- or induced-draft aeration to reduce carbon dioxide concentrations before softening. Because the high-pH environment of the softening process is not conducive to optimal removal of turbidity and color, when treating variable-quality surface supplies, it is usually preceded by conventional or high-rate sedimentation to reduce the levels of these constituents before softening.

Chemical treatment options for the lime softening process include lime only, lime–soda ash, caustic soda, and variations in the approach to pH adjustment preceding filtration. While water that contains low noncarbonate hardness can be softened adequately with lime alone, water with high noncarbonate hardness may require addition of both lime and soda ash to achieve the desired finished water hardness objectives. Low-alkalinity waters that also contain substantial noncarbonate hardness can be softened with sodium hydroxide (caustic soda) alone or in conjunction with lime, which also produces less sludge solids than conventional lime–soda ash softening. However, since the chemical costs for caustic softening are substantially higher than for lime–soda ash softening at equivalent levels of targeted hardness reduction, caustic softening is rarely employed in potable water treatment.

Water produced by precipitative softening contains high concentrations of caustic alkalinity and high pH and thus has significant scale formation potential. The high pH therefore must be reduced before filtration and distribution to prevent encrustation of the filter media and excessive deposition of calcium carbonate scale in the distribution system. This is typically accomplished using carbon dioxide in either a single- or two-stage process. In the single-stage recarbonation process, carbon dioxide is added to the settled water at the inlet to a small contact basin with a detention time of at least 20 minutes. A two-stage recarbonation process is used where maximum hardness reduction is required or to remove specific constituents such as magnesium hardness, heavy metals, radionuclides, and/or DOC. In the first stage of the two-stage process, the pH of the water is increased to 11.0 or higher to achieve maximum removal of targeted constituents. Carbon dioxide is added to the settled water to lower its pH to the point of minimum calcium carbonate solubility (pH 10.0–10.3). The excess lime initially fed to raise the pH to 11.0 or higher is then allowed to precipitate as calcium carbonate in a second sedimentation stage. Following secondary clarification, additional carbon dioxide is fed to further reduce pH and to adjust the scale formation potential of the finished water. While some utilities practicing lime softening have strived to lower finished water hardness to 70–80 mg/L as CaCO₃, a more common current goal is 125–150 mg/L in order to reduce both chemical costs and solids production. Since this trend is expected to continue, single-stage softening/recarbonation probably will become more prevalent because of its lower construction costs. However, the two-stage process has greater flexibility and lower carbon dioxide dosage requirements if high-pH treatment is needed, and it continues to be the preferred precipitative softening process for most large Midwestern utilities that treat surface-water supplies.

While precipitative softening also can be used to remove iron and manganese, it is not typically employed strictly for this purpose. A more common approach is precipitation and filtration following oxidation of reduced iron and manganese using molecular oxygen, potassium permanganate, or chlorine. When the source water contains iron at concentrations exceeding approximately 5–6 mg/L, common practice is to include provisions for sedimentation following aeration and chemical oxidation to reduce the solids loading on the filters and to increase filter efficiencies (see Chap. 7).

Increasingly stringent regulations governing discharge of membrane desalination process concentrate, particularly at inland locations, where surface discharge is not an option, have led to the use of chemical precipitation to increase overall treatment system conversion rates and to reduce the volume of concentrate to be disposed of, thus making membrane desalination of brackish water more economically feasible. While its use for pretreatment to remove scaling constituents such as silica, barium, strontium, and calcium has been evaluated extensively and, in some cases, implemented at full scale, its use as a key step in treating first-stage membrane concentrate is relatively recent. Chemical precipitation of first-stage RO membrane concentrate, followed by additional membrane treatment of the resulting process stream, can help to reduce the discharge of membrane concentrate to zero or near zero. The constituents of concern can be precipitated by conventional slurry-type softening processes or crystallized using a fluidized-bed reactor. However, recent research (Bond and Veerapeneni, 2007) indicates that the fluidized-bed crystallizer is more effective than conventional softening in reducing primary RO concentrate to achieve zero liquid discharge based on the following observations: (1) precipitation can be achieved at lower chemical doses and at lower pH, (2) the fluidized-bed crystallizer produces only about 10 percent of the amount of waste solids (by volume) generated by conventional softening, (3) waste solids produced by the fluidized-bed crystallizer can be dewatered by gravity without the need for additional equipment, such as thickeners, centrifuges, or filter presses, and (4) required footprint area is much less than for conventional precipitative softening processes.

Adsorption of Organic Compounds (Chap. 14)

Adsorption with activated carbon is the predominant method of removing organic contaminants from municipal water supplies. It has been used for decades to remove taste- and odor-causing compounds such as geosmin and 2-methyl isoborneol (MIB). More recently, it has been used to remove synthetic organic chemicals (SOCs), DOC, and DBP precursors. Adsorption with activated carbon is the USEPA-approved best available technology (BAT) for more than 50 organic contaminants regulated under the National Primary Drinking Water Regulations and for many emerging organic contaminants of concern, including EDCs. (Activated carbon is also listed in the Stage 1 Disinfectant/Disinfection By-Products Rule as BAT for TOC removal, although carbon exhaustion rates are typically high when TOC removal is the primary treatment objective. In contrast to oxidation processes, adsorption removes organic contaminants from water rather than chemically transforming them into oxidized by-products that remain in the treated water.

Activated carbon is produced by heating the starting material, typically coal, wood, peat, or coconut shell, to temperatures above 900°C and injecting the material with steam and oxygen or carbon dioxide to activate it. The activation process produces a vast network of internal pores, giving activated carbon an extremely large surface area per unit volume (typically 500–1500 m²/g). It is the large specific surface area and its chemical properties that make activated carbon a highly effective adsorbent. The affinity for adsorption to activated carbon varies among organic compounds. Hydrophobic compounds of medium to high molecular weight are adsorbed more effectively than low-molecular-weight hydrophilic compounds.

The surface of activated carbon provides a favorable environment for microbial attachment; consequently, under appropriate conditions, contaminant removal by adsorption can be augmented by biodegradation of organic compounds. The surface of activated carbon also provides catalytic destruction of certain chemicals in oxidation-reduction reactions. Examples of this include removal of excess ozone in ozonation off-gas treatment systems and removal of chlorine or chloramines in home point-of-use devices or as pretreatment for dialysis systems in hospitals.

Activated carbon is produced in two forms: granular activated carbon (GAC) and powdered activated carbon (PAC), both of which are produced from the same materials. The physical difference between the two is their particle size. The most commonly used GAC products are U.S. Standard sieve sizes 12×40 (1.68–0.42 mm diameter) and 8×30 (2.38–0.59 mm diameter). In contrast, most PAC particles pass through a 325 (44- μm) sieve and therefore are an order of magnitude smaller than GAC. Equal weights of GAC and PAC of the same material have the same equilibrium adsorption capacity because they have the same surface area. Adsorption equilibrium, however, is reached faster for the smaller-particle PAC because adsorption kinetics increase as particle diameter decreases.

The most important differences between the two forms of activated carbon that affect process selection are the method of their application and the relationship between the concentration of the contaminant being adsorbed and the capacity of the activated carbon for adsorption of the contaminant. GAC is installed in a fixed bed, where it serves as a constant barrier to organic contaminants for as long as it has sufficient adsorption capacity. GAC adsorption capacity is consumed with service time, and once it is exhausted, it is replaced with virgin or regenerated GAC. In contrast, PAC is dosed in the same manner as chemicals used in treatment and can be applied intermittently to coincide with the occurrence of contaminants and at dosages commensurate with contaminant concentrations. Contact time is the design criterion that has the greatest impact on GAC or PAC treatment effectiveness.

GAC is favored over PAC for the removal of organic contaminants in cases where concentrations are too high to be treated with practical doses of PAC and in situations where a constant barrier is desired for sources at risk of unexpected contaminant spikes from runoff, spills, or illegal discharges. GAC can be installed either immediately following coagulation/sedimentation, where it serves as a filter adsorber, or after filtration, where it serves as a postfilter adsorber. Some utilities have elected to replace existing conventional filter media, either partially or completely, with GAC to take advantage of its ability to provide both adsorption and filtration. The bed depth of filter adsorbers is limited by filter headloss considerations, and consequently, postfilter adsorbers are favored where a longer contact time (deeper bed) is needed for effective treatment. Biomass can develop in filter adsorbers and postfilter contactors and thus provide additional treatment by biodegradation. Ozonation ahead of GAC has been used to enhance biodegradation by oxidizing organic compounds into more biologically assimilable forms.

PAC may be more cost-effective than GAC where low to moderate PAC doses are sufficient to achieve treatment goals or where contaminants appear intermittently and therefore do not require continuous treatment. Examples include seasonal occurrences of taste- and odor-causing compounds or seasonal spikes of pesticides from agricultural runoff. PAC is fed as a slurry and can be injected at the raw water intake, at the head of the plant, or in the rapid mix basin. PAC treatment efficiency improves as contact time increases, and available contact time is an important factor in evaluating the cost and effectiveness of PAC treatment. PAC is removed during sedimentation or DAF in conventional treatment, and consequently, PAC use adds to the volume of solids that must be managed at the plant.

Treatment costs for GAC versus PAC can be compared by estimating the amount of each material required annually for treatment and multiplying the projected amount by the unit cost for each. For GAC, carbon use depends on the total bed volume initially installed and

the replacement frequency required to meet treatment goals. For PAC, carbon use depends on the PAC dose and its duration.

Air stripping is an alternative to GAC for treatment of groundwater supplies contaminated with VOCs such as trichloroethylene and carbon tetrachloride. Air stripping was discussed briefly earlier in this chapter and is presented in detail in Chap. 6. In situations where the off-gas from air stripping cannot be discharged to the atmosphere without treatment, air stripping and GAC are used in concert; VOCs are removed from the water phase by air stripping, and gas-phase GAC treatment is used to remove them from the stripper off-gas.

Natural Treatment Systems (Chap. 15)

Natural treatment can complement and enhance traditional water treatment methods through improvement of source water quality, thereby reducing the level of treatment required and the associated costs. Natural treatment systems employed most frequently in potable water production (i.e., riverbank filtration and aquifer storage and recovery) have demonstrated the ability to reduce turbidity, pathogens, natural organic matter, and, in some cases, organic contaminants by natural processes during subsurface filtration of surface water. While the concept of using aquifers as natural filtration devices is not new (riverbank filtration has been commonly employed for more than a 100 years in Europe; Kuehn and Mueller 2000), its emergence as a viable treatment technology and implementation in the United States have occurred only more recently.

Riverbank filtration (RBF), sometimes referred to as *bank filtration* or *induced infiltration*, can be defined broadly as the process of surface water flowing from the bank or bed of a river or a lake to extraction wells. During passage through the subsurface sand and gravel layers, the water is subjected to a combination of physical, chemical, and biological processes such as filtration, sorption, dilution, and biodegradation that can substantially improve the quality of the water. The extraction system typically consists of a series of conventional vertical wells or, more recently, one or more high-capacity collector wells equipped with radial horizontal collection laterals. The quality of the filtrate depends on many factors, including initial quality of the source water, degree of groundwater and surface water intermixing, properties of the filter layer, water temperature, and hydraulic detention time in the filter layer (Laszlo et al., 1990). Because of the numerous factors involved, performance of RBF with respect to contaminant-removal efficiencies is highly site-specific and thus difficult to characterize on a general basis. However, ability of RBF to remove NOM and organic micropollutants, such as pesticides and some pharmaceutical products, through adsorption and biodegradation has been well documented. The ability to remove pathogens effectively is also well documented, as evidenced by USEPA's recent inclusion of bank filtration in the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) "Microbial Toolbox" for removal/inactivation of *Cryptosporidium*. Under the LT2ESWTR, credits for *Cryptosporidium* removal of up to 1.0 log are available for wells with 15 m (50 ft) or more of setback from a surface-water source and with an average turbidity less than 1 ntu at their discharge.

While contaminant concentrations in surface waters may vary significantly, subsurface passage of the surface water before extraction serves as a barrier against shock loads at the treatment plant influent attributable to chemical spills or routine seasonal runoff. However, because of the residence time required for passage through the alluvium to the point of extraction, this same capability also can result in the presence of these contaminants in the RBF filtrate over longer periods than would be experienced when treating only surface water extracted directly from the source. In addition to suitable subsurface conditions, long-term viability of RBF is also highly dependent on locating the extraction wells where river

flows are sufficient to maintain consistent sediment deposition at the river-aquifer interface without excessive scouring.

Aquifer storage, recharge, and recovery (ASR) involves injection of water into the aquifer and subsequent removal to supplement available supplies during periods of high demand. A common approach is to collect and inject runoff into the aquifer during periods of heavy rain or snowmelt and then to extract and treat the water during drought periods or when finished water demands exceed the reliable sustained capacity of the primary raw water supply. ASR systems are designed to promote flow of the water through the aquifer between the points of injection and extraction, which improves its quality through physical, biological, and/or chemical processes similar to those achieved by RBF. However, not all injected water is reclaimed: Typical recovery rates range from 30–80 percent of the water injected (Kline, 2008). Widespread use of ASR has been constrained by obstacles such as permitting requirements, water rights considerations, and concerns regarding endangerment of aquifer quality and capacity.

Chemical Disinfection (Chap. 17)

Disinfection is a fundamental water treatment process for protection against waterborne disease, a long-established public health goal of water treatment. The importance of this aspect of water treatment is underscored by the fact that disinfection generally is accomplished in conjunction with particle-removal processes to provide multiple treatment barriers to waterborne disease. Chemical disinfectants, particularly chlorine, have served as the traditional means of achieving this goal, although other alternatives are becoming available. However, chemical disinfectants are likely to continue to play a significant role, even when these newer alternatives are in use, because maintenance of a protective chemical disinfectant residual in distribution systems remains a common practice in the United States.

Early disinfection practice tended to be confined to the use of free chlorine, with a primary focus on inactivation of bacteria. As new disinfecting agents have emerged, and understanding of microbial contaminants has increased, practitioners now have a choice of several widely available disinfecting agents to address the expanding array of known microbes, which now includes viral and protozoan pathogens as well as bacteria, and possible problems related to other microbes cannot be discounted.

Disinfectants commonly used in water treatment include free chlorine, chloramines, chlorine dioxide, and ozone. The effectiveness of these disinfectants stems from their being reactive in ways that trigger destructive reactions at sites within target organisms. However, their reactivity is not limited to these pathways, and other reactions are inevitable. The most basic are those which result in simple decay of disinfecting residuals even in the absence of other sources of demand. Key factors that affect the rates of decay include pH and temperature. Exposure to sunlight and other sources of light at certain wavelengths can also accelerate decay rates. In some cases, decay reactions are not completed, and undesired products can result, as in the case of chlorine dioxide, which can form chlorite and chlorate as its by-products.

Reactions with other contaminants in water create demand beyond the basic form of decay and generate by-products in the process. NOM and reduced inorganic compounds can produce such results. The availability of these constituents for reaction can be affected by upstream treatment steps that can remove or alter them. Notably, coagulation and other processes can remove NOM to reduce the formation of DBPs, whereas oxidation and pH adjustment can produce changes that can have a similar effect. In other areas of treatment, oxidation of iron and manganese reduces disinfectant demand, and removal of particles can reduce disinfectant demand and improve disinfection effectiveness. Therefore, there are strong relationships between the disinfection process and other components of a treatment train.

Following observations of chloroform in drinking water in Holland (Rook, 1974) and in Cincinnati (Bellar et al., 1974), Symons et al., (1975) showed that the problem of trihalomethanes (THMs) was widespread in drinking water. The list of disinfection by-products has increased since then, and concern over these by-products has become a major consideration in the selection of disinfection strategies. By-product problems are no longer confined to those produced by free chlorine because each disinfecting chemical produces a set of by-products.

Disinfection in the United States is applied to meet two sets of goals for controlling pathogens within a water system. Primary disinfection is used to meet goals for inactivating pathogens at the water treatment plant, thereby providing a barrier to entry into the distribution system, while secondary disinfection is applied to meet the goal of providing a protective disinfectant residual throughout the distribution system as protection against further intrusion. This two-tiered approach tends to be applied in other locations around the world, although there are exceptions where secondary disinfection is not practiced.

In the case of primary disinfection, each disinfectant has a characteristic set of chemical pathways that defines its mechanisms and effectiveness for inactivation of different target microbes. As the array of known microbes expands, several have been identified that are particularly resistant to some chemical disinfectants, thereby making these microbes a focus in developing a disinfection approach. In this regard, a good deal of attention is presently placed on the relative resistance of *Giardia*, *Cryptosporidium*, and some viruses when comparing the effectiveness of alternative disinfecting chemicals. Regulations for inactivation of viruses, *Giardia*, and *Cryptosporidium* are covered in the Surface Water Treatment Rule and the Enhanced Surface Water Treatment Rule (see Chap. 1). The requirements are based on the time of contact T and the concentration C of the disinfectant residual during the period of contacting. Configuration of contacting and the relative level of short-circuiting are also taken into account when establishing credit for contact time T . Regulations apply the product of these two variables ($C \times T$) to determine the level of inactivation credit for a given chemical disinfectant. The underlying basis for this approach is found in disinfection models that are relatively simple in form; more complex models and concepts also exist. The concepts are applied on a relatively conservative basis to provide a safety factor.

Among the chemical disinfectants, free chlorine, ozone, and chlorine dioxide are most frequently applied for primary disinfection. Compliance criteria exist for the use of chloramines, but the required $C \times T$ levels are large, demanding substantial contact times. While not widespread practice, a few utilities with hydraulic retention times sufficient for long periods of disinfectant contact have been able to achieve conditions required for inactivation of viruses and *Giardia* using only chloramines.

In comparing the merits of free chlorine, ozone, and chlorine dioxide as primary disinfectants, it is important to note that, with the exception of *Cryptosporidium*, each can meet the criteria for inactivating target pathogens. Free chlorine is the weakest of these, and while this might appear to be a disadvantage, adequate detention time typically is available within a plant, and the addition of new structures to accommodate this form of disinfection is often not required. Ozone, a much stronger disinfectant that is effective with less contact time, requires specialized contacting facilities for efficient gas transfer and facilities configured for containing and collecting off-gases. The logistics of locating and accommodating the additional structures within a hydraulic profile can be an important consideration for incorporation into a process sequence, especially in existing facilities. Ozone also requires relatively sophisticated generation equipment. The use of chlorine dioxide, also a stronger disinfectant than chlorine, also requires purchase of additional chemicals for on-site generation, and the process must be tightly controlled to avoid issues with excessive residuals and the production of excessive levels of its degradation products, chlorite and chlorate.

With respect to inactivation of *Cryptosporidium*, free chlorine is relatively ineffective. Ozone can be effective, but required $C \times T$ levels are relatively high, particularly in cold

water. Chlorine dioxide, while more effective than free chlorine, still requires high levels of $C \times T$ that prove impractical to maintain in many situations.

Each primary disinfectant must be assessed for its effectiveness under a given set of conditions. In many cases, when considering alternatives to free chlorine, more effective disinfection and control of disinfection by-products may offset the greater complexity and higher costs of chlorine dioxide and ozone. Factors beyond disinfection goals should also be considered because each of these disinfectants can provide oxidation functions as well, as discussed in the chemical oxidation section of this chapter. For example, ozone can be used to control tastes and odors, to improve coagulation, and to reduce the formation of total THMs and haloacetic acids (HAA5), whereas chlorine dioxide is effective for removal of manganese and can reduce the formation of total THMs and HAA5 in some situations.

Secondary disinfection operates under a different set of criteria from those which apply to primary disinfection. The most important criterion for secondary disinfection is capability to maintain a disinfectant residual throughout the distribution system. The high reactivity of ozone eliminates it from consideration, and the adverse effects of chlorine dioxide residuals tend to limit its suitability. This leaves free chlorine and chloramines as the secondary disinfectants available for most applications. Even where alternative disinfectants are applied with the intent to limit the use of free chlorine and chloramines for primary disinfection, one of these two disinfectants generally is used as the secondary disinfectant under present rules of practice, and this aspect of disinfection must be integrated into an overall treatment train that will limit disinfection by-product formation appropriately and produce a manageable level of disinfectant demand to allow reasonable use of these two chemicals. Free chlorine is the stronger disinfectant of the two, but chloramines have advantages of longer persistence and lower formation of THMs and HAA5s, although their use can result in other by-products. Chloramines are better at controlling biofilms within the distribution system in most cases. Both are approved for application under federal regulations, and selection is a matter of best fit in a given situation.

UV Technologies (Chap. 18)

Ultraviolet (UV) light, historically used primarily in small groundwater systems and to disinfect wastewater effluent, is rapidly emerging as the preferred primary disinfectant when provisions for inactivation of *Cryptosporidium* are required. There are more than 1000 U.S. facilities that currently use UV for disinfection of public drinking water supplies. UV inactivates pathogens by disrupting their DNA strands, rendering them noninfectious. It has demonstrated the ability to achieve 3.0-log to 5.0-log inactivation of *Cryptosporidium* oocysts and *Giardia* cysts. Benefits of UV disinfection include (1) significantly lower initial and operating costs than for comparable control processes (e.g., ozonation and low-pressure membrane processes), (2) a small footprint, (3) the usual ability to be cost-effectively retrofitted into existing plants, (4) potential reduction in halogenated DBP levels when free chlorine contact times following UV treatment are limited, and (5) high levels of achievable pathogen inactivation. Potential disadvantages include (1) fouling/plating of quartz sleeves housing the UV lamps, (2) inconsistent reliability/accuracy of the UV sensors used to monitor process effectiveness, (3) the need for periodic replacement of lamps, and (4) the potential for lamp breakage and associated exposure to mercury.

UV systems used in potable water facilities typically use medium- or low-pressure high-output lamps installed in stainless steel pipe-type reactor vessels, which facilitates incorporation into existing treatment facilities. The lamps typically are enclosed in high-purity quartz sleeves, which isolate the electrical components from the water, help to maintain optimal operating temperatures, and serve to protect the lamps from liquid-generated forces and thermal shock. Systems typically include online monitors for measuring the

UV transmittance (UVT) of the water being treated. Standby UV reactors are provided to avoid interruption of operation in the event of a breakdown or the need for servicing of online equipment. USEPA's *Ultraviolet Disinfection Guidance Manual for the Long Term 2 Enhanced Surface Water Treatment Rule* (USEPA, 2006b) recommends that UV systems be located after filtration. Drawbacks to placing the reactors upstream from filtration include lower UV transmittance, which results in higher energy requirements to maintain required UV dosages, and the potential for coagulation or softening precipitates to foul lamp sleeves and to shield microorganisms, thereby hindering their inactivation. Also, the UV dosages specified in the LT2ESWTR for inactivation of *Cryptosporidium* apply only to postfilter applications and to certain unfiltered supplies.

The LT2ESWTR dose requirements for inactivation of viruses by UV are based on adenovirus, the most UV resistant virus identified to date. According to the dose tables, UV disinfection is not as cost-effective for inactivation of viruses as it is for inactivation of *Giardia* and *Cryptosporidium*. Therefore, a brief period of free chlorine contact prior to or following UV exposure is usually provided to maintain conditions that will ensure effective inactivation of viruses.

Many water utilities using surface water supplies are taking preemptive measures to prevent exposure of their customers to chlorine-resistant pathogens such as *Cryptosporidium*. One such measure is the installation of UV disinfection. Because of the relatively high benefit-to-cost ratio, many utilities have come to view UV disinfection as a cost-effective additional barrier against outbreaks of waterborne disease, and some are considering its installation regardless of the outcome of source water monitoring mandated by the LT2ESWTR.

Interest in the use of UV and hydrogen peroxide (H_2O_2) as an advanced oxidation process (AOP) for the removal of taste- and odor-causing compounds and organic and inorganic micropollutants is growing. The effectiveness of AOP in removing geosmin and MIB, MTBE, perchlorate, pesticides, and PPCPs has been demonstrated by both pilot- and full-scale testing.

The reaction of UV with H_2O_2 forms hydroxyl radicals, which oxidize contaminants. Advantages of UV/ H_2O_2 include a smaller footprint than for other contaminant-control options such as ozonation or carbon adsorption and effective inactivation of *Cryptosporidium* and *Giardia* at all temperatures. Disadvantages include high energy consumption and high operation and maintenance costs when operating in AOP mode and the need for close monitoring of influent contaminant concentrations to maintain proper UV and H_2O_2 dosages. Also, because only about 10–15 percent of the applied hydrogen peroxide dosage is consumed during the oxidation process, the remaining hydrogen peroxide at the UV contactor discharge must be removed through reaction with a quenching agent such as chlorine or calcium thiosulfate. Approximately 2 mg/L of chlorine is required to remove 1 mg/L of hydrogen peroxide residual, which can result in the need to provide additional chlorine storage and feed capability to accommodate the increased chlorine demand.

DISTRIBUTION SYSTEM CONSIDERATIONS (CHAPS. 19–21)

Microbial and chemical changes in distribution system piping have become important considerations in managing the quality of water delivered to the customer's tap. The changes are responses to phenomena that occur both in the bulk water as it flows through the distribution network and at pipe surfaces that serve as habitat for microbes and locations of critical chemical reactions.

An important aspect of distribution system water quality is the practice of maintaining a disinfectant residual in the system. In the United States, this is accomplished by adding either free chlorine or chloramines. Both are reactive chemicals that continue to react as

water is conveyed through a system; the extent of these reactions varies with detention time and availability of contaminants with which to react. Some reactions occur with substances in the bulk water, such as NOM. These reactions cause loss of disinfectant residuals and can result in the formation of DBPs. When present, reduced forms of manganese and iron also can react with these residuals, which may result in discolored water at consumer taps.

Reactions with disinfectant residuals are not confined to those which occur in the bulk water because interactions at pipe surfaces can create a high disinfectant demand. These features complicate managing and modeling water quality because they can lead to variations in the rate of dissipation of disinfectant residuals and the formation of DBPs. Important variables that affect the extent of these reactions include the degree of accumulated sediments, effectiveness of corrosion-control practices, and the system's maintenance procedures.

While both free chlorine and chloramines have provided acceptable results in maintaining a disinfectant residual in the distribution system, there are some important differences between them. In the case of chloramines, the presence of ammonia as a component of the chemical structure may require measures to prevent deterioration of microbial quality as a result of biological nitrification. Also, while both chlorine and chloramines are acceptable disinfectants when used alone, mixing chloraminated and chlorinated water should be avoided because their incompatibility can result in water quality problems such as loss of disinfectant residual.

Chemical conditioning of finished water to minimize corrosion in the distribution system is another critical step in water treatment. Goals include protection against damage to distribution infrastructure, development of discolored water, and leaching of regulated contaminants, particularly lead and copper. Indirect effects of corrosion, such as the harboring of microbes and reactions that reduce disinfectant residuals, are often more pronounced at corroded surfaces, and corrosion control can provide improvements in these areas as well. Conditioning methods include pH control, provision of scale-forming conditions, and application of agents that react at the surface of the pipe to form a protective passivating layer.

Consistency of water quality in a distribution system is an important consideration because protective coatings on the pipe surface that prevent corrosion can be compromised as a result of changes in water quality. Several factors can change and create imbalances that accelerate corrosion, including intermixing of sources with different water quality characteristics, such as alkalinity, hardness, pH, chlorine residual, oxygen concentration, conductivity, temperature, and TOC concentration. Recent evaluations indicate that changes in the chloride-to-sulfate ratio, which can occur with changes in coagulant chemicals, can accelerate lead corrosion in some cases. Mixing of water from multiple sources also can affect chemical stability. Another unintended consequence of changes in water quality is the potential for release of absorbed arsenic when iron oxide deposits are released from the walls of old cast iron distribution mains that distribute well water that contains arsenic.

Biological stability is an additional distribution system water quality concern. Biologically stable water can be achieved by maintaining low levels of biodegradable organic material in the water to limit microbial growth in the system. Assimilable organic carbon (AOC) and biodegradable organic carbon (BDOC) measurements have been developed to characterize this biological material. These types of constituents can be removed by biological filtration, which is often applied after ozonation, where levels of biodegradable organics are typically high. Other oxidants, including chlorine and chlorine dioxide, also can form these types of substances because these phenomena are not confined to the effects of ozone oxidation.

Physical conditions and proper maintenance of distribution system components to limit adverse effects have important effects on changes in water quality. Accumulation of sediment and periodic cleaning by flushing or other means can have a significant effect on

chlorine demand and availability of sites that harbor bacteria. Where such deposits are problematic, increasing the chlorine residual to offset increased chlorine depletion can result in higher levels of DBP formation.

The integrity of the distribution system is critical to protecting it against intrusion of microbial and chemical agents. Cross-connection programs to maintain integrity traditionally have been a component of water system quality management practices. Other considerations in this area involve procedures for main breaks, cleaning and disinfection practices for new pipes, and methods for protecting storage facilities against intrusion. Adequate system pressure is an important aspect of protecting against intrusion through incidental leaks that can occur in systems, and low-pressure conditions should serve as an alert to possible contamination. More recently, security issues have emerged, and these have resulted in new strategies for monitoring and managing distribution systems.

TREATMENT PROCESS RESIDUALS MANAGEMENT (CHAP. 22)

Water treatment residuals are broadly classified into three categories: solids from clarification (settling or DAF), spent filter backwash solids, and membrane and IX residuals. While historically water treatment residuals were discharged to surface waters, this is rarely permitted (particularly for new treatment facilities), and alternative solids handling methods therefore are being used with increasing frequency. Solids generated through coagulation and lime softening processes have significantly different characteristics but are often thickened and dewatered by many of the same treatment technologies.

Water treatment residuals production is a function of the raw water quality and the quantity of chemicals added during treatment. Solids production varies widely for different water sources and the treatment methods used (e.g., coagulation versus lime softening versus membrane treatment) and often varies seasonally as source water quality changes. Consequently, good historical plant treatment data are imperative to accurately determine solids production rates.

Solids treatment processes can be divided into evaporative and mechanical processes. Evaporative processes are typically used in hot or dry climates that allow rapid evaporation. Since evaporative processes require considerable area, they are difficult to implement at treatment plants with space constraints. Evaporative processes include lagoon dewatering and sand or paved drying beds. Design of evaporative processes is based primarily on local evaporation rates, and approaches therefore vary greatly from region to region. Evaporative processes tend to be less labor-intensive than mechanical processes.

Mechanical processes include both thickening and dewatering technologies. Gravity thickening is typically used for water treatment residuals, which tend to settle well. Mechanical dewatering processes employ belt filter presses, centrifuges, and pressure filters (plate and frame). Both thickening and dewatering system designs are most effective when based on site-specific residuals characteristics, such as settleability and dewaterability, and on pilot-scale testing data. However, in the absence of this information, “rules of thumb” or approximations are often used. Mechanical treatment processes require less space than evaporative processes but are usually more labor-intensive and have higher operating costs.

Regardless of the treatment method employed, final use and ultimate disposal need to be carefully considered when evaluating residuals-handling options. Several options are available, with the most common being disposal of the dewatered cake by landfilling or monofilling (disposal to landfills dedicated solely to water treatment residuals). Beneficial use options include land application, use by soil blenders as a liming/pH adjustment agent, or use as a raw material in a manufacturing process.

OTHER CONSIDERATIONS

Pilot Testing

Pilot-scale testing can provide invaluable information in assessing the applicability of various unit processes to meet site-specific treatment requirements. Side-by-side pilot-scale testing of alternative unit processes or process trains conducted during project predesign phases not only assists in identification of the optimal treatment process configuration and associated design criteria (e.g., process loading rates, filter media configuration, etc.) but also can provide information on chemical requirements and appropriate operating parameters that is useful during startup and initial operation of the full-scale treatment facilities. Pilot testing may be required in some cases to demonstrate the effectiveness of newer, high-rate unit processes in order to obtain state regulatory agency approval.

It is now common practice to incorporate permanent pilot-plant facilities into the design of new or upgraded treatment plants. Pilot-scale testing offers a reliable, low-cost method to evaluate different treatment techniques without the risk of compromising the quality of the water delivered to consumers. Other potential benefits of permanent pilot-plant installations include (1) verification of the ability to operate at increased production rates and associated changes in treatment, (2) identification of optimal treatment conditions as source water quality changes seasonally, (3) evaluation of treatment to address specific source water quality issues such as periodic taste and odor episodes, elevated turbidity, and/or increases in source water iron and manganese concentrations, (4) training of new plant operators, and (5) public tours to increase consumer awareness and confidence in the utility.

Permanent pilot plants typically include all the unit processes that comprise the full-scale treatment process and are commonly sized to treat 0.19–0.63 L/s (3–10 gpm). Since some unit processes do not lend themselves to being scaled down to this capacity range (e.g., DAF and ballasted flocculation/sedimentation), permanent pilot plants have been constructed with some unit processes capable of treating 3.15–6.30 L/s (50–100 gpm) and with downstream processes sized to treat only a small portion of the flow produced by the upstream unit processes.

Flexibility to Meet More Stringent Future Requirements

Considering recent advances in analytical measurements and the current regulatory environment, the ability of a water treatment facility to readily adapt to future changes in regulatory requirements is an important consideration in the selection and design of the unit processes that constitute the overall treatment process. Many utilities that have recently constructed new treatment facilities have specified that the facilities must be able to produce finished water of a quality that not only meets current regulations but also exceeds them by a significant margin, in anticipation of more restrictive future regulations. The ability to produce higher-quality finished water with minimal or no physical modifications often can be incorporated during design and construction of the treatment facility at minimal additional cost by providing flexibility in chemical feed locations and dosing capabilities. Providing greater operational flexibility can enhance the operating staff's capability to cope with unanticipated future water quality conditions.

Environmental Considerations

Recent concerns regarding the potential impacts of climate change on water supply, source water quality, and system demands have resulted in increased attention to many environment-related issues. Water utilities are increasingly dealing with water sustainability concerns,

specific areas of system vulnerability, and the impact of their operations on greenhouse gas emissions. Utilities are increasingly monitoring their carbon footprint (an estimate of the amount of carbon dioxide–equivalent gases released into or removed from the environment). In the United Kingdom, assessment of the carbon footprint of any proposed capital improvements is required as part of the preparation of asset-management funding plans (Strutt et al., 2008). Energy use and chemical treatment practices are two key elements contributing to the carbon footprint and associated greenhouse gas emissions.

While raw and finished water pumping constitutes the majority of energy consumption of a water system, continuing increases in energy costs may also influence the selection of unit processes, with those which are less energy-intensive being viewed more favorably during the design of new treatment facilities. The need to treat lower-quality source waters that until recently have remained untapped as potential sources of drinking water, combined with the necessity to meet increasingly stringent regulatory requirements while minimizing the cost of constructing new facilities, has spurred interest in more sophisticated unit processes. However, many of these newer, high-rate processes may be more energy-intensive than older, more conventional ones. AOPs incorporating UV oxidation in conjunction with the addition of hydrogen peroxide have demonstrated the ability to effectively control taste and odors attributable to geosmin and MIB and typically can be incorporated into the treatment facility at significantly lower capital cost than other means of taste and odor control such as ozonation or GAC contactors. However, AOPs also exhibit higher energy demands than alternative processes because of the need to operate the system at high UV dosages. Considering the continuing escalation in energy costs, evaluation of specific energy requirements of alternative unit processes during plant predesign is expected to increase as plant designers and utilities continue to seek methods to reduce overall energy use.

Similar to the need to consider energy consumption when evaluating the various treatment processes, the costs of water treatment chemicals must be considered. Often there are alternatives (e.g., various coagulants) that should be evaluated to minimize their costs.

Use of “Demonstrated Technology”

While plant designers and regulatory agencies sometimes tend to prefer older, “tried and true” technologies when evaluating the requirements for new or expanded treatment facilities, the newer, high-rate unit processes frequently offer substantial benefits with respect to both initial construction and annual operating and maintenance costs. For example, use of the conventional large rectangular flocculation and sedimentation basins with extended hydraulic retention times (4–6 hours) in new treatment facilities has become rare because other unit processes such as inclined-plate sedimentation, ballasted flocculation/sedimentation, and dissolved air flotation continue to demonstrate equal or superior performance. It is also common practice now to consider membrane filtration as an alternative to conventional granular media filtration when evaluating unit process options for new or upgraded/expanded treatment facilities, particularly when there is concern about the presence of microbial pathogens such as *Cryptosporidium* in the source water.

TREATMENT PROCESS CONFIGURATIONS

Information on the applicability of various unit processes for the removal of selected contaminants is presented in Table 5-1. Particulate contaminants are not included in the table; these contaminants are removed by the various filtration processes listed in

TABLE 5-1 Applicability of Unit Treatment Processes for Removal of Contaminants

Contaminant categories	Aeration and stripping	Coagulation, sedimentation or DAF, filtration	Precoat filtration	Lime softening	Chemical oxidation and disinfection	Membrane processes			Ion exchange		Adsorption

the table and by microfiltration and ultrafiltration. Because site-specific conditions and other factors determine whether a unit process is capable of effectively removing a contaminant, the information presented in the table should be regarded as general guidance. Further information can be obtained from the chapters covering the various unit processes.

The following paragraphs present several treatment process schematics that illustrate how unit processes are typically incorporated into water plants. These are presented for various types of source waters. Since residuals handling and disposal facilities depend on the availability of site space, ultimate disposal requirements, and utility preferences, which are highly site-specific, these facilities are not shown on the process schematics. Also, for simplicity, raw, intermediate, and finished water pumping facilities and some commonly provided chemical feed systems such as fluoride addition are not shown. It is also recognized that other unit process configurations may produce performance results equivalent to the treatment processes illustrated here, depending on site-specific conditions.

High-Quality Reservoir Supply

The membrane filtration treatment process shown in Fig. 5-2 is applicable to treatment of high-quality reservoir sources with little or no iron and manganese, low to moderate levels of turbidity and TOC, low DBP potential, and no history of significant algal blooms and taste and odor episodes. Because membrane filtration does not remove dissolved organic material, provisions for adding coagulant ahead of MF/UF may be needed to remove TOC and DBP precursor compounds. While TOC in some cases can be removed by in-pipe addition of coagulant immediately upstream of MF/UF, the need for flocculation and, potentially, for sedimentation preceding MF is site-specific and must be assessed through bench- and pilot-scale testing.

While a more conventional direct filtration process (i.e., coagulant addition, flocculation, and granular media filtration) also could be considered for this source water, it should be noted that direct filtration does not provide the high levels of microbial pathogen (i.e., *Giardia* cysts and *Cryptosporidium* oocysts) removal that MF/UF membrane filtration processes routinely achieve. Therefore, if direct filtration is specified, it may be necessary to include provisions for postfiltration UV disinfection to achieve overall microbial pathogen removal/inactivation levels comparable with those provided by membrane filtration processes.

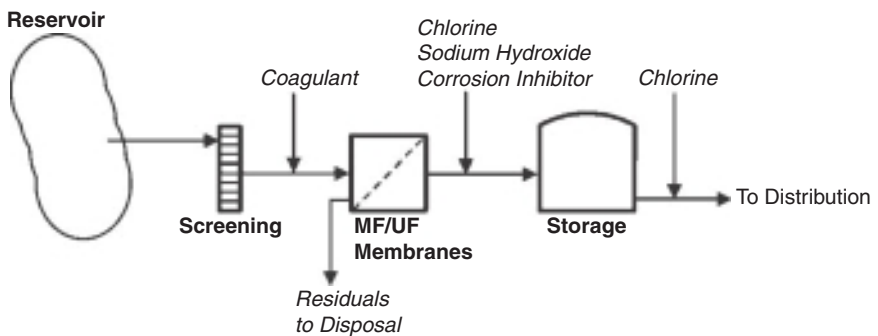

FIGURE 5-2 Membrane filtration of high-quality surface supply.

Reservoir with Algae and Color/TOC

The treatment process train shown in Fig. 5-3 is appropriate for a reservoir supply to address the following water quality conditions:

- Low to moderate levels of non-mineral turbidity (turbidity caused by organic constituents such as algae)
- Moderate to high levels of algae
- Low to high color/TOC
- Provision of high levels of pathogen removal/inactivation
- Iron and manganese may or may not be present.

This approach assumes use of dissolved air flotation to provide effective removal of color and TOC and to ensure acceptable filter run times and productivities when algae concentrations in the source water are high enough to have a negative impact on granular media filter performance. Should manganese concentrations in the source water increase to the extent that treatment is required, the filters could be chemically conditioned to establish a manganese oxide coating on the media, which would ensure highly efficient removal of manganese in the presence of free chlorine residual across the filters.

River or Reservoir Supply with Low to Moderate Hardness

Figure 5-4 presents a typical treatment process train for a reservoir or river supply when reduction of hardness is not required. This process is appropriate to address the following water quality conditions:

- Moderate to high levels of mineral turbidity (turbidity caused by silts/clays)
- Low to moderate levels of color/TOC
- Provision of high levels of pathogen removal/inactivation

This approach assumes use of high-rate clarification with inclined-plate sedimentation basins to reduce the unit process footprint area and construction costs. Provisions for optimization of coagulation pH through the addition of acid or base and for postfiltration adjustment of finished water pH using sodium hydroxide, as shown in Fig. 5-4, are commonly included in the design of new or upgraded treatment facilities. Postfiltration UV

FIGURE 5-3 Dissolved air flotation treatment of reservoir supply.

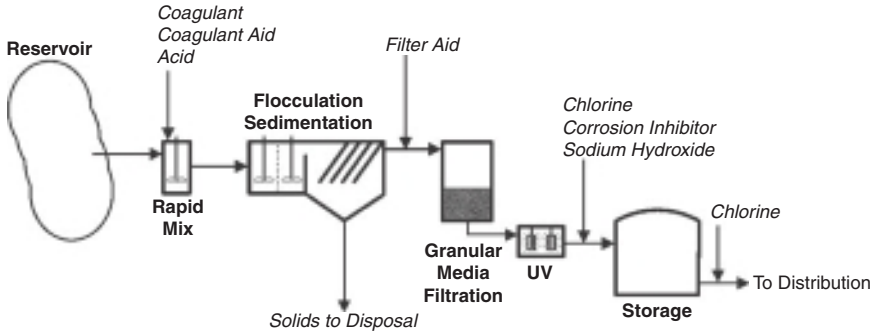

FIGURE 5-4 Conventional treatment of surface supply.

disinfection can be provided if significant concerns regarding source water pathogen levels exist or if inactivation of *Cryptosporidium* oocysts is required to comply with regulatory requirements.

For a reservoir supply having consistently low turbidity but high color and/or episodes of high algae concentrations that would be detrimental to granular filter performance, DAF could be substituted for the sedimentation process shown in Fig. 5-4 because DAF is better able to cope with high color and algae conditions.

River Supply with Hardness

The treatment process shown in Fig. 5-5 is appropriate when both clarification and softening of a river supply with highly variable turbidity and high hardness levels are required, and constitutes the approach currently used by many utilities throughout the Midwestern United States. This treatment process incorporates the following:

- High-rate presedimentation with inclined-plate sedimentation basins to reduce turbidity and color before softening
- Two-stage lime softening/recarbonation with upflow solids contact clarifiers to achieve high lime–soda ash utilization efficiencies and softening performance

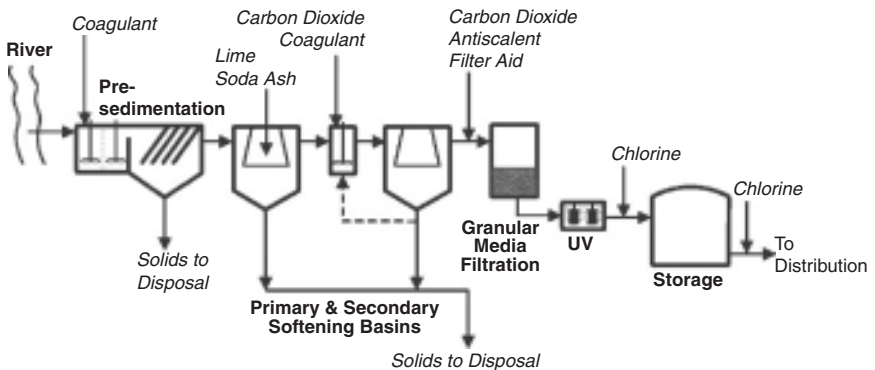

FIGURE 5-5 Clarification/softening of surface supply.

- Provisions for recycling a portion of the solids removed in the secondary softening basins to the secondary basin influent rapid mix to minimize encrustation of mixer impellers and basin influent piping
- Provisions for postfiltration UV disinfection, if needed, to comply with *Cryptosporidium* removal/inactivation requirements

Groundwater with Iron and Manganese

The treatment process shown in Fig. 5-6 is appropriate for a groundwater supply to address the following water quality conditions:

- Iron and/or manganese at concentrations that must be reduced to achieve acceptable finished water quality
- Hydrogen sulfide and/or radon
- Hardness at levels that do not warrant softening treatment

Forced- or induced-draft cascade aeration is provided to initiate the oxidation of iron and manganese and to remove hydrogen sulfide, radon, and other dissolved gases. Because oxidation of manganese to insoluble/filterable form is relatively slow under typical groundwater pH conditions, provisions for maintaining a free chlorine residual across the filters would be included to ensure that effective manganese oxide coatings are maintained on the filter media, thereby ensuring high manganese removal efficiencies.

When removal of hydrogen sulfide or other dissolved gases is not required, aeration may be eliminated, and chemical oxidation of iron and manganese preceding filtration can be employed to reduce construction costs. Use of proprietary high-rate pressure filtration systems for iron and manganese removal is also becoming more common as utilities seek to reduce the complexity of their treatment facilities and to minimize construction costs.

When radon is the only contaminant present at levels that require treatment, aeration and disinfection would be the only unit processes needed. When arsenic is the only contaminant present, aeration is not provided, but chlorine addition for oxidation and a ferric coagulant could be used followed by granular media filtration.

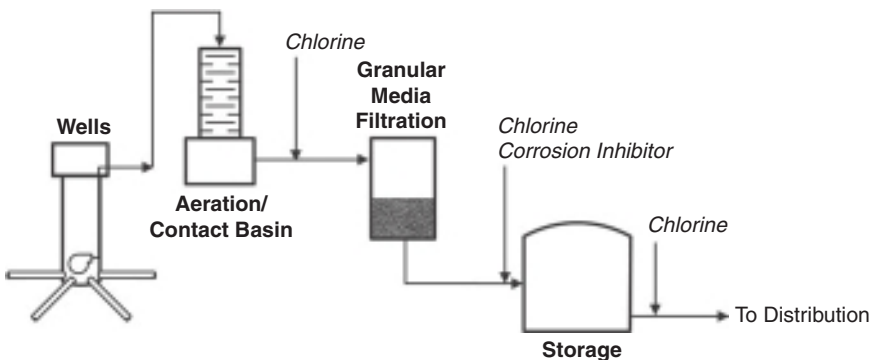

FIGURE 5-6 Iron and manganese removal: groundwater supply.

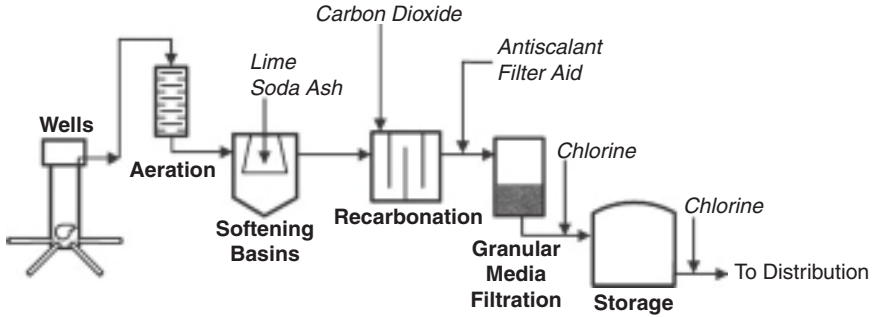

FIGURE 5-7 Lime softening of groundwater supply.

Groundwater with Hardness

Figure 5-7 presents a typical process configuration for a groundwater supply with the following treatment requirements:

- Removal of iron and/or manganese
- Removal of hydrogen sulfide and/or radon
- Reduction of hardness to meet customer expectations

In addition to stripping sulfide and radon, aeration also reduces carbon dioxide concentrations, thereby reducing both the lime dosage and the associated chemical solids production. Following single-stage lime softening, a recarbonation basin with a detention time of at least 20 minutes is typically provided to ensure adequate stabilization of softened water pH before filtration, and provisions for adding an antiscalant (typically sodium hexametaphosphate) at the filter inlet are included to minimize encrustation of filter media by calcium carbonate.

For facilities with capacities of approximately 19 ML/day (5 mgd) or less, IX is often used when softening treatment is required. Because the IX process produces near-zero-hardness water, a portion of the raw water is blended with IX-treated water to achieve the desired finished water hardness. When iron and manganese are present in the source water, provisions for their removal from the IX bypass flow may be required. Treatment of IX feed water to reduce iron and manganese concentrations may also be required to prevent deterioration of the IX resin.

Membrane softening using NF or RO membranes also could be used to treat this source. Pretreatment of membrane feed water typically will be required to ensure that membrane fouling rates are maintained within acceptable ranges.

INTRODUCTION

Air stripping is defined as a process whereby volatile constituents such as gases and organic compounds are transferred from the water to the air. Absorption is the opposite of air stripping—where constituents such as gases are transferred from the air to the water. Several types of air stripping and aeration systems are used for a variety of water treatment applications. The most common types are diffused air, surface aerator, spray, and packed tower systems. Water treatment applications for these systems include the absorption of

reactive gases for water stabilization and disinfection, precipitation of inorganic contaminants, and air stripping of volatile organic compounds (VOCs) and nuisance-causing dissolved gases. The diffused aeration (or bubble) systems are primarily used for the absorption of reactive gases such as oxygen (O_2), ozone (O_3), and chlorine (Cl_2). For example, ozone is used for disinfection, oxidation of VOCs and pesticides, taste and odor control, disinfection by-products control, as a coagulant aid, and for some other uses. Chlorine is primarily used for disinfection and sometimes as a preoxidant for the oxidation of iron and manganese and for other purposes. Diffused aeration systems have also been used for stripping of odor-causing compounds and VOCs. Surface aeration systems are primarily used for removal of gases and VOCs. The packed tower and spray nozzle systems are primarily used for the removal of NH_3 , CO_2 , H_2S , and VOCs. The packed tower systems include countercurrent flow, cocurrent flow, and cross-flow configurations. Spray nozzle systems include tower and fountain-type configurations.

Another application is the dissolution of air into recycled water under pressure in packed towers called saturators and subsequent production of air bubbles when the pressurized recycle water is injected into an open tank for water clarification. This application is called dissolved air flotation and is covered in Chap. 9.

A fundamental understanding of the theory of gas transfer is first discussed, followed by a description of the various unit operations, development of the governing equations, and example design calculations.

THEORY OF GAS TRANSFER

Proper design and operation of aeration and air stripping devices require a fundamental understanding of equilibrium partitioning of chemicals between air and water as well as an understanding of the mass transfer rate across the air-water interface is required. Equilibrium is the final state that the system is moving towards. The displacement of the system from equilibrium dictates how much fluid (air) is required for stripping or aeration and defines the driving force that governs mass transfer, i.e., the rate at which chemicals move from one phase to another, which in turn determines the vessel size required for stripping or aeration. Both equilibrium and mass transfer concepts are incorporated into mass balance equations to formulate the governing equations. Consequently, these concepts are reviewed first.

Equilibrium

FIGURE 6-1 Schematic of equilibrium conditions for component A in air and water.

For most aeration and air stripping applications in water treatment, equilibrium partitioning of a gas or organic contaminant between air and water can be described by Henry's law. The Henry's law equilibrium description can be derived by considering the closed vessel shown in Fig. 6-1. If the vessel contains both water and air and component A is in equilibrium with both phases at a constant temperature, equilibrium can be described by the following expression:

$$K_{eq} = \frac{a_{air}}{a_{aq}} \quad (6-1)$$

where K_{eq} is the equilibrium constant, a_{air} is the activity of component A in the gas phase, and a_{aq} is the activity of component A in the aqueous phase.

At a pressure of 1 atm, the gas behaves ideally, and Eq. 6-1 reduces to:

$$H = K_{\text{eq}} = \frac{P_A}{\gamma_A A} \quad (6-2)$$

where H is the Henry's law constant (atm-L/mole) of component A, P_A is the pressure A exerts in the gas phase (atm), γ_A is the activity coefficient of A in the aqueous phase, and A is the aqueous-phase molar concentration of A (mole/L).

The presence of air does not affect the Henry's law constant for organic chemicals or gases. For low ionic strength, Henry's law may be written as follows:

$$P_A = H[A] \quad (6-3)$$

When other dissolved organic and inorganic species are present at concentrations less than 0.01 mole/L, the equilibrium partitioning according to Eq. 6-3 is not affected and is generally valid. Further, it has been shown in some cases to be valid for concentrations as high as 0.1 mole/L (Rogers, 1994). The units of H in Eq. 6-3 are atm-L/mole, but H has other units. Figure 6-2 displays the three most commonly used unit measures of H . H is reported in units of atm when the gas-phase concentration of component A is expressed in atm and the aqueous-phase concentration of component A is expressed in terms of mole fraction. H is reported in units of liters of water times atm per mole of gas (L · atm/mole) when the gas-phase concentration of component A is expressed in atm and the aqueous-phase concentration of component A is expressed in terms moles of component A per liter of water. H is also reported in dimensionless units when both the gas and aqueous phases are expressed in the same concentration units. Because the reported units of H vary, it is necessary to convert from one system of units to another. Table 6-1 displays various unit conversions that can be used to perform this conversion. Dimensionless units are convenient for mass balances; consequently, dimensionless units are preferred and are used in this chapter.

Estimating Henry's Constant. When the Henry's law constant for a component of interest is not readily available, it can be estimated if the component's vapor pressure and aqueous solubility are known. There are two situations in which it is possible to estimate the Henry's constant of component A: (1) when component A is perfectly miscible in the aqueous phase and (2) when component A is immiscible in the aqueous phase. When component A is perfectly miscible and the mole fraction of A is equal to 1 ($x_{\text{H}_2\text{O}} = 0$), the pressure exerted by A is equal to the vapor pressure of pure A at a given temperature. In this case H , can be expressed as:

$$H = P_{v,A} \quad (6-4)$$

in which $P_{v,A}$ is the vapor pressure of pure component A at a given temperature (atm).

When component A is immiscible in the aqueous phase, a third or separate phase of component A is formed within the aqueous phase once the solubility of A is exceeded. If this third phase contains water, then H cannot be determined from vapor pressure and solubility data because the partitioning in the third phase is unknown. However, if the third phase contains only pure component A, then the following expression can be used:

$$H = \frac{P_{v,A}}{C_{s,A}} \quad (6-5)$$

in which $C_{s,A}$ is the aqueous solubility of component A (mg/L). Equations 6-4 and 6-5 are estimation techniques that give H values within ± 50 to 100 percent of experimentally reported values and should therefore only be used when measured values of the constants are not available.

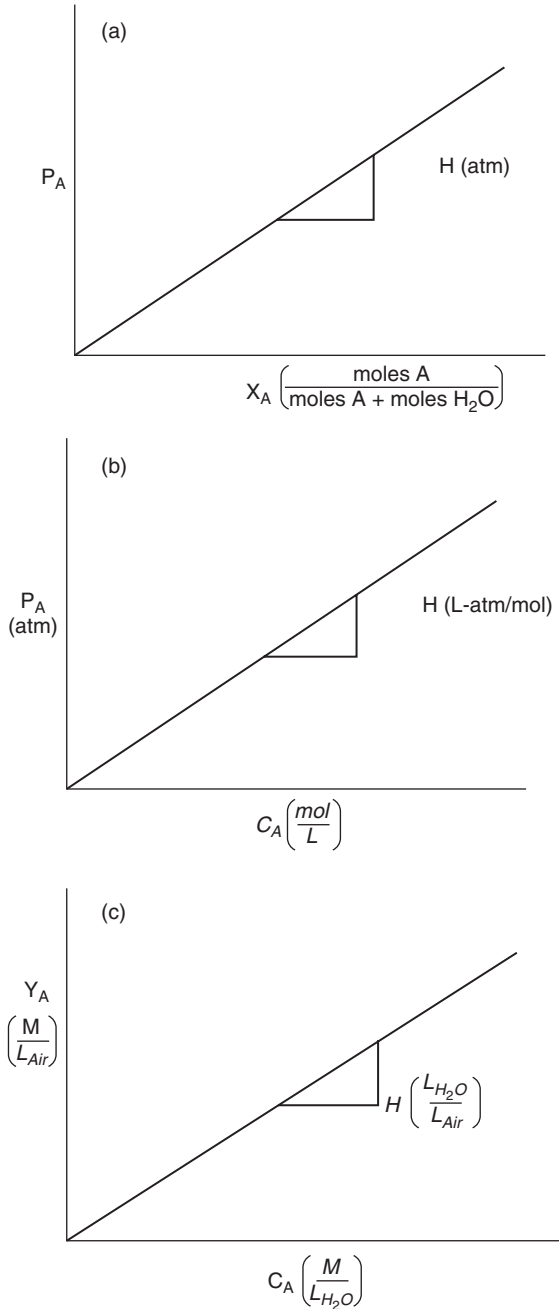

FIGURE 6-2 (a) plot of H displayed in atm, (b) plot of H displayed in liters of water \cdot atm/mol, (c) plot of H displayed in liters of water per liter of air.

TABLE 6-1 Unit Conversions for Henry's Law Constants

$$\begin{aligned}
 H(L_{\text{H}_2\text{O}}/L_{\text{Air}}) &= \frac{H\left(\frac{\text{L}\cdot\text{atm}}{\text{mol}}\right)}{RT} \\
 H\left(\frac{\text{L}\cdot\text{atm}}{\text{mol}}\right) &= H(L_{\text{H}_2\text{O}}/L_{\text{Air}}) \times RT \\
 H(L_{\text{H}_2\text{O}}/L_{\text{Air}}) &= \frac{H(\text{atm})}{RT \times 55.6 \frac{\text{molH}_2\text{O}}{\text{LH}_2\text{O}}} \\
 H\left(\frac{\text{L}\cdot\text{atm}}{\text{mol}}\right) &= \frac{H(\text{atm})}{55.6 \frac{\text{molH}_2\text{O}}{\text{LH}_2\text{O}}} \\
 H(\text{atm}) &= H\left(\frac{\text{L}\cdot\text{atm}}{\text{mol}}\right) \times 55.6 \frac{\text{molH}_2\text{O}}{\text{LH}_2\text{O}} \\
 H(\text{atm}) &= H(L_{\text{H}_2\text{O}}/L_{\text{Air}}) \times RT \times 55.6 \frac{\text{molH}_2\text{O}}{\text{LH}_2\text{O}} \\
 R &= 0.08205 \frac{\text{atm}\cdot\text{L}}{\text{mol}\cdot\text{K}} \quad T = \text{K}
 \end{aligned}$$

Effects of Temperature and Solution Properties. Temperature, pressure, ionic strength, surfactants, and solution pH (for ionizable species such as NH_3 and CO_2) can influence the equilibrium partitioning between air and water.

Pressure. The impact of total system pressure on H is negligible because most aeration and stripping devices operate at atmospheric pressure.

Temperature. For the range of temperatures encountered in water treatment, H tends to increase with increasing temperature because the aqueous solubility of the component decreases while its vapor pressure increases. Values of H for several organic compounds at different temperatures are given in Table 6-2. Table 6-3 displays H values for gases at 20°C . Assuming the standard enthalpy change (ΔH°) for the dissolution of a component in water is constant over the temperature range of interest, the change in H with temperature can be estimated using the following van't Hoff-type equation:

$$H_2 = H_1 \times \exp\left(\frac{-\Delta H^\circ}{R} \left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right) \quad (6-6)$$

in which ΔH° is the standard enthalpy change in water due to the dissolution of a component in water (kcal/kmol), R is the universal gas constant (1.987 kcal/kmol-K), H_1 is a known value of Henry's constant at temperature T_1 (K), H_2 is the calculated Henry's law constant at the desired temperature T_2 (K), and C is a constant.

Equation 6-6 can be simplified to Eq. 6-7, and values of ΔH° and C for selected compounds are summarized in Table 6-4.

$$H = C \times \exp\left(-\frac{\Delta H^\circ}{RT}\right) \quad (6-7)$$

Another common method of expressing the temperature dependence of H is to treat ΔH° , R , and C as fitting parameters A and B using the following equation:

$$H = \exp\left(A - \frac{B}{T}\right) \quad (6-8)$$

Table 6-5 lists values of A and B for several compounds. These are valid for temperatures ranging from 283 to 303 K (Ashworth et al., 1988).

TABLE 6-2 Henry's Law Constants in atm m³/mole and the H Values in Liters of Water per Liter of Air Are Given in Parentheses for 45 Organic Compounds (Ashworth et al., 1988).

Ionic Strength. In water supplies, gases or VOCs that are high in dissolved solids have higher volatility (or have a higher apparent Henry's law constant) than those with low dissolved solids. This results in a decrease in the solubility of the volatile component, i.e., a "salting-out effect," that can be represented mathematically as an increase in the activity coefficient of component A, γ_A in aqueous solution. γ_A will increase ($\gamma_A > 1$) with increasing ionic strength; this in turn causes the apparent Henry's law constant, H_{app} , to be greater than the thermodynamic value of H . The following equation can be used to calculate H_{app} :

$$H_{app} = \gamma_A H = \frac{P_A}{[A]} \quad (6-9)$$

in which γ_A is a function of ionic strength and can be calculated using the following empirical equation:

$$\log_{10} \gamma_A = K_s \times I \quad (6-10)$$

where K_s is the Setschenow, or "salting-out," constant (L/mole) and I is the ionic strength of the water (mole/L).

Ionic strength (I), which is discussed in Chap. 3, is defined as follows:

$$I = \frac{1}{2} \sum_i (C_i Z_i^2) \quad (6-11)$$

in which C_i is the molar concentration of ionic species i (mole/L) and Z_i is the charge of species i . The values of K_s need to be determined by experimental methods because there is no general theory for predicting them. Table 6-6 displays the salting-out coefficients for several compounds at 20°C. For most water supplies, the ionic strength is less than 10 mM and the activity coefficient is equal to 1. Significant increases in volatility and the apparent Henry's constant are only observed for high ionic strength waters, such as seawater.

pH. pH does not affect the Henry's constant per se but it does affect the distribution of species between ionized and unionized forms. This, in turn, influences the overall gas-liquid

TABLE 6-6 Setschenow or Salting-Out Coefficients, K_s , at (20°C)

distribution of the compound because only the unionized species are volatile. For example, ammonia is present as ammonium ion at neutral pH and is not strippable. However, at high pH (greater than 10), ammonia is not an ion and may be stripped. To predict the effect of pH on solubility, one must consider the value of the appropriate acidity constant pK_a . If the acid is uncharged, such as HCN or H₂S, and the pH is much less than the pK_a (2 units lower), then equilibrium partitioning can be described using the Henry's law constant for the uncharged species. If the acid is charged, such as NH₄⁺, and the pH is much higher than the pK_a (2 units higher), then the compound will be volatile and its equilibrium partitioning can be described using Henry's law constant for the uncharged species. See Chap. 3 for a presentation of acid-base chemistry.

Surfactants. Surfactants can also affect the volatility of compounds. Most natural waters do not have high concentrations of surfactants; consequently, they do not affect the design of most stripping devices. However, surfactants, if present, lower the volatility of compounds by several mechanisms. The most important factor is that they tend to collect at the air-water interface, diminishing the mole fraction of the compound at the interfacial area, thereby lowering its apparent Henry's law constant. In untreated wastewater, for example, the solubility of oxygen can be lowered by 30 to 50 percent due to the presence of surfactants. Another effect for hydrophobic organics is the incorporation of the dissolved organics into micelles in solution (this would occur only above the critical micelle concentration) that, in turn, decreases the concentration of the organic compound at the air-water interface and lowers the compound's volatility (Vane and Giroux, 2000). O'Haver et al. (2004) provide a more detailed discussion of the impact of surfactants on air stripping of VOCs.

Mass Transfer

The driving force for mass transfer between one phase and another derives from the displacement of the system from equilibrium. Figure 6-3 displays two situations where mass transfer is occurring between the air and water. Figure 6-3a displays the situation where mass is being transferred from the water to the air, and Fig. 6-3b displays the situation where mass is being transferred from the air to the water. Because the mechanisms and assumptions for mass transfer are essentially the same for both cases, a detailed explanation of only one is warranted. Consider the case where a volatile contaminant is being stripped from water to air (Fig. 6-3a). The contaminant concentration in the water is high relative to the equilibrium concentration between the air and water. The tendency to achieve equilibrium is sufficient to cause diffusion of the aqueous-phase contaminant molecules from the bulk solution at some concentration, C_b (μg/L), to the air-water interface, where the aqueous phase concentration is C_s (μg/L). Because C_b is larger than C_s , the difference between

FIGURE 6-3 Diagram describing the equilibrium partitioning of a contaminant between the air and water phases using two film theory.

them provides the aqueous-phase driving force for stripping. Similarly, the contaminant concentration in the air at the air-water interface, y_s , is larger than the contaminant concentration in the bulk air, y_b , and diffusion causes the molecules to migrate from the air-water interface to the bulk air. The difference between y_s and y_b is the driving force for stripping in the gas phase.

Mass Flux. Local equilibrium occurs at the air-water interface because on a local scale of tens of Angstroms random molecular movement causes the contaminant to dissolve in the aqueous phase and volatilize into the air. (On a larger scale, these motions equalize the displacement of the system from equilibrium and cause diffusion.) Accordingly, Henry's law can be used to relate y_s to C_s (Lewis and Whitman, 1924).

$$y_s = HC_s \quad (6-12)$$

Fick's law can be simplified to a linear driving force approximation whereby the flux (the mass transferred per unit of time per unit of interfacial area) across the air-water interface is proportional to the concentration gradient. Mathematically, the flux of A across the air-water interface, J_A , is given by:

$$J_A = k_l(C_b - C_s) = k_g(y_s - y_b) \quad (6-13)$$

in which k_l is the liquid-phase mass transfer coefficient that describes the rate at which contaminant A is transferred from the bulk aqueous phase to the air-water interface (L/t) and k_g is the gas-phase mass transfer coefficient that describes the rate at which contaminant A is transferred from the air-water interface to the bulk gas phase (m/s). Both k_l and k_g are sometimes called local mass transfer coefficients for the liquid and gas phases because they depend upon the conditions at or near the air-water interface in their particular phase. Because the interfacial concentrations y_s and C_s cannot be measured and are unknown, the flux cannot be determined from Eq. 6-13. Consequently, it is necessary to define another flux equation in terms of hypothetical concentrations, which are easy to determine and describe the displacement of the system from equilibrium. If it is hypothesized that all the resistance to mass transfer is on the liquid side, then there is no concentration gradient on the gas side and a hypothetical concentration C_s^* can be defined as shown in Fig. 6-3a.

$$y_b = HC_s^* \quad (6-14)$$

in which C_s^* is the aqueous-phase concentration of A at the air-water interface assuming no concentration gradient in the air phase ($\mu\text{g/L}$), i.e., equilibrium exists between the bulk gas-phase concentration and the aqueous phase at the interface.

Alternatively, if it is hypothesized that all the resistance to mass transfer is on the gas side, there is no concentration gradient on the liquid side and a hypothetical concentration y_s^* can be defined as shown in Fig. 6-3a.

$$y_s^* = HC_b \quad (6-15)$$

in which y_s^* is the equilibrium gas-phase concentration of A at the air-water interface assuming no concentration gradient in the liquid phase ($\mu\text{g/L}$); it can be calculated from the bulk liquid-phase concentration.

Mass Flux Based on Water Side. For stripping operations, mass balances are normally written based on the liquid phase. It is convenient to calculate the mass transfer rate using the hypothetical concentration, C_s^* , and an overall mass transfer coefficient, K_L , as shown in the following equation:

$$J_A = K_L(C_b - C_s^*) \quad (6-16)$$

Equating Eq. 6-13 and 6-16 results in:

$$J_A = k_l(C_b - C_s) = k_g(y_s - y_b) = K_L(C_b - C_s^*) \quad (6-17)$$

From Fig. 6-3a, one can obtain the following relationship:

$$(C_b - C_s^*) = (C_b - C_s) + (C_s - C_s^*) \quad (6-18)$$

Substituting $C_s = \frac{y_s}{H}$ and $C_s^* = \frac{y_b}{H}$ into Eq. 6-18 and combining with Eq. 6-17 yields:

$$\frac{J_A}{K_L} = \frac{J_A}{k_l} + \frac{J_A}{Hk_g} \quad (6-19)$$

or

$$\frac{1}{K_L} = \frac{1}{k_l} + \frac{1}{Hk_g} \quad (6-20)$$

Equation 6-20 states simply that the overall resistance to mass transfer is equal to the sum of the mass transfer resistances for the liquid and gas phases. It describes the overall mass transfer rate without the use of the unknown local concentrations at the air-water interface.

Volumetric Mass Transfer Expression. For aeration and stripping process design equations, the rate of mass transfer is often expressed on a volumetric basis rather than an interfacial area basis. The flux term, J_A , is converted to a volumetric basis by multiplying by the specific interfacial area, “ a ,” which is defined as the interfacial area available for mass transfer divided by the system unit volume (m^2/m^3). Equation 6-20 can be expressed in terms of a volumetric mass transfer rate by multiplying J_A by a in Eq. 6-19 and rewriting as:

$$\frac{1}{K_L a} = \frac{1}{k_l a} + \frac{1}{Hk_g a} \quad (6-21)$$

This modification is based on the liquid side controlling the mass transfer and also includes the resistance to mass transfer in the gas phase to provide an exact representation of the mass flux across the air-water interface. For compounds with Henry’s law constants less than 0.002 and low solubility, the gas side controls the mass transfer rate. A similar relationship may be developed for an overall mass transfer coefficient on the gas side, which is useful for absorption or scrubbing operations where the constituent is transferred from the air side to the water side. The final equation is given as:

$$\frac{1}{K_G a} = \frac{H}{k_l a} + \frac{1}{k_g a} \quad (6-22)$$

in which K_G is the overall gas-phase mass transfer coefficient (m/s). The mass flux may be obtained from the gas-phase mass balance by multiplying K_G by the hypothetical driving force, $(C_b - C_s^*)$.

Phase Controlling Mass Transfer. Determining which phase controls the mass transfer rate is important in optimizing the design and operation of aeration and air stripping processes. For example, when the mass transfer rate is controlled by the liquid-phase resistance, an increase in the mixing of the air has little impact on removal efficiency. Increasing the interfacial area will increase the removal efficiency. Equation 6-20 states simply that the overall resistance to mass transfer is equal to the sum of the resistance in liquid and gas phases and can be rewritten as:

$$R_T = R_L + R_G \quad (6-23)$$

in which $R_T(1/K_L)$ is the overall resistance to mass transfer (s/m), $R_L(1/k_l)$ is the liquid-phase resistance to mass transfer (s/m), and $R_G(1/k_g)$ is the gas-phase resistance to mass

transfer (s/m). Equation 6-20 can also be rearranged into the following equation to evaluate which phase controls the rate of mass transfer:

$$\frac{R_L}{R_T} = \frac{\frac{1}{k_l}}{\frac{1}{k_l} + \frac{1}{Hk_g}} = \frac{1}{1 + \frac{1}{\left(\frac{k_g}{k_l}\right)H}} \quad (6-24)$$

or

$$\frac{R_L}{R_T} (\%) = \frac{100}{1 + \frac{1}{\left(\frac{k_g}{k_l}\right)H}} \quad (6-25)$$

Literature-reported values of the ratio k_g/k_l range from 40 to 200 (Munz and Roberts, 1989) depending upon the type of aeration or stripping system. Assuming k_g/k_l is 100, Eq. 6-25 can be used to determine which phase controls the rate of mass transfer across the interface. Table 6-7 gives the phases that control the rate of mass transfer for a number of compounds with a wide range of Henry's law constants. In general, the liquid phase controls the rate of mass transfer for compounds with H values greater than 0.05 and low liquid solubility. The gas phase controls mass transfer for compounds with H values less than 0.002 and high liquid solubility. For compounds with H values between 0.002 and 0.05 either phase may be preferred, and both the liquid and gas phases affect the rate of mass transfer.

TABLE 6-7 Summary of Controlling Phase for Several Compounds

Compound	H (25°C)	R_L/R_T (%)	Controlling phase
Oxygen	29.29	100	Liquid
CarbonTetrachloride	1.2	99	Liquid
Trichloroethene	0.40	98	Liquid
Chloroform	0.15	94	Liquid
Acetone	0.001	9	Gas

PACKED TOWERS

The primary applications of packed towers in water treatment are the addition of air under pressure in packed towers called saturators in dissolved air flotation (Chap. 9) and stripping of VOCs, carbon dioxide, hydrogen sulfide, and ammonia. An example of a packed tower system is displayed in Fig. 6-4. Water is pumped to the top of the tower and through a liquid distributor, where it then flows by gravity over packing material. At the same time, a blower introduces fresh air into the bottom of the tower; the air flows countercurrent to the water up through the void spaces between the wetted packing material. The packing material provides a large air-water interfacial area, resulting in efficient transfer of the volatile contaminant from the water to the air. The contaminant-free, air-stripped water leaves the bottom of the tower while the air containing the contaminant exits the top of the tower for further treatment or exhaustion to the atmosphere. The packing material consists of individual pieces randomly dumped into the column. Figure 6-5 displays several varieties of commercially available packing material. Table 6-8 lists several packing materials and their physical properties as reported by the manufacturers. The packing materials are made of plastic with a surface tension of 0.033 N/m (0.024 lb/ft).

Cross-flow, cascade, and cocurrent packed tower systems have similar configurations, but the air flow is introduced differently. In the cross-flow system, the air flows across the

FIGURE 6-4 Schematic of a packed tower.

tower packing at a 90° angle to the direction of the water flow. Methods for estimating the performance of the cross-flow system are available in the literature (Little and Selleck, 1991). In the cascade system, fresh air is introduced at various points along the tower, and fluid flows countercurrent to the water flow (Nirmalakhandan, Jang, and Speece., 1991, 1992). Both the cross-flow and cascade systems provide larger air flow rates at lower gas pressure drops than those typically used in the conventional countercurrent system. The larger air flow rates provide a greater driving force for stripping, leading to more efficient removal of contaminants with low volatility. The cross-flow and cascade systems are recommended for packed tower systems that require high air-to-water ratios to remove semi-volatile and low-volatility contaminants from water as well as larger air treatment devices to remove the VOCs. In the co-current system, both the air and water enter the top of the tower, flow through the packing, and exit at the bottom of the tower. The co-current system is rarely used in water treatment for stripping because it cannot achieve removal efficiencies that are as high as those in the countercurrent process.

Recently, sieve tray columns and low-profile air strippers have been used to remove VOCs from contaminated waters. Sieve tray columns operate as a countercurrent process. The columns are typically less than 3 m (10 ft) high and consist of several perforated trays placed in series along the column. Water enters at the top of the tower and flows horizontally across each tray. Inlet and outlet channels, referred to as downcomers, are placed at the ends of each tray to allow the water to flow from tray to tray. At the same time, fresh air flows up from the bottom of the tower through the tray holes and the layer of water flowing across each tray. Large air flow rates are typically used, causing small bubbles or frothing

to occur upon air contact with the water. The frothing provides a high air-to-water surface area for mass transfer to occur. Because the water flows horizontally across each tray, the desired removal efficiency can be obtained by increasing the length or width of the trays instead of the height. The advantages of using a low-profile air stripper over a conventional packed tower stripper are that the low-profile air stripper is smaller and more compact and it is easier to provide periodic maintenance. The disadvantage is that for a given removal, the low-profile air stripper requires a significantly higher air flow than the conventional packed tower and the operational costs may be greater. In addition, low-profile air strippers are limited to water flow rates less than 0.0630 m³/s (1000 gpm) because of manufacturing size constraints.

Governing Equations

Mathematical models that describe countercurrent packed tower processes for water treatment are well established in the literature (e.g., Sherwood and Hollaway, 1940; Treybal, 1980; Kavanaugh and Trussell, 1980; Ball, Jones, and Kavanaugh, 1984; Singley et al., 1981; Umphres et al., 1983; Cummins and Westrick, 1983; McKinnon and Dyksen, 1984; Roberts et al., 1985; Gross and TerMaath, 1985; Roberts and Levy, 1985; Hand et al., 1986; Dzombak, Roy, and Fang, 1993; Hokanson, 1996). These models have been used successfully to describe the packed tower air stripping process and, consequently, to size the towers for a given removal.

Development of Packed Tower Height Expression. Figure 6-6 displays a mathematical representation of the packed tower process shown in Fig. 6-4. The overall assumptions in development of the model are (1) plug-flow conditions prevail in the air and water streams, (2) the incoming air contains no contaminant, (3) the contaminant concentration in the influent water stream is constant, (4) air and water temperatures are constant and equal to the inlet water temperature, and (5) Henry's law describes the chemical equilibrium between the air

FIGURE 6-6 Schematic of a packed tower used in the development of the design equations.

and water phases. The first step in development of the design equations is to establish the relationship between the air and water phase contaminant concentrations within the packed tower. Figure 6-7 compares the equilibrium line, as defined by Henry’s law equation, with the operating line for packed tower air stripping. The operating line relates the bulk air-phase contaminant concentration to the bulk water-phase contaminant concentration and is based on a mass balance around the bottom of the air stripping tower of:

$$y_b(z) = \frac{Q}{\dot{V}} [C_b(z) - C_e] \tag{6-26}$$

FIGURE 6-7 Operating line diagram for a packed tower.

in which y_b is the bulk air-phase concentration of the contaminant at any point along the packed tower height ($\mu\text{g/L}$), Q is the water flow rate to the tower (m^3/s), \dot{V} is the volumetric air flow rate to the tower (m^3/s), C_b is the bulk water-phase concentration of the contaminant at any point along the packed tower height ($\mu\text{g/L}$), and C_e is the bulk water-phase contaminant concentration at the bottom of the tower ($\mu\text{g/L}$). The driving force for stripping is quantified by comparing the operating line to the equilibrium line. The bulk air-phase contaminant concentration corresponding to a given water-phase contaminant concentration is found by holding C constant and moving vertically until the operating line is intersected. This is the bulk air-phase contaminant concentration. The water-phase contaminant concentration, which would be in equilibrium with the air-phase contaminant concentration, is found by holding y constant until it intersects the equilibrium line. The difference between these two concentrations is the driving force for stripping; it must be positive in order for stripping to occur.

Incorporating the above assumptions into an aqueous-phase mass balance around the differential element circumscribed by the dashed box in Fig. 6-6 yields the following expression for removal of a contaminant within a packed tower:

$$\frac{dC_b}{dz} = \frac{K_L a A}{Q} (C_b - C_s^*) \quad (6-27)$$

in which C_s^* is the water-phase concentration of the contaminant in equilibrium with the bulk air-phase contaminant concentration at any point along the packed tower. The integral form of Eq. 6-27 is expressed as:

$$\int_0^L dz = \frac{Q}{AK_L a} \int_{C_e}^{C_o} \frac{dC_b}{C_b - C_s^*} \quad (6-28)$$

Integration of Eq. 6-28 requires an expression for C_s^* in terms of C_b . From Fig. 6-7, C_s^* is expressed in terms of the bulk air-phase contaminant concentration using Henry's law and substituting into Eq. 6-26 to yield

$$C_s^* = \frac{Q}{\dot{V}H} [C_b - C_e] \quad (6-29)$$

Substitution of Eq. 6-29 into Eq. 6-28 and integrating yields the following design equations for the countercurrent packed tower process:

$$L = \frac{Q}{AK_L a} \left[\frac{C_o - C_e}{C_o - C_e - C_o^*} \right] \log_e \left[\frac{C_o - C_o^*}{C_e} \right] \quad (6-30)$$

$$C_o^*(z=L) = \left(\frac{Q}{\dot{V}H} \right) (C_o - C_e) \quad (6-31)$$

where C_o^* is the aqueous-phase concentration of the contaminant in equilibrium with the exiting air-phase contaminant concentration y_e ($\mu\text{g/L}$). C_o^* is obtained by rearranging Eq. 6-26 assuming y_b equals y_e and C_b equals C_o and then substituting C_o^* for y_e/H . Equations 6-30 and 6-31 are sometimes combined, and the quantity $\dot{V}H/Q$, defined as the stripping factor (S), is introduced.

Minimum Air-to-Water Ratio and Stripping Factor. The minimum air-to-water ratio required for stripping can be determined by considering the driving force for stripping at the top of the tower. Under the best scenario, the exiting air will be in equilibrium with the

incoming water, which implies that C_o^* in Eq. 6-31 is equal to C_o and, upon substitution into Eq. 6-31, the following expression may be obtained:

$$\left(\frac{\dot{V}}{Q}\right)_{\min} = \frac{(C_o - C_e)}{HC_o} \quad (6-32)$$

The minimum air-to-water ratio, $\left(\frac{\dot{V}}{Q}\right)_{\min}$, is the lowest air-to-water ratio that can be applied for a packed tower and meet a given contaminant's treatment objective, C_e . If the air-to-water ratio applied is less than the minimum air-to-water ratio, it will not be possible to design a packed tower capable of meeting the treatment objective because equilibrium will be established in the tower before the treatment objective is reached. This can be explained using the stripping factor, S , which represents an equilibrium capacity parameter. When S is greater than 1, there is sufficient capacity in the air to convey all the solute in the entering water, and complete removal by stripping is possible given a sufficiently long column. When $S < 1$, the system performance is limited by equilibrium and the fractional removal is asymptotic to the value of S (i.e., $1 - C_e/C_o \rightarrow S$ as $L \rightarrow \infty$, as shown by Eq. 6-32. When $S = 1$, the tower is operating at the minimum air-to-water ratio required for stripping.

Optimum Air-to-Water Ratio. With respect to the selection of the optimum air-to-water ratio, Hand et al. (1986) demonstrated that minimum tower volumes and power requirements are achieved for high-percentage removals using approximately 3.5 times the minimum air-to-water ratio for contaminants with Henry's law constants greater than 0.05. This corresponds to a stripping factor of 3.5.

Packed Tower Height Expression in Terms of Transfer Units. In packed tower air stripping, the tower length is often defined as the product of the height of a transfer unit (HTU) and the number of transfer units (NTU). The following two equations define HTU and NTU :

$$HTU = \frac{Q}{AK_L a} \quad (6-33)$$

$$NTU = \left[\frac{C_o - C_e}{C_o - C_e - C_o^*} \right] \ln \left[\frac{C_o - C_o^*}{C_e} \right] \quad (6-34)$$

or incorporating Eq. 6-31 and R into Eq. 6-30 yields:

$$NTU = \left[\frac{R}{R-1} \right] \ln \left[\frac{\frac{C_o}{C_e}(R-1)+1}{R} \right] \quad (6-35)$$

Substituting Eq. 6-33 and Eq. 6-34 or 6-35 into Eq. 6-30 results in:

$$L = HTU \times NTU \quad (6-36)$$

The NTU is determined by the driving force for stripping and corresponds to the number of stages (or hypothetical completely mixed tanks at equilibrium) required for stripping. Equation 6-35 shows that NTU depends upon R and VOC removal efficiency; this relationship is displayed in Fig. 6-8. For a given R , the removal efficiency increases with increasing NTU (or number of hypothetical completely mixed tanks). In addition, for a given removal efficiency, increasing R or the air-to-water ratio will decrease the number of $NTUs$ required. HTU is the height of one stage, as determined by the rate of mass transfer, K_{La} , and the tower area, A , which must be known to calculate the packed tower height in Eq. 6-36.

FIGURE 6-8 Dependence of removal efficiency on NTU on and stripping factor. (Source: Treybal, 1980.)

Determination of K_La . K_La values for packed towers can be determined by performing pilot plant studies or can be obtained from experimental values reported by packing manufacturers and previously reported field studies. When experimental K_La values are not available, they can be estimated from mass transfer correlations. A pilot plant study is the preferred way to determine K_La for a given VOC in contaminated water. Pilot-scale packed towers range in size from 2 to 6 m (6.5 to 20 ft) in height and 0.3 to 0.61 m (1 to 4 ft) in diameter. The column diameter that is used will depend upon the desired packing size. It is generally recommended that ratios of column diameter to packing diameter be greater than 10:1 (>15:1 desired) in order to minimize error due to channeling of the water down the column walls (Treybal, 1980). It is also recommended that the ratio of packed column height to diameter be greater than 1:1 in order to provide for proper liquid distribution (Roberts et al., 1985; Treybal, 1980). Pilot plant design guidelines such as these as well as construction and operation of pilot-scale packed tower units are presented elsewhere (Crittenden et al., 2005).

Equation 6-36 is used in conjunction with pilot plant data to determine K_La for a given VOC. The experimental value of K_La can be determined from HTU , as shown in Eq. 6-33. The value of K_La is based on VOC removal due to the packed height portion of the tower. However, VOC removal also occurs as the water contacts the air above the packing at the top of the tower and at the bottom of the tower as the water falls into the clearwell below the packing. This removal is sometimes referred to as “end effects” (Umphres et al., 1983). Consequently, an NTU correction factor for VOC removal due to end effects is used when determining K_La . The following equation can be used to calculate the NTU of the packing (Umphres et al., 1983):

$$NTU_{\text{packing}} = NTU_{\text{measured}} - NTU_{\text{end effects}} \quad (6-37)$$

where NTU_{measured} is the experimentally determined value from pilot data and $NTU_{\text{end effects}}$ is the NTU due to the end effects. Combining Eqs. 6-36 and 6-37 yields the following linear expression, which can be used to determine K_La :

$$NTU_{\text{measured}} = \frac{1}{HTU}(Z) + NTU_{\text{end effects}} \quad (6-38)$$

where Z is the distance from the top of the packing to a sample port location along the packed portion of the tower. For a given water and air loading rate, aqueous-phase concentration measurements are evaluated at the influent and effluent and at various sample port locations along the packed column. Equation 6-35 can be used to calculate NTU_{measured} at each sample port location or distance, Z , from the top of the packing, where C_e is assumed to be the concentration measured at each sample port along the packed column. A plot is constructed of NTU_{measured} as a function of Z and should coincide with the linear expression given by Eq. 6-38. K_La is determined from the slope ($1/HTU$) and Eq. 6-33. Experimentally determined K_La values can be correlated as a function of water loading rate for several air-to-water ratios that would be expected during operation of the full-scale column. For a given water loading rate and air-to-water ratio of interest, a correlated K_La value can be determined and used with Eqs. 6-33 through 6-36 to determine the required full-scale packed tower height.

A full-scale packed tower height calculated using a K_La value determined from a pilot study is generally conservative. For a given packing size, K_La values generally increase as the tower diameter increases (Wallman and Cummins, 1986). This is caused by channeling of the water down the inside of the column walls, which is sometimes referred to as “wall effects.” The VOC removal rate is less along the walls of the column as compared to the removal within the packing because the air-to-water contact time, surface area, and mixing are less. As the tower diameter increases, the percentage of flow down the walls of the column decreases, minimizing the wall effects. Consequently, the K_La value in a full-scale column will be larger than that in a smaller pilot column.

Table 6-9 displays numerous packed tower field studies that reported experimentally determined K_La values for several VOCs and various contaminated water sources. The K_La values reported in these studies can be used provided the operating conditions (temperature, water, and air loading rate) and packing type and size are the same.

Example 6-1 Determination of K_La from Pilot-Plant Data

An air stripping packed tower pilot plant study was performed on a groundwater contaminated with methyl tert-butyl ether (MTBE). A packed tower with a height of 3.0 m (10 ft) and a diameter of 0.30 m (1 ft) with sample ports distributed down the column every 0.76 m (2.5 ft) was used. The column was operated at an air-to-water

ratio of 100 for 30 minutes to reach steady-state operation. Water samples were then taken at sample ports and analyzed for MTBE. Given the results tabulated below, determine K_La .

Pilot-Plant Parameters

Parameter	Value
Temperature, °C	15
Influent concentration, µg/L	125
Treatment objective, µg/L	5
Packing type	No. ½ Tripacks
Water flow rate, L/s	0.3
Air flow rate, L/s	300

Measured MTBE Concentration at Each Depth
for $\dot{V}/Q=100$

Depth, m	MTBE concentration, $\mu\text{g/L}$
0	125
0.76	66.3
1.52	48.5
2.29	34.5
3.05	25.7

Solution

- Using the Henry's law constant from Table 6-2, calculate the stripping factor for an air-to-water ratio of 100. H from Table 6-2 for MTBE is 0.0177.

$$R = \frac{\dot{V}}{Q} H = 100 \times 0.0177 = 1.77$$

- For each sample port depth and MTBE concentration, calculate the NTU using Eq. 6-35. Sample calculation is made for the sample port at a depth of 0.76 m.

$$NTU = \left[\frac{R}{R-1} \right] \ln \left[\frac{\frac{C_0}{C_e} (R-1) + 1}{R} \right]$$

$$NTU_{\text{Depth}=0.762\text{m}} = \left[\frac{1.77}{1.77-1} \right] \ln \left[\frac{\frac{125 \mu\text{g/L}}{66.3 \mu\text{g/L}} (1.77-1) + 1}{1.77} \right] = 0.75$$

Depth, m	MTBE concentration, $\mu\text{g/L}$	NTU
0	125	0
0.76	66.3	0.75
1.52	48.5	1.20
2.29	34.5	1.75
3.05	25.7	2.27

- Plot the NTU as a function of column depth and linearly fit Eq. 6-38 to the data to obtain the HTU from the slope.

From Eq. 6-38, the HTU is determined:

$$\begin{aligned} \text{Slope} &= \frac{1}{HTU} = 0.67 \text{ m}^{-1} \\ HTU &= 1.5 \text{ m} \end{aligned}$$

4. Using Eq. 6-33, $K_L a$ is calculated from HTU as

$$\begin{aligned} HTU &= \frac{Q}{A \cdot K_L a} \\ K_L a &= \frac{Q}{A \cdot HTU} = \frac{0.0003 \text{ m}^3/\text{s}}{\left(\frac{\pi}{4}\right)[0.3 \text{ m}]^2 (1.5 \text{ m})} = 0.0028 \text{ s}^{-1} \quad \blacktriangle \end{aligned}$$

Estimating $K_L a$. When $K_L a$ values are not readily available, they can be estimated from the following mass transfer correlations (Onda, Takeuchi, and Okumoto, 1968):

$$a_w = a_t \left\{ 1 - \exp \left[-1.45 \left(\frac{\sigma_c}{\sigma} \right)^{0.75} \left(\frac{L_m}{a_t \mu_l} \right)^{0.1} \left(\frac{L_m^2 a_t}{\rho_l^2 g} \right)^{-0.05} \left(\frac{L_m^2}{\rho_l a_t \sigma} \right)^{0.2} \right] \right\} \quad (6-39)$$

$$k_l = 0.0051 \left(\frac{L_m}{a_w \mu_l} \right)^{2/3} \left(\frac{\mu_l}{\rho_l D_l} \right)^{-0.5} (a_t d_p)^{0.4} \left(\frac{\rho_l}{\mu_l g} \right)^{-1/3} \quad (6-40)$$

$$k_g = 5.23 (a_t D_g) \left(\frac{G_m}{a_t \mu_g} \right)^{0.7} \left(\frac{\mu_g}{\rho_g D_g} \right)^{1/3} (a_t d_p)^{-2} \quad (6-41)$$

in which a_t is the total specific surface area of the packing material (m^2/m^3), a_w is the wetted surface area of the packing material, d_p is the nominal diameter of the packing material (m), D_g is the gas-phase diffusivity of the contaminant to be removed (m^2/s), D_l is the liquid-phase diffusivity of the contaminant to be removed (m^2/s), g is the gravitational constant (m/s^2), G_m is the air mass loading rate ($\text{kg}/\text{m}^2/\text{s}$), L_m is the water mass loading rate ($\text{kg}/\text{m}^2/\text{s}$), μ_l is the viscosity of water ($\text{kg}/\text{m}/\text{s}$), μ_g is the viscosity of air ($\text{kg}/\text{m}/\text{s}$), ρ_l is the density of water (kg/m^3), ρ_g is the density of air (kg/m^3), σ is the surface tension of water (kg/s^2), and σ_c is the critical surface tension of the packing material (kg/s^2).

Equation 6-40 is valid for water loading rates between 0.8 and 43 $\text{kg}/\text{m}^2/\text{s}$ (1.1 and 63 gpm/ft^2), and Eq. 6-41 is valid for air loading rates between 0.014 and 1.7 $\text{kg}/\text{m}^2/\text{s}$ (2.206 and 267.9 cfm/ft^2). To use these correlations, it is assumed that a_w is equivalent to a . Equations 6-40 and 6-41 were correlated for nominal packing sizes up to 0.05 m (2 in.). The Onda correlation is perhaps the best correlation for predicting $K_L a$ for VOCs in packed tower air stripping applications (Cummins and Westrick, 1983; Roberts et al., 1985; Lamarche and Droste, 1989; Staudinger, Knocke, and Randall, 1990). Although the Onda correlation yields favorable results for laboratory and pilot-plant data, work comparing observed $K_L a$ values for full-scale systems with those obtained by Eqs. 6-39 to 6-41 shows differences of ± 30 to 40 percent deviations depending upon the tower operating conditions (Lenzo, Frielinghaus, and Zienkiewicz, 1990; Staudinger, Knocke, and Randall, 1990; Djebbar and Narbaitz, 1995, 1998; Dvorak et al., 1996). Generally, the Onda correlation tends to underpredict $K_L a$ for some large packing material and high gas flow rates ($>3.5 \text{ kg}/\text{m}^2/\text{s}$) while overpredicting $K_L a$ for large liquid loadings ($>15 \text{ kg}/\text{m}^2/\text{s}$) (Staudinger, Knocke, and Randall, 1990; Djebbar and Narbaitz, 1998, 2002; Dvorak et al., 1996). Djebbar and Narbaitz (1998, 2002) have proposed modifications that improve the predictive capabilities of the Onda correlation. Based

FIGURE 6-9 Flooding and pressure drop in random-packed towers. (Source: Treybal, 1980.)

on the literature cited above, it is recommended that a safety factor 0.7 to 0.8 (i.e., $K_L a$ /Onda $K_L a$) for packed towers be applied to provide a conservative estimate of the packing height required.

Determination of the Tower Diameter. The tower diameter for a single packed tower is typically designed to provide for a low gas pressure drop (i.e., 50–100 N/m² · m (0.06–0.12 in H₂O/ft)). Sizing the tower diameter for a low gas pressure drop minimizes the operational power requirements and provides flexibility for the process operation (Hand et al., 1986). The diameter for a single packed tower can be determined using the generalized pressure drop curves shown in Fig. 6-9 combined with the manufacturer’s pressure drop properties for a specific packing type. Once the packing factor for the media, the air-to-water ratio, and the air pressure drop per packing height have been specified, it is possible to determine the air loading rate and the tower diameter from Fig. 6-9 or the following set of equations (Cummins and Westrick, 1983):

$$G_m = \sqrt{\frac{M \rho_g (\rho_l - \rho_g)}{C_f (\mu_l)^{0.1}}} \tag{6-42}$$

The empirical parameter M is defined by the following relationship:

$$\log_{10} (M) = a_0 + a_1 E + a_2 E^2 \tag{6-43}$$

The parameter E is defined as follows:

$$E = -\log_{10} \left[\left(\frac{\dot{V}}{Q} \right) \sqrt{(\rho_g / \rho_l) - (\rho_g / \rho_l)^2} \right] \tag{6-44}$$

The parameters a_0 , a_1 , and a_2 are defined by the following relationships:

$$a_0 = -6.6599 + 4.3077F - 1.3503F^2 + 0.15931F^3 \quad (6-45)$$

$$a_1 = 3.0945 - 4.3512F + 1.6240F^2 - 0.20855F^3 \quad (6-46)$$

$$a_2 = 1.7611 - 2.3394F + 0.89914F^2 - 0.11597F^3 \quad (6-47)$$

The parameter F that appears in Eqs. 6-41 through 6-43 is defined as:

$$F = \log_{10} (\Delta P/L) \quad (6-48)$$

The pressure drop correlation is valid for $\Delta P/L$ values between 50 and 1200 N/m²/m. Equations 6-42 through 6-48 were developed using a particular set of units. When applying them, it must be assured that values are supplied in the appropriate units: G_m is the air mass loading rate (kg/m²/s); M is a calculated empirical parameter; ρ_g is the air density (kg/m³); ρ_l is the water density (kg/m³); C_f is the packing factor (m⁻¹); μ_l is the water viscosity (kg/m/s); a_0 , a_1 , a_2 are calculated empirical parameters; E is a calculated empirical parameter; $\frac{V}{Q}$ is the air-to-water ratio on a volumetric basis (m³/m³); F is a calculated empirical parameter; and $\Delta P/L$ is the air pressure drop gradient (N/m²/m). The tower diameter can be determined by dividing G_m by the air mass flow rate.

Determination of the tower diameter from Fig. 6-9 is conservative at low gas pressure drops typically used by designers for air treatment of VOCs. If a more accurate value of the pressure drop is desired for a given packing type, the manufacturer's pressure drop curves for a particular packing type can be obtained and used.

The practical operating range for packed towers is between abscissa values of 0.02 and 4.0 in Fig. 6-9. For abscissa values greater than 4, large water loading rates can reduce the water-to-air contact area provided by the packing surface and inhibit proper air flow through the column causing a decrease in VOC removal efficiency. Similarly, high air flow rates (abscissa values less than about 0.02) can cause entrained water in the tower as well as channeling of the air through the tower. For situations where high air flow rates are required for high removal efficiencies (>95 percent), it is important to provide an even air inlet distribution at the bottom of the tower (Thom and Byers, 1993).

Determination of the Operating Power Requirements. The total operating power for a single air stripping packed tower system is the sum of the blower and pump brake power requirements. The blower brake power can be determined from the following relationship (Metcalf and Eddy, 2003):

$$P_{\text{blower}} = \left(\frac{G_m R_g T_{\text{air}}}{1000 n_a \text{Eff}_b} \right) \left[\left(\frac{P_{\text{in}}}{P_{\text{out}}} \right)^{n_a} - 1 \right] \quad (6-49)$$

in which Eff_b is the blower net efficiency (expressed as a decimal), which accounts for both the fan and motor on the blower; G_m is the mass flow rate of air (kg/s); n_a is a constant used in determining blower brake power and is equal to 0.283 for air; P_{in} is the inlet air pressure in the packed tower (bottom of tower) (N/m²); P_{out} is the outlet air pressure in the packed tower (top of the tower) and is usually equal to the ambient pressure (N/m²); R_g is the universal gas constant; and T_{air} is the absolute air temperature, which is typically assumed equal to T .

The term P_{in} refers to the pressure at the bottom of the tower, which is the inlet for the air stream. P_{in} is calculated as the sum of the ambient pressure and the pressure drop caused by the packing media, demister, packing support plate, duct work, and tower inlet and outlet. The equation used to find P_{in} is

$$P_{\text{in}} = P_{\text{ambient}} + \left[\left(\frac{\Delta P}{L} \right) L \right] + \Delta P_{\text{losses}} \quad (6-50)$$

ΔP_{losses} is determined by (Hand et al., 1986):

$$\Delta P_{\text{losses}} = \left(\frac{\dot{V}}{A} \right)^2 k_p \quad (6-51)$$

in which \dot{V} is the volumetric air flow rate (m^3/s), A is the tower cross-sectional area (m^2), and k_p is a constant equal to $275 \text{ NS}^2/\text{m}^4$ and is used to estimate the air pressure drop for losses other than those caused by the tower packing.

Equation 6-51 represents the air pressure drop through the demister, packing support plate, duct work, and tower inlet and outlet. It is assumed that turbulent flow conditions prevail and most of the losses occur in the tower (i.e., in the packing support plate and the demister).

The pump power requirement can be determined from the following equation:

$$P_{\text{pump}} = \frac{\rho_l Q H g}{1000 \text{Eff}_p} \quad (6-52)$$

in which Eff_p is the pump efficiency and H is the vertical distance from the pump to the liquid distributor at the top of the tower (m). Equation 6-52 accounts only for the pressure loss resulting from the head required to pump the water to the top of the tower.

Design Procedure

The procedures used in designing packed towers depend upon the type of design problem. The most common design problems are modifications to existing towers and development of design criteria for new towers. Consequently, the design engineer may use a different approach for each problem. For example, one problem may be to determine ways of improving process efficiency of an existing tower by increasing the air flow rate, inserting a more efficient packing type, or increasing the packed tower height. In another situation, a designer may need to design a new packed tower system using standard vendor column sizes. Problems such as these require many tedious calculations that can easily be performed using commercially available software. Software tools such as ASDC1 (Dzombak, Roy, and Fang, 1993), AIRSTRIP (Haarhoff, 1988), and ASAP (Hokanson, 1996) can be used to evaluate the impact of process variables on process performance. These tools contain the design equations and correlations presented above and graphical user interfaces for ease in software application and provide databases for many commercially available packing types and physical properties of several VOCs that have been encountered in surface and groundwaters.

Presented herein is a step-by-step design procedure for sizing a packed tower and important considerations that should be addressed during the design and operation phases. This procedure is only one of several methods (Kavanaugh and Trussell, 1980; Crittenden et al., 2005) that have been used successfully to design a packed tower. This procedure was presented in detail elsewhere (Hand et al., 1986) and will simply be highlighted herein.

The design parameters for packed tower air stripping are (1) the air-to-water ratio, (2) the gas pressure drop, and (3) the type of packing material. Once the physical properties of the contaminant(s) of interest, the influent concentration(s), treatment objective(s), and water and air properties are known, these design parameters can be selected to give the lowest capital and operation and maintenance costs. As discussed above, the optimum air-to-water ratio for contaminants with Henry's law constants greater than 0.05, which will minimize the tower volume and total power consumption, is around 3.5 times the minimum air-to-water ratio or a stripping factor of about 3.5 (Crittenden et al., 2005). Therefore, the optimum air-to-water ratio can be estimated by multiplying the minimum air-to-water ratio calculated from Eq. 6-32 by 3.5 or using a stripping factor of 3.5. A low gas pressure drop should be chosen to minimize the blower power consumption. In most cases, a gas pressure drop of 50 to 100 N/m^2 is chosen. In order to determine the optimum gas pressure drop that will result in a least-cost design, a

detailed cost analysis should be performed to determine the true costs associated with the tower volume and power requirement. A number of researchers have performed detailed cost analyses, and their results show that using a low gas pressure drop of around 50 to 100 N/m²/m and an air-to-water ratio of around 3.5 times the minimum yields the lowest total annual treatment cost (Cummins, 1985; Dzombak, Roy, and Fang, 1993). An additional advantage of operating at a low gas pressure drop is that if the blower is sized conservatively, the air flow rate can be increased to meet a greater removal demand without major changes in the process operation. However, the required height using this approach may sometimes be too great for a particular application. In this case, the air-to-water ratio can be increased by increasing the air flow rate to obtain a shorter tower height for a given removal.

The criteria for choosing the type and size of packing depend upon the water flow rate and the desired degree of operational flexibility of the design. For low water flow rates, it is recommended that nominal diameter packing of 0.05 m (2 in.) or less be used to minimize channeling or short-circuiting of the water down the wall of the tower. Minimizing the impact of channeling requires that the ratio of tower diameter to nominal packing diameter be greater than 12 to 15. If a design is needed with a high degree of operational flexibility, a larger, less efficient packing type should be chosen for the initial design of the tower. Tower designs with larger packing sizes will result in larger tower volumes, because the larger packing sizes usually have a lower specific area than the smaller ones. However, if the treatment objective becomes more stringent or other fewer strippable compounds appear in the influent, the less efficient, larger packing can be replaced with smaller, more efficient packing to provide for the needed removal. Building in this type of operational flexibility is much cheaper than adding additional height to the existing tower (if possible) or adding another tower in series. Spending additional capital on providing operational flexibility in the initial design can ultimately reduce future costs and prevent headaches.

***In most water treatment situations, multiple contaminants are present in the water, and the packed tower must be designed to remove all the contaminants to some specified treatment level. For a given tower design, the following equation can be used to determine the effluent concentrations of multiple contaminants for a given tower design:

$$C_e = \frac{C_0(S-1)}{\left\{ S \exp \left[\frac{LK_L a(S-1)}{\left(\frac{Q}{A}\right)S} \right] - 1 \right\}} \quad (6-53)$$

However, at the design stage, the limiting contaminant that controls the design must first be identified. In general, the contaminant with the lowest Henry's constant is used to determine the required air-to-water ratio and the contaminant with the highest removal efficiency is used to determine the required packing height. The following example problem illustrates a typical design procedure for sizing a packed tower.

Example 6-2 Packed Tower Aeration Calculation for TCA

Design a packed tower to reduce the 1,1,1-trichloroethane (TCA) concentration from 165 to 5.0 µg/L. Listed below are the operating conditions; TCA, air, and water physical and chemical properties; and packing type and packing parameters. For a design water flow of 0.158 m³/s (2500 gpm), determine the tower diameter, packed tower height, and power consumption requirements.

Operating Conditions

Property	Value
Temperature (T, T_{air}), C	15
Pressure (P, P_{ambient}), atm	1

TCA, Water, and Air Characteristics

Property	Value
Molecular weight	133.4
Henry's constant (H), dimensionless	0.487
Influent concentration (C_i), $\mu\text{g/L}$	165
Effluent concentration (C_e), $\mu\text{g/L}$	5.0
Molar volume @ boiling point (V_b), cm^3/mole	109
Normal boiling point temperature, $^\circ\text{C}$	74.1
Density of water (ρ_l), kg/m^3	999.15
Viscosity of water (μ_l), $\text{kg/m} \cdot \text{s}$	1.15×10^{-3}
Density of air (ρ_g), kg/m^3	1.22
Viscosity of air (μ_g), $\text{kg/m} \cdot \text{s}$	1.75×10^{-5}
Surface tension of water (σ), N/m	0.0735

Packing Characteristics

Packing type: 3.5-in. nominal diameter LANPAC-XL

Property	Value
Nominal diameter (d_p), m	0.0889
Nominal surface area (a_p), m^2/m^3	242
Critical surface tension (σ_c), N/m	0.0330
Packing factor (C_p), m^{-1}	33

Constants

Property	Value
Acceleration due to gravity (g), m/s^2	9.81
Blower efficiency (Eff_b), %	40
Pump efficiency (Eff_p), %	85

Solution

1. Calculate the minimum air-to-water ratio $(\dot{V}/Q)_{\min}$ using Eq. 6-32.

$$(\dot{V}/Q)_{\min} = \frac{C_o - C_e}{HC_o} = \frac{165 \frac{\mu\text{g}}{\text{L}} - 5.0 \frac{\mu\text{g}}{\text{L}}}{0.487 \times 165 \frac{\mu\text{g}}{\text{L}}} = 2.0$$

2. Calculate a reasonable \dot{V}/Q that is some multiple, i.e., assume 3.5 times of $(\dot{V}/Q)_{\min}$.

$$(\dot{V}/Q)_{\text{mult}} = (\dot{V}/Q)_{\min} \times 3.5 = 2.0 \times 3.5 = 7.0$$

3. Calculate the air flow rate, \dot{V} .

$$\dot{V} = \frac{\dot{V}}{Q} \times Q = 7.0 \times 0.158 \frac{\text{m}^3}{\text{s}} = 1.10 \frac{\text{m}^3}{\text{s}}$$

4. Calculate the tower diameter, D .

- a. Choose a low value of $\Delta P/L = 75 \text{ N/m}^2/\text{m}$.

- b. Calculate F , a_0 , a_1 , a_2 , E , M , and G_m using Eqs. 6-42 through 6-48. The tower area can then be determined from either G_m or L_m .

$$F = \log_{10}(\Delta P/L) = \log_{10}\left(75 \frac{N}{m^2 \cdot m}\right) = 1.875$$

$$\begin{aligned} a_0 &= -6.6599 + 4.3077F - 1.3503F^2 + 0.15931F^3 \\ &= -6.6599 + 4.3077(1.875) - 1.3503(1.875)^2 + 0.15931(1.875)^3 \\ &= -2.280 \end{aligned}$$

$$\begin{aligned} a_1 &= 3.0945 - 4.3512F + 1.6240F^2 - 0.20855F^3 \\ &= 3.0945 - 4.3512(1.875) + 1.6240(1.875)^2 - 0.20855(1.875)^3 \\ &= -0.22287 \end{aligned}$$

$$\begin{aligned} a_2 &= 1.7611 - 2.3394F + 0.89914F^2 - 0.11597F^3 \\ &= 1.7611 - 2.3394(1.875) + 0.89914(1.875)^2 - 0.11597(1.875)^3 \\ &= -0.2287 \end{aligned}$$

$$\begin{aligned} E &= -\log_{10}\left[\left(\frac{\dot{V}}{Q}\right)\sqrt{(\rho_g/\rho_l) - (\rho_g/\rho_l)^2}\right] \\ &= -\log_{10}\left[15.0\sqrt{\left(\frac{1.22 \frac{\text{kg}}{\text{m}^3}}{999.15 \frac{\text{kg}}{\text{m}^3}}\right) - \left(\frac{1.22 \frac{\text{kg}}{\text{m}^3}}{999.15 \frac{\text{kg}}{\text{m}^3}}\right)^2}\right] \\ &= 0.6118 \end{aligned}$$

$$\begin{aligned} \log_{10}(M) &= a_0 + a_1E + a_2E^2 \\ &= -2.280 + (-0.7293)(0.6118) + (-0.2287)(0.6118)^2 \\ &= -2.8120 \Rightarrow \\ M &= 0.0015424 \end{aligned}$$

- c. Calculate air mass loading rate, G_m , using Eq. 6-42.

$$\begin{aligned} G_m &= \sqrt{\frac{M\rho_g(\rho_l - \rho_g)}{C_f(\mu_l)^{0.1}}} \\ &= \sqrt{\frac{1.5424 \times 10^{-3} \times 1.22 \frac{\text{kg}}{\text{m}^3} \left(999.15 \frac{\text{kg}}{\text{m}^3} - 1.22 \frac{\text{kg}}{\text{m}^3}\right)}{33 \left(1.15 \times 10^{-3} \frac{\text{kg}}{\text{m} \cdot \text{s}}\right)^{0.1}}} \\ &= 0.335 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}} \end{aligned}$$

- d. Calculate water mass loading rate, L_m .

$$L_m = \frac{G_m}{\left(\frac{\dot{V}}{Q}\right)\left(\frac{\rho_g}{\rho_l}\right)} = \frac{0.335 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}}}{\left(7.0 \frac{\text{m}^3}{\text{m}^3}\right)\left(\frac{1.22 \frac{\text{kg}}{\text{m}^3}}{999.15 \frac{\text{kg}}{\text{m}^3}}\right)} = 39.2 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}}$$

- e. Calculate tower cross-sectional area, A .

$$A = \frac{Q\rho_l}{L_m} = \frac{0.1577 \frac{\text{m}^3}{\text{s}} \times 999.15 \frac{\text{kg}}{\text{m}^3}}{39.2 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}}} = 4.0 \text{ m}^2$$

- f. Calculate tower diameter, D .

$$D = \sqrt{\frac{4A}{\pi}} = \sqrt{\frac{4(4.0 \text{ m}^2)}{\pi}} = 2.26 \text{ m (7.4 ft)}$$

Standard packed column sizes are typically available in diameter increments of 0.3048 m (1 ft). Consequently, a tower diameter of 2.44 m (8.0 ft) is chosen for this design. The following design parameters were adjusted for a tower diameter of 2.44 m:

$$A = 4.68 \text{ m}^2 \quad L_m = 33.74 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}} \quad G_m = 0.287 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}} \quad \frac{\Delta p}{L} = 64.5 \frac{\text{Pa}}{\text{m}}$$

5. Calculate tower length, L .

- a. Calculate the TCA aqueous phase concentration in equilibrium with the exiting air, C_0^* , using Eq. 6-31.

$$\begin{aligned} C_0^* &= \left(\frac{1}{\left(\frac{V}{Q}\right) \times H} \right) (C_0 - C_e) = \left(\frac{1}{(7.0) \times 0.487} \right) \left(1665 \frac{\mu\text{g}}{L} - 5.0 \frac{\mu\text{g}}{L} \right) \\ &= 46.93 \frac{\mu\text{g}}{L} \end{aligned}$$

- b. Calculate the specific surface area available for mass transfer, a_w , using Eq. 6-39.

$$\begin{aligned} a &= a_w \\ a_w &= a_t \left\{ 1 - \exp \left[-1.45 \left(\frac{\sigma_c}{\sigma} \right)^{0.75} \left(\frac{L_m}{a_t \mu_l} \right)^{0.1} \left(\frac{L_m^2 \rho_l}{\rho_l^2 g} a \right)^{-0.05} \left(\frac{L_m^2}{\rho_l a_t \sigma} \right)^{0.2} \right] \right\} \\ &= 125 \frac{\text{m}^2}{\text{m}^3} \left\{ 1 - \exp \left[-1.45 \left(\frac{0.0330 \frac{\text{N}}{\text{m}}}{0.0742 \frac{\text{N}}{\text{m}}} \right)^{0.75} \left(\frac{33.74 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}}}{242 \frac{\text{m}^2}{\text{m}^3} \times 1.15 \times 10^{-3} \frac{\text{kg}}{\text{m} \cdot \text{s}}} \right)^{0.1} \right. \right. \\ &\quad \times \left. \left. \frac{\left(33.74 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}} \right)^2 \times 242 \frac{\text{m}^2}{\text{m}^3}}{\left(999.15 \frac{\text{kg}}{\text{m}^3} \right)^2 \times 9.81 \frac{\text{m}}{\text{s}^2}} \right)^{-0.05} \right. \\ &\quad \times \left. \left. \frac{\left(33.74 \frac{\text{kg}}{\text{m}^2 \cdot \text{s}} \right)^2}{999.15 \frac{\text{kg}}{\text{m}^3} \times 242 \frac{\text{m}^2}{\text{m}^3} \times 0.0742 \frac{\text{N}}{\text{m}}} \right)^{0.2} \right] \right\} \\ &= 193 \frac{\text{m}^2}{\text{m}^3} \end{aligned}$$

- c. Calculate the TCA diffusivity in water, D_l , using the following correlation (Hayduk and Laudie, 1974):

$$D_l = \frac{13.26 \times 10^{-5}}{\mu_w^{1.14} \times V_b^{0.589}} = \frac{13.26 \times 10^{-5}}{(1.15 \text{ cp})^{1.14} \times (109 \frac{\text{cm}^3}{\text{gmol}})^{0.589} \times \frac{(100 \text{ cm}^2)}{1 \text{ m}^2}}$$

$$= 7.13 \times 10^{-10} \frac{\text{m}^2}{\text{s}}$$

μ_w = viscosity of water (centipoise)

V_b = molar volume, cm^3/gmol

- d. Calculate the liquid phase mass transfer coefficient, k_l , using Eq. 6-40.

$$k_l = 0.0051 \left(\frac{L_m}{a_w \mu_l} \right)^{2/3} \left(\frac{\mu_l}{\rho_l D_l} \right)^{-0.5} (a_r d_p)^{0.4} \left(\frac{\rho_l}{\mu_l g} \right)^{-1/3}$$

$$= 0.0051 \left(\frac{33.74 \frac{\text{kg}}{\text{m}^3}}{193 \frac{\text{m}^2}{\text{m}^3} \times 1.15 \times 10^{-3} \frac{\text{kg}}{\text{m}^3}} \right)^{2/3} \left(\frac{1.15 \times 10^{-3} \frac{\text{kg}}{\text{m}^3}}{999.15 \frac{\text{kg}}{\text{m}^3} \times 7.13 \times 10^{-10} \frac{\text{m}^2}{\text{s}}} \right)^{-0.5}$$

$$\times \left(2425 \frac{\text{m}^2}{\text{m}^3} \times 0.08899 \text{ m} \right)^{0.4} \left(\frac{999.15 \frac{\text{kg}}{\text{m}^3}}{1.15 \times 10^{-3} \frac{\text{kg}}{\text{m}^3} \times 9.81 \frac{\text{m}}{\text{s}^2}} \right)^{-1/3}$$

$$= 2.76 \times 10^{-4} \frac{\text{m}}{\text{s}}$$

- e. Calculate the gas-phase diffusivity, D_g , using the following correlation by Hirschfelder, Bird, and Spotz (1949) (Treybal, 1980):

- i. To calculate the gas diffusivity, the following parameters must be determined:

$$r_A = 1.18(V_b)^{1/3} = 1.18 \times \left(0.109 \frac{\text{m}^3}{\text{kgmol}} \right)^{1/3} = 0.564 \text{ nm(TCA)}$$

$$\epsilon_A / K = 1.21(T_b)_A = 1.21 \times (74.1 + 273.15) \text{ K} = 420.2 \text{ K(TCA)}$$

in which r_A is the radius of molecule A, nm (TCA); V_b is the molar volume of molecule A at the boiling point (TCA); ϵ_A is the force constant of molecule A, joule (TCA); K is the Boltzmann's constant, joule/K; T_{bA} is the boiling temperature of molecule A, K (TCA); and r_b is the characteristic radius of the gas medium, nm, and is equal to 0.371 nm for air.

Calculate the molecular separation at collision r_{AB} for TCA in air.

$$r_{AB} = (r_A + r_B) / 2 = \frac{0.564 \text{ nm} + 0.371 \text{ nm}}{2} = 0.4676 \text{ nm(TCA in Air)}$$

Calculate the energy of molecular attraction between molecule A (TCA) and molecule B (air). The force constant for air, ϵ_B/K , is 78.6.

$$\frac{\epsilon_{AB}}{K} = \sqrt{\frac{\epsilon_A}{K} \times \frac{\epsilon_B}{K}} = \sqrt{420.2 \times 78.6} = 181.7 \text{ (TCA in Air)}$$

Calculate the collision function for diffusion of molecule A (TCA) in B (air) (The collision function was presented by Treybal (1980) and correlated by Cummins and Westrick (1983)).

$$EE = \log_{10}(KT/\epsilon_{AB}) = \log_{10}\left(\frac{283.15 \text{ K}}{185.0}\right) = 0.185$$

$$NN = \left. \begin{aligned} & \left(-0.14329 - 0.48343(EE) + 0.1939(EE)^2 + 0.13612(EE)^3 \right) \\ & \left(-0.20578(EE)^4 + 0.083899(EE)^5 - 0.011491(EE)^6 \right) \\ & \left(-0.14329 - 0.48343(0.193) + 0.1939(0.193)^2 \right) \\ & \left(+0.13612(0.193)^3 - 0.20578(0.193)^4 + 0.083899(0.193)^5 \right) \\ & \left(-0.011491(0.193)^6 \right) \end{aligned} \right\} \\ = -0.235$$

$$f(KT/\epsilon_{AB}) = 10^{NN} = 10^{-0.235} = 0.582$$

ii. Calculate gas-phase diffusivity, D_g , as follows:

$$D_g = \left\{ \frac{10^{-4} \left(1.084 - 0.249 \sqrt{\frac{1}{M_A} + \frac{1}{M_B}} \right) (T^{1.5}) \sqrt{\frac{1}{M_A} + \frac{1}{M_B}}}{P_t (r_{AB})^2 f\left(\frac{KT}{\epsilon_{AB}}\right)} \right\} \frac{\text{m}^2}{\text{s}}$$

$$= \left\{ \frac{10^{-4} \left(1.084 - 0.249 \sqrt{\frac{1}{133.4} + \frac{1}{22895}} \right) (288.15)^{1.5} \sqrt{\frac{1}{133.4} + \frac{1}{2895}}}{101325 \frac{\text{N}}{\text{m}^2} (0.46766 \text{ m})^2 (0.582)} \right\} \frac{\text{m}^2}{\text{s}}$$

$$= 8.03 \times 10^{-6} \frac{\text{m}^2}{\text{s}}$$

f. Calculate gas-phase TCA mass transfer coefficient, k_g , using Eq. 6-41.

$$k_g = 5.23 (a_t D_g) \left(\frac{G_m}{a_t \mu_g} \right)^{0.7} \left(\frac{\mu_g}{\rho_g D_g} \right) (a_t d_p)^{-2}$$

$$= 5.23 \left(125 \frac{\text{m}^2}{\text{m}^3} \times 8.03 \times 10^{-6} \frac{\text{m}^2}{\text{s}} \right) \left(\frac{0.287 \frac{\text{kg}}{\text{m}^3}}{242 \frac{\text{m}^2}{\text{m}^3} \times 1.75 \times 10^{-5} \frac{\text{kg}}{\text{m}^3}} \right)^{0.7}$$

$$\times \left(\frac{1.75 \times 10^{-5} \frac{\text{kg}}{\text{m}^3}}{1.22 \frac{\text{kg}}{\text{m}^3} \times 8.03 \times 10^{-6} \frac{\text{m}^2}{\text{s}}} \right)^{1/3} \left(2442 \frac{\text{m}^2}{\text{m}^3} \times 0.0889 \text{ m} \right)^{-2}$$

$$= 5.09 \times 10^{-4} \frac{\text{m}}{\text{s}}$$

- g. Calculate $K_L a$ using Eq. 6-21.

$$\begin{aligned} \frac{1}{K_L a} &= \frac{1}{k_l a_w} + \frac{1}{k_g a_w H} \\ &= \frac{1}{2.76 \times 10^{-4} \frac{\text{m}}{\text{s}} \times 193 \frac{\text{m}^2}{\text{m}^3}} + \frac{1}{5.09 \times 10^{-4} \frac{\text{m}}{\text{s}} \times 193 \frac{\text{m}^2}{\text{m}^3} \times 0.487} \\ K_L a &= 0.0252 \text{ s}^{-1} \end{aligned}$$

- h. Calculate $K_L a$ assuming a safety factor of 0.75.

$$\begin{aligned} K_L a &= K_L a \times (SF)_{K_L a} = 0.0252 \text{ s}^{-1} \times 0.75 \\ &= 0.0189 \text{ s}^{-1} \end{aligned}$$

- i. Calculate tower length, L , using Eq. 6-30.

$$\begin{aligned} L &= \frac{Q}{A K_L a} \left[\frac{C_o - C_{TO}}{C_o - C_{TO} - C_o^*} \right] \ln \left[\frac{C_o - C_o^*}{C_{TO}} \right] \\ &= \frac{00.157 \frac{\text{m}^3}{\text{s}}}{4.68 \text{ m}^2 \times 0.0189 \text{ s}^{-1}} \left[\frac{165 \frac{\text{kg}}{\text{L}} - 5.0 \frac{\text{kg}}{\text{L}}}{165 \frac{\text{kg}}{\text{L}} - 5.0 \frac{\text{kg}}{\text{L}} - 46.93 \frac{\text{kg}}{\text{L}}} \right] \ln \left[\frac{165 \frac{\text{kg}}{\text{L}} - 46.93 \frac{\text{kg}}{\text{L}}}{5.0 \frac{\text{kg}}{\text{L}}} \right] \\ &= 8.0 \text{ m} \quad (26.0 \text{ ft}) \end{aligned}$$

6. Calculate power requirements.

- a. Calculate blower power requirements.

- i. Calculate the air mass flow rate, G_m , from the volumetric air flow rate.

$$G_m = \dot{V} \times \rho_g = 1.10 \frac{\text{m}^3}{\text{s}} \times 1.22 \frac{\text{kg}}{\text{m}^3} = 1.34 \frac{\text{kg}}{\text{s}}$$

- ii. Calculate the pressure drop through the demister, the packing support plate, duct work, and inlet and outlet, ΔP_{losses} , using Eq. 6-51.

$$\Delta P_{\text{losses}} = \left(\frac{\dot{V}}{A} \right)^2 k_p = \left(\frac{1.1 \text{ m}^3/\text{s}}{4.0 \text{ m}^2} \right)^2 \times 275 \text{ N} \cdot \text{s}^2 \cdot \text{m}^4 = 20.80 \text{ N/m}^2$$

k_p = a constant used to estimate gas pressure drop in a tower for losses other than that in the packing, $275 \frac{\text{N} \cdot \text{s}^2}{\text{m}^4}$ (Hand et al., 1986).

- iii. Calculate the inlet pressure to the packed tower, P_{in} , using Eq. 6-50.

$$\begin{aligned} P_{\text{in}} &= P_{\text{ambient}} + \left[\left(\frac{\Delta P}{L} \right) L \right] + \Delta P_{\text{losses}} = 101325 \frac{\text{N}}{\text{m}^2} + \left[\left(64.50 \frac{\text{N/m}^2}{\text{m}} \right) 9.33 \text{ m} \right] \\ &\quad + 20.80 \frac{\text{N}}{\text{m}^2} = 101948 \frac{\text{N}}{\text{m}^2} \end{aligned}$$

- iv. Calculate the blower brake power, P_{blower} , using Eq. 6-49.

$$\begin{aligned} P_{\text{blower}} &= \left(\frac{G_m R_g T_{\text{air}}}{1000 n_a \text{Eff}_b} \right) \left[\left(\frac{P_{\text{in}}}{P_{\text{out}}} \right)^{n_a} - 1 \right] \\ &= \left(\frac{1.34 \frac{\text{kg}}{\text{s}} \times 286.7 \frac{\text{J}}{\text{kg} \cdot \text{K}} \times 288.15 \text{ K}}{1000 \frac{\text{W}}{\text{kW}} (0.283)(0.40)} \right) \left[\left(\frac{101948 \frac{\text{N}}{\text{m}^2}}{101325 \frac{\text{N}}{\text{m}^2}} \right)^{0.2283} - 1 \right] \left(\frac{1 \text{ W}}{1 \frac{\text{J}}{\text{s}}} \right) \\ &= 1.70 \text{ kW} \end{aligned}$$

- b. Calculate pump power requirements, P_{pump} , using Eq. 6-52.

$$\begin{aligned}
 P_{\text{pump}} &= \frac{\rho_l Q L g}{1000 \text{Eff}_p} \\
 &= \left(\frac{999.15 \frac{\text{kg}}{\text{m}^3} \times 0.1577 \frac{\text{m}^3}{\text{s}} \times 9.33 \text{m} \times 99.8 \frac{\text{m}}{\text{s}^2}}{1000 \frac{\text{W}}{\text{kW}} \times 0.85} \right) \left(\frac{1 \text{W}}{1 \frac{\text{kg} \cdot \text{m}}{\text{s}^2}} \right) \\
 &= 17.0 \text{kW} \\
 \text{Eff}_p &= \text{pump efficiency}
 \end{aligned}$$

- c. Calculate total power requirements, P_{total} .

$$P_{\text{Total}} = P_{\text{Blower}} + P_{\text{Pump}} = 1.7 \text{kW} + 17.0 \text{kW} = 18.7 \text{kW} \quad \blacktriangle$$

Impact of Dissolved Solids on Tower Performance

One major concern with packed tower air stripping is the potential for precipitation of inorganic compounds such as calcium, iron, and manganese onto packing media, causing a steady decrease in the tower void volume and a steady increase in tower pressure drop, eventually leading to possible plugging of the tower. This is especially true for some groundwaters and hypolimnetic waters from stratified lakes and reservoirs that contain considerable amounts of dissolved carbon dioxide. It is not uncommon to encounter groundwaters with 30 to 50 mg/L of carbon dioxide. In an air stripping tower, carbon dioxide together with VOCs can be removed from the water. Because carbon dioxide is an acidic gas, its removal increases the water's pH. The reader can find principles of the effects of pH on the speciation of inorganic carbon in Chap. 3. Applying these principles here as the pH increases above 8.3, carbonate (CO_3^{2-}) becomes the dominant species of inorganic carbon. In natural waters containing appreciable amounts of Ca^{2+} , calcium carbonate precipitates when the CO_3^{2-} concentration becomes high enough that the calcium carbonate solubility product (pK_{so} of 8.34) is exceeded.

Air contains about 0.038 percent by volume of carbon dioxide. The Henry's law constant for carbon dioxide at 25°C is about 61.1 (1500 mg/L-atm); therefore the equilibrium concentration of carbon dioxide with air is about 0.57 mg/L. Air stripping can reduce the dissolved carbon dioxide concentration to its equilibrium concentration with air. In most situations, theoretical precipitation calculations can be performed to determine the maximum amount and rate of precipitation that will cause plugging of the tower. However, the carbon dioxide concentration is usually reduced to that above its equilibrium concentration with air, and the time taken to plug the air stripping tower is much longer than that predicted from the maximum theoretical precipitation. The actual rate of precipitation can only be determined using pilot-plant testing. The control of precipitation using acid or scale inhibitors can be expensive and, in some cases, it can be a major expense. Consequently, this needs to be carefully considered.

Air Stripping Off-Gas Control Using Adsorption

Air pollution resulting from VOC removal in air stripping processes has prompted many regulatory agencies to set emissions standards. Off-gas treatment technologies such as gas-phase granular activated carbon (GAC) adsorption, thermal incineration, and catalytic incineration are capable of reducing and, in some cases, eliminating the discharge of VOCs from air strippers. Thermal and catalytic incineration is used where the VOC concentrations are high or the VOCs are weakly adsorbing. VOC concentrations are usually dilute in most water treatment applications. Consequently, GAC fixed-bed adsorption is the most widely used process because it is cost effective for treating dilute off-gas streams and many of

the common VOC contaminants (e.g., trichloroethene, tetrachloroethene, toluene, xylene isomers) are amenable to adsorption onto GAC (Crittenden et al., 1988). A brief discussion of the important parameters that need to be considered for fixed-bed adsorber design and operation for VOC off-gas control from air strippers is presented below.

The design principles and application of adsorption for water treatment are presented in Chap. 14. The fundamental principles for gas-phase adsorption are similar to those for liquid-phase adsorption, with the exception that the transport fluid is air instead of water. For example, the same equilibrium and mass transfer concepts used in design of liquid-phase systems are used in gas-phase adsorber design. The main differences between these two adsorption processes are the impact of water vapor on VOC adsorption must be considered in gas-phase adsorption; the impact of NOM on the adsorption of organic contaminants is negligible and does not need to be considered; gas-phase adsorbents have properties (e.g., particle size, pore size distribution, hydrophobicity) that are designed to be more amenable to gas-phase adsorption; and the adsorbent reactivation techniques may be different depending upon the type of adsorbent that is used.

A schematic of a typical GAC off-gas control system for an air stripper is displayed in Fig. 6-10. The VOC-laden air stripper off-gas contains water vapor that has a relative humidity (*RH*) of 100 percent. Water vapor can have a large influence on the adsorption capacity of

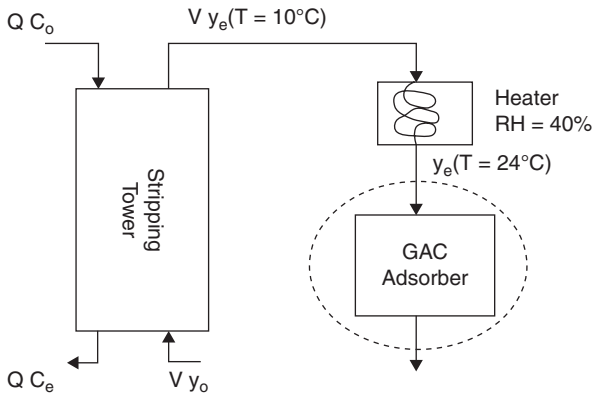

FIGURE 6-10 Schematic of air stripping off-gas control using a GAC adsorber.

adsorbents such as GAC. Figure 6-11 displays water vapor isotherms for several GAC adsorbents. For most of these GAC adsorbents, the adsorption of water is significant when the *RH* is greater than about 40 percent. At high *RH* values, a phenomenon called capillary condensation takes place where the water vapor can condense in the micropores of the adsorbent. The condensed water can then compete with the VOCs for adsorption sites, and the VOC capacity of the adsorbent can be significantly reduced. However, for *RH* values less than about 40 percent, the amount of water adsorbed onto the GAC is small, because capillary condensation of the water vapor is negligible and, consequently, its impact on VOC adsorption capacity can be neglected (Crittenden et al., 1988). For most gas-phase GAC adsorbents, it is recommended the off-gas *RH* be reduced to less than 40 percent prior to the adsorption process. A water vapor isotherm performed on a particular adsorbent of interest should be used to determine the *RH* value that will provide the most cost-effective design. As shown in Fig. 6-11, heating the off-gas is usually the most common method used to reduce the *RH* when GAC is used.

Typical design parameters for gas-phase GAC fixed-bed adsorbents consist of empty bed contact times (EBCTs) from 1.5 to 5.0 s and air loading rates from 0.25 to 0.50 m/s (0.82 to 1.64 ft/s). The GAC used in gas-phase applications is usually a microporous carbon with nominal particle sizes ranging from 4×6 to 6×16 U.S. standard mesh size. Gas-phase GAC particles are typically larger than those for liquid-phase applications so as to minimize

FIGURE 6-11 Water vapor isotherms for various granular activated carbons. (Source: Tang et al., 1987.)

the air pressure drop through the fixed-bed. The air pressure drop in gas-phase fixed-bed adsorbers ranges from 0.2 to 5.0 kPa/m of packed bed depth.

In gas-phase adsorption, the mass transfer zone of an organic contaminant is short and occupies a small fraction of the fixed-bed. For moderate to strongly adsorbing VOCs (e.g., trichloroethylene, toluene, tetrachloroethylene), mass transfer zone lengths range from 0.025 to 0.043 m (Crittenden et al., 1988). For a typical packed bed depth of 1.0 m, the mass transfer zone would occupy less than 4.3 percent of the bed. Consequently, for preliminary design calculations, equilibrium models can be used to determine the GAC usage rate for organic contaminants. Based on the preliminary design calculations, pilot studies can be performed and used to evaluate the most cost-effective design and operation.

The Dubinin-Raduskevich (D-R) equation was shown to correlate the isotherms of several gas-phase VOCs (Crittenden et al., 2005). Based on the work of several researchers (Reucroft, Simpson, and Jonas, 1971; Rasmuson, 1984; Crittenden et al., 1988), the following form of the D-R equation can be used to estimate the single solute gas-phase capacity for a VOC:

$$q = \rho_L W = \rho_L W_o \exp \left[\frac{-B\epsilon^2}{\alpha^2} \right] \quad (6-55)$$

$$\epsilon = RT \ln \left(\frac{P_s}{P} \right) \quad (6-56)$$

where q is the solid-phase VOC concentration in equilibrium with P (M/M), W is the adsorption space or pore volume occupied by the adsorbate (mL/gm), W_o is the maximum adsorption space (mL/gm), B is the microporosity constant (cm⁶/cal²), ϵ is the adsorption potential (cal/mole), T is the temperature (K), P_s is the saturation vapor pressure of the VOC at T K (N/m²), P is the partial pressure of the VOC in the gas (N/m²), ρ_L is the liquid density of the VOC (kg/m³), and α is the polarizability of the VOC (m³/kg) and can be calculated from the Lorentz-Lorentz equation if it is not known.

$$\alpha = \frac{(\eta^2 - 1)M}{(\eta^2 + 2)\rho_L} \quad (6-57)$$

where η is the refractive index of the VOC and M is the molecular weight of the VOC. Equations 6-55 and 6-56 were correlated with isotherm data for several compounds with dipole moments less than 2 debyes (2×10^{-18} esu-cm) (Reucroft, Simpson, and Jonas, 1971; Crittenden et al., 1988). W_o and B depend only on the nature of the adsorbent. When isotherm data is plotted as W versus $(\epsilon/\alpha)^2$ for a given adsorbent, the data conform to essentially one line for different VOCs and temperatures (Crittenden et al., 2005). Table 6-10 summarizes W_o and B values for three gas-phase adsorbents. The D-R values are based on toluene, which was used as the reference compound. Two important limitations of the D-R equation (Eqs. 6-55 and 6-56) are: it is only valid for relative pressures, P/P_s , less than 0.2 because capillary condensation of the VOC occurs, and it is only valid for RH values less than about 50 percent. For relative pressures greater than 0.2, the adsorbent capacity can be calculated by assuming the adsorbent micropore volume is filled with the condensed VOC. For cases where multiple VOCs are present in an air stripper off-gas, equilibrium column model (ECM) calculations can be used to estimate the adsorbent usage rate for each VOC (Cortright, 1986; Crittenden et al., 1987). When the GAC capacity is exhausted, it is usually sent back to the manufacturer for reactivation and reuse.

TABLE 6-10 Typical W_o and B Values for Several Commercial Gas-Phase Adsorbents

Adsorbent type	W_o (cm ³ /gm)	B (cm ⁶ /cal ²)	Reference

Example 6-3 Air Stripper Off-Gas Control Using Adsorption Calculation

Perform preliminary design calculations for a gas-phase adsorber that will remove TCA from the air stripper off-gas in Example 6-2. Determine the GAC usage rate that will be required to meet a nondetectable limit for TCA and the bed life for the following conditions: an EBCT of 2.5 s and a loading rate of 0.5 m/s. A summary of the air stripper off-gas and TCA properties required to perform the calculations is listed below.

Air Stripper Data:

$$\dot{V} = Q \times \frac{\dot{V}}{Q} = 0.158 \frac{\text{m}^3}{\text{s}} \times 7.0 \frac{\text{m}^3 \text{air}^3/\text{s}}{\text{m}^3 \text{water}/\text{s}} = 1.10 \frac{\text{m}^3}{\text{s}}$$

$$C_o(TCA) = 165 \frac{\mu\text{g}}{\text{L}} \quad C_e(TCA) = 5.0 \frac{\mu\text{g}}{\text{L}}$$

Off-gas temperature is assumed to be 15°C, $RH = 100$ percent, the relative humidity entering the adsorber is 40 percent, and air temperature entering the adsorber is 25°C.

Solution

1. Calculate the off-gas TCA concentration leaving the air stripper.

$$y_e \left(\begin{array}{l} \text{TCA conc.} \\ \text{in off-gas} \\ \text{at } 15^\circ\text{C} \end{array} \right) = \frac{C_o - C_e}{\dot{V}/Q} = \frac{(165.0 - 5.0) \frac{\mu\text{g}}{\text{L}}}{7.0} = 22.9 \frac{\mu\text{g}}{L_{\text{Air}}}$$

2. Calculate the TCA gas-phase concentration entering the adsorber.

The TCA concentration in the heated off-gas will be decreased by a small amount due to heating of the off-gas. The ideal gas law at constant pressure of 760 mm Hg can be used to adjust for this change as shown below.

$$y_e(25^\circ\text{C}) = 22.9 \frac{\mu\text{g}}{L_{\text{Air}}} (10^\circ\text{C}) \left(\frac{273+15}{273+25} \right) = 22.1 \frac{\mu\text{g}}{L_{\text{Air}}}$$

3. Calculate the best possible GAC usage rate assuming no mass transfer resistance. Assume the adsorbent that will be used in the design is Calgon BPL 4 × 6 mesh GAC (D-R Parameters: $B = 3.22 \times 10^{-5} \text{ cm}^6/\text{cal}^2$, $W_o = 0.460 \text{ cm}^3/\text{gm}$). Performing a mass balance on the GAC adsorber, the following expression can be obtained for calculating the GAC usage rate:

$$\frac{\hat{M}}{V t_e} = \frac{y_e}{q_e} = \text{GAC Usage Rate}$$

where \hat{M} is mass of GAC in the fixed-bed, t_e is the time it takes to exhaust the GAC fixed-bed, and q_e is the adsorbed phase concentration on TCA in equilibrium with y_e . q_e can be calculated using Eq. 6-55.

If Eqs. 6-55 and 6-56 are combined and divided by $M \times 10^{-6}$, the following expression can be used to calculate q_e :

$$q_e = \left(\frac{W_o p_i}{M \times 10^{-6}} \right) \exp \left[\frac{-B}{\alpha^2} \left\{ RT \ln \left(\frac{P_s}{P} \right) \right\}^2 \right]$$

From *Lange's Handbook of Chemistry* (Speight, 2004), P_s for TCA at 25°C is equal to 78.8 mm Hg.

y_e can be converted in terms of P using the following expression:

$$P(25^\circ\text{C}) = y_e RT$$

$$\begin{aligned} &= \left(22.1 \frac{\mu\text{g}}{L} \right) \left(0.08205 \frac{L\text{-atm}}{\text{mol-K}} \right) (298\text{K}) \left(\frac{\text{mol}}{133.4\text{ gm}} \right) \left(\frac{\text{gm}}{10^6 \mu\text{g}} \right) \left(\frac{760\text{ mmHg}}{1\text{ atm}} \right) \\ &= 3.1 \times 10^{-3} \text{ mm Hg} \end{aligned}$$

Equation 6-57 is used to calculate the polarizability of TCA. From the CRC 85th edition, $\eta(\text{TCA}) = 1.4313$ and $\rho_l(\text{TCA}) = 1.33 \text{ gm/cm}^3$.

$$\alpha(\text{TCE}) = \frac{((1.4313)^2 - 1) 33.4 \frac{\text{gm}}{\text{mol}}}{((1.4313)^2 + 2) .33 \frac{\text{gm}}{\text{cm}^3}} = 25.98 \frac{\text{cm}^3}{\text{mol}}$$

$$q_e = \left(\frac{(0.460 \frac{\text{cm}^3}{\text{gm}})(1.33 \frac{\text{gm}}{\text{cm}^3})}{133.4 \times 10^{-6} \frac{\text{gm}}{\mu\text{mol}}} \right) \times \exp \left[\frac{-3.22 \times 10^{-5} \frac{\text{cm}^6}{\text{mol}^2}}{(25.98)^2 \frac{\text{cm}^6}{\text{mol}^2}} \left\{ \left(1.987 \frac{\text{cal}}{\text{mol-K}} \right) (298\text{K}) \ln \left(\frac{78.8 \text{mmHg}}{3.1 \times 10^{-3} \text{mmHg}} \right) \right\}^2 \right]$$

$$q_e = 820 \frac{\mu\text{ mol TCA adsorbed}}{\text{gm GAC}}$$

$$\left\{ \begin{array}{l} \text{GAC} \\ \text{Usage} \\ \text{Rate} \end{array} \right\} = \frac{y_e}{q_e} = \frac{(22.1 \frac{\mu\text{g}}{\text{L Air}}) (\frac{1\text{kg}}{1000\text{gg}})}{(820 \frac{\mu\text{mol}}{\text{gm}}) (133.4 \frac{\mu\text{g}}{\mu\text{mol}}) (\frac{\text{m}^3}{1000\text{L}})} = 2.02 \times 10^{-4} \frac{\text{kg GAC}}{\text{m}^3 \text{Air treated}}$$

or

$$\left\{ \begin{array}{l} \text{GAC} \\ \text{Usage} \\ \text{Rate} \end{array} \right\} = 4,953 \frac{\text{m}^3 \text{Air treated}}{\text{kg GAC}}$$

4. Calculate the mass of GAC required and the bed life of the GAC adsorber assuming an EBCT = 2.5 s and $v_s = 0.5$ m/s.

$$\left\{ \begin{array}{l} \text{Mass of GAC} \\ \text{in 2.5 s EBCT} \\ \text{Bed} \end{array} \right\} = \text{EBCT} \dot{V} \rho_f = (2.5\text{s}) \left(1 \frac{\text{m}^3}{\text{s}} \right) \left(531 \frac{\text{kg}}{\text{m}^3} \right) = 1,460 \text{kg}$$

$$\left\{ \begin{array}{l} \text{Volume of Air} \\ \text{Treated for a} \\ \text{2.5 s EBCT} \end{array} \right\} = \frac{\left(\begin{array}{l} \text{Mass of GGAC} \\ \text{fo 2.5 s EBCT} \end{array} \right)}{(\text{TCA Usage Rate})} = \frac{1460 \text{kg GAC}}{\left(\frac{\text{kg GAAC}}{4953 \text{m}^3 \text{Air}} \right)} = 7.3 \times 10^6 \text{m}^3 \text{Air}$$

$$\{\text{GAC Bed Life}\} = \frac{(7.3 \times 10^6 \text{m}^3 \text{Air})}{\left(1.1 \frac{\text{m}^3 \text{Air}}{\text{s}} \right) \left(\frac{86,400\text{s}}{\text{d}} \right)} = 77 \text{days} \quad \blacktriangle$$

DIFFUSED OR BUBBLE AERATION

The diffused or bubble aeration process consists of contacting gas bubbles with water for the purposes of transferring gas to the water (e.g., O₃, CO₂, O₂) or removing VOCs from the water by air stripping. The process can be carried out in a clearwell or special rectangular concrete tanks typically 3 to 5 m (9 to 15 ft) in depth. Figure 6-12 displays different types of diffused aeration systems. The most commonly used diffuser system consists of a matrix of perforated tubes (or membranes) or porous plates arranged near the bottom of the tank to provide maximum gas-to-water contact. Various types of diffusers and diffuser system layouts are presented in the U.S. Environmental Protection Agency's technology transfer design manual on fine-pore aeration systems (USEPA, 1989). Jet aerator devices are also used to provide good air-to-water contact (Mandt and Bathija, 1987). These aerators consist of jets that discharge fine gas bubbles and provide enhanced mixing for increased absorption efficiency.

(a) Bubble type

(b) diffused jet aeration

FIGURE 6-12 Schematic of various bubble aeration systems.

Governing Equations: Air Stripping of VOCs

Figure 6-13 shows a schematic of a bubble aeration system for a single tank. Model development for air stripping using bubble aeration has been described in the literature (Matter-Müller, Gujer, and Giger, 1981; Munz and Roberts, 1982; Roberts, Munz, and Dändliker, 1984). The development of the process design equations for bubble aeration incorporates the following assumptions: (1) the liquid phase is completely mixed, (2) the gas phase is plug flow, (3) the process is at steady state, and (4) the inlet VOC gas concentration is zero. A liquid-phase mass balance around the tank shown in Fig. 6-13, incorporating the above assumptions, results in the following relationship:

$$QC_0 - QC_e - \dot{V}(y_o - y_e) = 0 \tag{6-58}$$

FIGURE 6-13 Schematic of a completely mixed bubble aeration tank for development of the design equations.

Applying the assumptions that the inlet VOC gas concentration is zero (i.e., $y_o = 0$) and the exiting air is in equilibrium with the bulk liquid (i.e., $y_e = HC_e$), Eq. 6-58 can be solved for $\left(\frac{\dot{V}}{Q}\right)$, which is for the minimum air-to-water ratio for bubble aeration.

$$\left(\frac{\dot{V}}{Q}\right)_{\min} = \frac{C_o - C_e}{HC_e} \tag{6-59}$$

The minimum air-to-water ratio represents the smallest air-to-water ratio that can be applied to a bubble aeration tank in order to meet the treatment objective, C_e .

Figure 6-14 shows a schematic of a gas bubble within a bubble aeration tank. Eliminating the assumption of equilibrium between the bulk liquid and the exiting air and performing a mass balance around the gas bubble (assuming plug flow conditions prevail in the gas phase) results in an expression for y_e in Eq. 6-58 (Hokanson, 1996; Matter-Müller, Gujer, and Giger, 1981):

FIGURE 6-14 Schematic of a single bubble inside a bubble aeration tank.

$$y_e = HC_e(1 - e^{-\phi}) \tag{6-60}$$

in which ϕ is equal to the Stanton number, defined by

$$\phi = \frac{K_L a V}{H \dot{V}} \tag{6-61}$$

in which $K_L a$ is the overall mass transfer coefficient for bubble aeration (s^{-1}), V is the volume of a bubble aeration tank (m^3), H is the Henry's law constant (dimensionless), and \dot{V} is the air flow rate (m^3/s).

Substitution of Eq. 6-60 into Eq. 6-58 yields the design equation for bubble aeration:

$$QC_o - QC_e - \dot{V}HC_e(1 - e^{-\phi}) = 0 \tag{6-62}$$

To design a new bubble aeration tank, Eq. 6-62 can be rearranged and solved for V (note that C_e in Eq. 6-62 represents the treatment objective):

$$V = -\frac{H\dot{V}}{K_L a} \ln \left\{ 1 - \left[\left(\frac{C_o}{C_e} - 1 \right) \left(\frac{1}{\left(\frac{\dot{V}}{Q} H \right)} \right) \right] \right\} \tag{6-63}$$

Recall that the air-to-water ratio, \dot{V}/Q in Eq. 6-63, must be greater than the minimum air-to-water ratio, $(\dot{V}/Q)_{\min}$ defined in Eq. 6-59, for the bubble aeration tank to be able to meet the treatment objective. To estimate the effluent concentrations of various compounds for an existing bubble aeration tank with volume, V , it is necessary to solve Eq. 6-63 for C_e :

$$C_e = \frac{C_0}{1 + \frac{\dot{V}}{Q} H(1 - e^{-\theta})} \quad (6-64)$$

In either case (new tank or existing tank), the gas-phase effluent concentration from the tank, y_e , can be determined from:

$$y_e = \frac{C_0 - C_e}{\frac{\dot{V}}{Q}} \quad (6-65)$$

Tanks in Series Development. Process performance can often be improved significantly (i.e., lower total volume requirements) by configuring the bubble aeration system as tanks in series. Figure 6-15 shows a schematic of a bubble aeration system operated in a tank in series configuration. Sometimes this is easy to accomplish by placing baffles in the tank. The general case for development of n tanks in series is discussed in Chap. 4. If it is assumed that all the tanks are equally sized and all the assumptions for a single tank system are valid here, the following expression can be used to calculate the effluent concentration for n tanks in series:

$$C_n = \frac{C_{n-1}}{1 + \frac{\dot{V}}{Q} H(1 - e^{-\theta})} = \frac{C_0}{\left[1 + \frac{\dot{V}}{Q} H(1 - e^{-\theta})\right]^n} \quad (6-66)$$

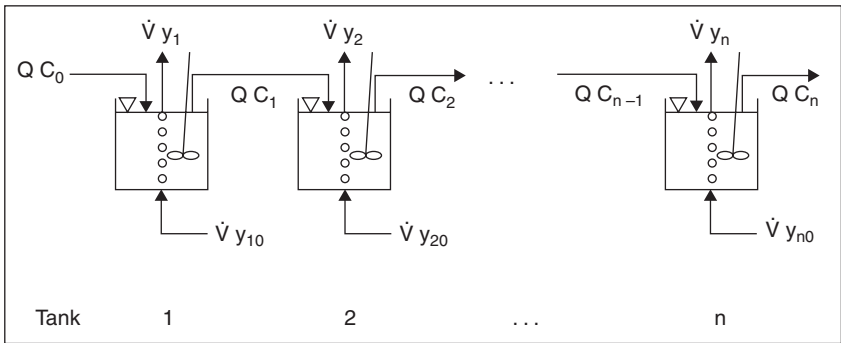

FIGURE 6-15 Schematic of a tanks in series bubble aeration system.

in which C_n is the effluent liquid-phase concentration from tank n . Equation 6-66 is the general expression for the effluent concentration for a bubble aeration system consisting of tanks in series. For the case of designing new tanks in a series systems, both the influent and desired effluent concentrations are known. Consequently, Eq. 6-66 can be rearranged to determine the volume of each individual tank, V_n , using the following equation:

$$V_n = -\frac{H\dot{V}}{K_L a} \ln \left\{ 1 - \left[\left(\frac{C_0}{C_e} \right)^{1/n} - 1 \right] \left[\frac{1}{\frac{\dot{V}}{Q} H} \right] \right\} \quad (6-67)$$

As for the single-tank case, the air-to-water ratio supplied to each tank must exceed the minimum air-to-water ratio so that the system will be able to meet its treatment objective. The minimum air-to-water ratio for a tanks-in-series configuration can be determined as follows:

$$\left(\frac{\dot{V}}{Q}\right)_{\min} = \left[\left(\frac{C_0}{C_e}\right)^{1/n} - 1\right] \frac{1}{H} \quad (6-68)$$

It is sometimes necessary to determine the gas-phase concentration leaving the tanks. The gas-phase effluent concentration from each tank in series may be calculated from the following:

$$y_n = \frac{C_{n-1} - C_n}{\frac{\dot{V}}{Q}} \quad (6-69)$$

Governing Equations: Gas Absorption

Equations that describe the transfer of compounds from the gas to the water phase are similar to those used to describe stripping in a bubble aeration tank, a process known as absorption. Figure 6-13, the bubble aeration schematic shown previously, is also relevant to this case. The development of the process design equations for absorption using bubble aeration incorporates the same assumptions as for stripping, except that the inlet liquid concentration, rather than the inlet gas phase concentration, is zero. A mass balance around the tank shown in Fig. 6-13 results in the following:

$$-QC_e + \dot{V}y_0 - \dot{V}y_e = 0 \quad (6-70)$$

For sizing a tank, and substituting Eq. 6-60 into Eq. 6-70 and solving it for V , the following expression can be derived:

$$V = -\frac{H \cdot \dot{V}}{K_L a} \ln \left(1 - \left[\frac{1}{H \frac{\dot{V}}{Q} (y_0 - 1)} \right] \right) \quad (6-71)$$

As for the stripping case, there is a minimum water-to-air ratio that must be exceeded in order for absorption to be viable:

$$\frac{Q}{\dot{V}} \geq \left(\frac{Q}{\dot{V}}\right)_{\min} = H \left(\frac{y_0}{y_e} - 1 \right) \quad (6-72)$$

In order to estimate the gas-phase effluent concentrations of various compounds for an existing bubble aeration tank with volume V , it is necessary to solve Eq. 6-70 for C_e , substitute the result into Eq. 6-71, and solve for y_e :

$$y_e = \frac{y_0}{1 + \left[\frac{1}{H \frac{\dot{V}}{Q} (1 - e^{-\theta})} \right]} \quad (6-73)$$

For bubble and surface aeration, it is difficult to determine $K_L a$ for a compound from Eq. 6-21 because the quantities k_f and k_g vary greatly from system to system and are difficult to

measure. The general equation for estimating the $K_L a$ of a compound in bubble or surface aeration is found by expanding Eq. 6-21 based on oxygen as a reference compound:

$$K_L a_i = K_L a_{O_2} \left(\frac{D_{l,i}}{D_{l,O_2}} \right)^m \left[1 + \frac{1}{H_i \left(\frac{k_g}{k_l} \right)} \right]^{-1} \quad (6-74)$$

where $K_L a_{O_2}$ is the overall mass transfer coefficient for oxygen (1/s), $D_{l,i}$ is the liquid diffusivity of component i (m^2/s), and m is the diffusivity exponent (dimensionless). k_g/k_l is the ratio of gas-phase to liquid-phase mass transfer coefficient (dimensionless), which tends to be relatively constant for a given type of aeration system. $D_{l,i}$ can be found from the Hayduk and Laudie (1974) correlation for small molecules in water. D_{l,O_2} is found from a correlation presented in Holmén and Liss (1984):

$$D_{l,O_2} = [10^{(3.15 + (-831.0)/T)}] (1.0 \times 10^{-9}) \quad (6-75)$$

where T is the temperature in K. The recommended value for the diffusivity exponent, m , in bubble aeration is 0.6 (Holmén and Liss, 1984). Munz and Roberts (1989) pointed out that a constant value of $k_g/k_l \approx 100$ to 150 is widely used in air-water mass transfer. Therefore, a value of $k_g/k_l = 100$ is recommended as a conservative estimate in bubble aeration. $K_L a_{O_2}$ can be found from clean water oxygen transfer test data (Brown and Baillod, 1982; Baillod et al., 1986):

$$K_L a_{O_2} = K_L a_{20}^* (1.024)^{T-20} \quad (6-76)$$

where T is the temperature in $^{\circ}C$, $K_L a_{20}^*$ is the true mass transfer coefficient of oxygen at $20^{\circ}C$, and $K_L a_{20}^*$ can be determined from the following series of relationships:

$$K_L a_{20}^* = \frac{K_L a_{20}}{1 - \frac{K_L a_{20}}{2\phi_O}} \quad (6-77)$$

$$K_L a_{20} = \frac{SOTR}{VC_{\infty}^*} \quad (6-78)$$

$$C_{\infty}^* = C_s^* \left[\frac{P_b - P_v + \gamma_w d_e}{P_s - P_v} \right] \quad (6-79)$$

$$\phi_O = \frac{M_O \rho_a Q_a}{M_a H_O (P_b + \gamma_w d_e)} \quad (6-80)$$

where ϕ_O is the oxygenation coefficient (1/s), C_{∞}^* is the dissolved oxygen saturation concentration attained at infinite time ($\mu g/L$), SOTR is the standard oxygen transfer rate (kg/s), V is the water volume in the tank (m^3), C_s^* is the dissolved oxygen saturation concentration at $20^{\circ}C$ ($\mu g/L$), P_b is the barometric pressure (N/m^2), P_s is the barometric pressure under standard conditions (N/m^2), P_v is the vapor pressure of water at $20^{\circ}C$ (N/m^2), γ_w is the weight density of water (kg/m^3), d_e is the effective saturation depth (m), which is equal to one third times the water depth, M_O is the molecular weight of oxygen (amu), M_a is the molecular weight of air (amu), Q_a is the volumetric flow rate of air (m^3/s), and H_O is Henry's constant for oxygen (dimensionless). These correlations are valid only for clean waters and should not be used for wastewaters.

The total operating power for bubble aeration is equal to the blower brake power requirement for each tank times the number of tanks times the number of blowers per tank. The

blower brake power is calculated from Eq. 6-49. The term P_{in} refers to the pressure at the top of the tank, which represents the sum of the ambient pressure and the head required to raise the water to the inlet of the tank. The equation used to find P_{in} is

$$P_{in,b} = P_{ambient} + \rho_l H_b g \quad (6-81)$$

where the pressure head, H_b , is assumed equal to the water depth in the tank, d_b .

Example 6-4 Bubble Aeration Sample Calculation

A portion of an existing clearwell is to be modified to include a bubble aeration system capable of reducing radon concentration from 6000 pCi/L to less than 300 pCi/L. The total volume of the clearwell is 3750 m³ (1 Mgal) (depth = 5.0 m, length = 30 m, width = 25 m). The average plant flow rate is 0.22 m³/s (5 mgd) and the water temperature is 20°C. The chemical and physical properties of radon are summarized below. Tank manufacturer information on clean water oxygen transfer data necessary to determine $K_L a_{O_2}$ is also provided below.

Determine the retention time, air flow rate, and power requirements necessary to meet the treatment objective for a single tank. Also, assume that the clearwell can be modified to perform like three tanks in series. Assume a blower efficiency of 35 percent.

Chemical and physical properties of radon at 20°C.

Property	Value
Molecular Weight (g/mole)	222
D_g (m ² /s)	2.0×10^{-5}
D_l (m ² /s)	1.4×10^{-9}
H (L/L)	4.08

Manufacturer's clean water oxygen transfer test data for a tank with a diffuser/bubble system.

Property	Value
SOTR (kg O ₂ /day)	1500
Volumetric air flow rate (m ³ /hr)	1700
Tank volume (m ³)	500
Tank depth (m)	3

Solution

- Determine the retention time for a single tank.

$$\tau = \frac{V}{Q} = \frac{3785 \text{ m}^3}{(0.22 \frac{\text{m}^3}{\text{s}})(60 \text{ s/min})} = 287 \text{ min} = 4.79 \text{ hr}$$

- Find the oxygen mass transfer rate coefficient, $K_L a_{O_2}$.

- In the calculation of $K_L a_{O_2}$, the following quantities in addition to the clean water oxygen test data that was given are needed:

C_s^* Dissolved oxygen surface saturation concentration at 20°C = 9.09 mg/L (see App. D)

P_b Barometric pressure = 1 atm

P_s Barometric pressure under standard conditions = 1 atm

P_v Vapor pressure of water at 20°C = 2.34 kN/m² (see App. D)

d_e Effective saturation depth = $\frac{1}{3} \times$ water depth = 1.67 m

M_O Molecular weight of oxygen (g/mole) = 32.0

ρ_a Density of air at 20°C = 1240 mg/L

M_a Molecular weight of air (g/mole) = 28.0

H_O Henry's constant for oxygen = 50 mg/L/atm

Using these quantities along with those provided in the problem statement, $K_L a_{O_2}$ is calculated as follows:

- b. Calculate C_∞^* using Eq. 6-79.

$$C_\infty^* = C_s^* \left[\frac{P_b - P_v + \gamma_w d_e}{P_s - P_v} \right] = 9.09 \frac{\text{mg}}{\text{L}} \left[\frac{1 \text{ atm} - \frac{2340 \text{ Pa}}{101325.0 \frac{\text{Pa}}{\text{atm}}} + \frac{62.3 \frac{\text{lb}}{\text{ft}^3} \times 1.67 \text{ m} \times 3.281 \frac{\text{ft}}{\text{m}}}{144 \frac{\text{in}^2}{\text{ft}^2} \times 14.696 \frac{\text{psi}}{\text{atm}}}}{1 \text{ atm} - \frac{2,340 \text{ Pa}}{101325.0 \frac{\text{Pa}}{\text{atm}}}} \right]$$

$$= 10.59 \frac{\text{mg}}{\text{L}}$$

- c. Calculate $K_L a_{20}$ using Eq. 6-78.

$$K_L a_{20} = \frac{SOTR}{V C_\infty^*} = \frac{1500 \frac{\text{kg}}{\text{d}} \cdot (10^6 \frac{\text{mg}}{\text{kg}}) (\frac{1 \text{ d}}{86400 \text{ s}})}{500 \text{ m}^3 \cdot 10.59 \frac{\text{mg}}{\text{L}} \cdot 1000 \frac{\text{L}}{\text{m}^3}} = 3.28 \times 10^{-3} \frac{1}{\text{s}}$$

- d. Calculate ϕ_o from Eq. 6-80.

$$\phi_o = \frac{M_o \rho_a Q_a}{M_a H_o V_{\text{test}} (P_b + \gamma_w d_e)}$$

$$= \frac{32 \times 1240 \frac{\text{mg}}{\text{L}} \times \frac{1700 \frac{\text{m}^3}{\text{hr}}}{33600 \frac{\text{hr}}{\text{d}}}}{28.95 \cdot 50 \frac{\text{mg}}{\text{L} \cdot \text{atm}} \cdot 500 \text{ m}^3 \left(1 \text{ atm} + \frac{62.4 \frac{\text{lb}}{\text{ft}^3} \times 1.667 \text{ m} \times 3.281 \frac{\text{ft}}{\text{m}}}{144 \frac{\text{in}^2}{\text{ft}^2} \times 14.696 \frac{\text{psi}}{\text{atm}}} \right)}$$

$$= 0.0030 \frac{1}{\text{s}}$$

- e. Calculate $K_L a_{20}^*$ using Eq. 6-77.

$$K_L a_{20}^* = \frac{K_L a_{20}}{1 - \frac{K_L a_{20}}{2\phi_o}} = \frac{3.28 \times 10^{-3} \frac{1}{\text{s}}}{1 - \frac{3.28 \times 10^{-3} \frac{1}{\text{s}}}{2(0.0030 \frac{1}{\text{s}})}} = 3.5 \times 10^{-3} \frac{1}{\text{s}}$$

- f. Calculate $K_L a_{O_2}$ using Eq. 6-78.

$$K_L a_{O_2} = K_L a_{20}^* (1.024)^{T-20} = 3.5 \times 10^{-3} \frac{1}{\text{s}} (1.024)^{20-20} = 3.5 \times 10^{-3} \frac{1}{\text{s}}$$

3. Calculate the liquid diffusivity of oxygen using the correlation of Holmén and Liss (1984).

$$D_l (\text{O}_2) = 10^{3.15 + \frac{-831}{293.15}} \times 10^{-9} = 2.07 \times 10^{-9} \frac{\text{m}^2}{\text{s}}$$

4. Calculate the overall mass transfer rate of the radon.

$$K_L a_{\text{radon}} = 3.5 \times 10^{-3} \frac{1}{\text{s}} \left(\frac{1.4 \times 10^{-9} \frac{\text{m}^2}{\text{s}}}{2.07 \times 10^{-9} \frac{\text{m}^2}{\text{s}}} \right)^{0.6} \left(1 + \frac{1}{4.08 \times 100} \right)^{-1} = 2.76 \times 10^{-3} \frac{1}{\text{s}}$$

5. Calculate the air-to-water ratio needed for stripping. First calculate the minimum air-to-water ratio required for stripping using Eq. 6-59; assume a safety factor (SF) of 2.0 to account for the error in estimation of the mass transfer resistance.

$$\left(\frac{\dot{V}}{Q}\right) = \left(\frac{C_0 - C_e}{HC_e}\right)_{\min} \times SF = \left(\frac{(6,000 - 300) \frac{\text{pCi}}{\text{L}}}{4.08 \times 300 \frac{\text{pCi}}{\text{L}}}\right) \times 2.0 \approx 10$$

6. Calculate the air flow rate.

$$\dot{V} = \left(\frac{\dot{V}}{Q}\right) \times Q = 10 \times 0.2191 \frac{\text{m}^3}{\text{s}} = 2.191 \frac{\text{m}^3}{\text{s}}$$

7. Calculate the Stanton number, ϕ_{radon} , for radon using Eq. 6-61.

$$\phi_{\text{radon}} = \frac{2.76 \times 10^{-3} \frac{1}{\text{s}} \times 3785 \text{m}^3}{2.191 \frac{\text{m}^3}{\text{s}} \times 4.08} = 1.17$$

8. Calculate the radon effluent concentration, $C_{e,\text{radon}}$, from the tank using Eq. 6-64.

$$C_{e,\text{radon}} = \frac{6,000 \frac{\text{pCi}}{\text{L}}}{1 + 10 \times 4.08 \times (1 - e^{-1.17})} = 206 \frac{\text{pCi}}{\text{L}}$$

The radon effluent concentration of 206 pCi/L is conservative using a factor of safety of 2.0.

9. Calculate the total blower power required to meet the treatment objective.

- a. Calculate the air mass flow rate, G_{me} .

$$G_{me} = 2.191 \frac{\text{m}^3}{\text{s}} \times 1.24 \frac{\text{kg}}{\text{m}^3} = 2.72 \frac{\text{kg}}{\text{s}}$$

- b. Calculate the inlet air pressure to the aeration basin, $P_{in,b}$, using Eq. 6-81.

$$P_{in,b} = 101325 \frac{\text{N}}{\text{m}^2} + 998.26 \frac{\text{kg}}{\text{m}^3} \times 5 \text{m} \times 9.81 \frac{\text{m}}{\text{s}^2} = 150290 \frac{\text{N}}{\text{m}^2}$$

- c. Calculate the total blower power, P_{blower} , using Eq. 6-49.

$$P_{blower} = \left[\frac{2.72 \frac{\text{kg}}{\text{s}} \times 286.7 \frac{\text{J}}{\text{kg} \times \text{K}} \times 293.15 \text{K}}{1000 \frac{\text{W}}{\text{kW}} \times 0.283 \times 0.35} \right] \times \left[\left(\frac{150290 \frac{\text{N}}{\text{m}^2}}{101325 \frac{\text{N}}{\text{m}^2}} \right)^{0.283} - 1 \right] \times \left(\frac{1 \text{W}}{1 \frac{\text{J}}{\text{s}}} \right)$$

$$= 272 \text{ kW}$$

For comparison purposes, assume a portion of the clearwell can be modified to provide a system of three tanks in series with a total retention time of 1 hour.

1. Calculate the total volume if the total retention time is 1 hour.

$$V_n = Q\tau_n = 0.2191 \frac{\text{m}^3}{\text{s}} \times 1 \text{ hr} \times \frac{3600 \text{ s}}{1 \text{ hr}} = 789 \text{ m}^3$$

2. Determine the volume per tank, V .

$$V = \frac{V_n}{\# \text{ of tanks}} = \frac{789 \text{ m}^3}{3 \text{ tanks}} = 266 \text{ m}^3$$

Assume the same tank depth as the single tank and assume that mass transfer coefficients do not change for tanks in series. The removal efficiency after the third tank can be determined as shown in the following calculations.

3. Determine the minimum air-to-water ratio for the system of three tanks in series using Eq. 6-70. Assume a radon effluent concentration of 300 pCi/L and a safety factor of 2.0 for the air-to-water ratio.

$$\left(\frac{\dot{V}}{Q}\right)_{\min} = \left[\left(\frac{C_0}{C_e}\right)^{1/n} - 1\right] \frac{1}{H} \times SF = \left[\left(\frac{6,000 \frac{\text{pCi}}{\text{L}}}{300 \frac{\text{pCi}}{\text{L}}}\right)^{1/3} - 1\right] \frac{1}{4.08} \times 2.0 = 0.840$$

4. Determine the air flow rate for each tank.

$$\dot{V} = \left(\frac{\dot{V}}{Q}\right)_{\min} \times Q = 0.84 \times 0.2191 \frac{\text{m}^3}{\text{s}} = 0.184 \frac{\text{m}^3}{\text{s}}$$

5. Calculate the Stanton number, ϕ , for radon.

$$\phi_{\text{radon}} = \frac{2.76 \times 10^{-3} \frac{1}{\text{s}} \times 266 \text{m}^3}{0.184 \frac{\text{m}^3}{\text{s}} \times 4.08} = 0.98$$

6. Determine the total effluent radon concentration from the tank, C_3 .

$$C_{3_{\text{C3CH}}} = \frac{6,000 \frac{\text{pCi}}{\text{L}}}{[1 + 0.84 \times 4.08 \times (1 - e^{-0.98})]^3} = 194 \frac{\text{pCi}}{\text{L}}$$

The effluent concentration for the three tanks in series design meets the radon treatment objective of 300 pCi/L.

7. Determine the required blower power for the three tanks in series.

- a. Find the air mass flow rate, G_{me} .

$$G_{me} = 0.184 \frac{\text{m}^3}{\text{s}} \times 1.24 \frac{\text{kg}}{\text{m}^3} = 0.23 \frac{\text{kg}}{\text{s}}$$

- b. Calculate the inlet air pressure to the aeration basin, $P_{in,b}$.

$$P_{in,b} = 101325 \frac{\text{N}}{\text{m}^2} + 998.26 \frac{\text{kg}}{\text{m}^3} \times 5 \text{m} \times 9.81 \frac{\text{m}}{\text{s}^2} = 150290 \frac{\text{N}}{\text{m}^2}$$

- c. Calculate the total blower power, P_{blower} .

$$P_{blower} = \left[\frac{0.23 \frac{\text{kg}}{\text{s}} \times 286.7 \frac{\text{J}}{\text{kg} \times \text{K}} \times 293.15 \text{K}}{1000 \frac{\text{W}}{\text{kW}} \times 0.283 \times 0.35} \right] \times \left[\left(\frac{150290 \frac{\text{N}}{\text{m}^2}}{101325 \frac{\text{N}}{\text{m}^2}} \right)^{0.283} - 1 \right] \times \left(\frac{1 \text{W}}{1 \frac{\text{J}}{\text{s}}} \right)$$

$$= 23 \text{ kW per tank}$$

The total blower power required for three tanks in series with a retention time of 1 hour is 69 kW. The power consumption for the single tank is 272 kW, which is significantly larger than the three-tank design. ▲

Example 6-5 Ozone Absorption Problem

A diffused ozone system with a retention time of 15 minutes is set up to apply ozone to surface water at a dosage of 3.0 mg/L. Air is used to generate the ozone at a generation rate of 0.02 mg $\text{O}_3/\text{mg O}_2$. The water flow rate is 0.32 m^3/s (7.2 mgd). The temperature of the system (water and air) is 23°C and the pressure is 1 atm. Ozone properties are provided below. The tank manufacturer has provided the clean water oxygen transfer test data needed to estimate $K_L a_{\text{O}_2}$. This information is shown below.

Assuming that the decay rate of ozone in the water is negligible, determine the effluent concentration of the ozone in the exiting gas, y_e , and in the water. (Note that one can account for the decay rate by incorporating a first-order reaction term in Eq. 6-58 and solving).

Properties of Ozone		Manufacturer's Clean Water Oxygen Transfer Test Data for a Tank	
Property	Value	Property	Value
Molecular weight (mg/mmol)	48.0	SOTR (kg O ₂ /day)	1500
Henry's constant (-)	3.77	Volumetric air-flow rate (m ³ /hr)	1700
Liquid diffusivity (m ² /s)	1.7×10^{-9}	Test tank volume (m ³)	500
		Tank depth (m)	3

Solution

1. Calculate the air flow rate, \dot{V} .

$$\dot{V} = \frac{Q \cdot \text{dosage}}{\rho_a \cdot (\% \text{O}_3 \text{ in Air})} = \frac{(0.32 \frac{\text{m}^3}{\text{s}} \times \frac{1000 \text{ L}}{\text{m}^3}) \cdot 3 \frac{\text{mg}}{\text{L}}}{1.19 \frac{\text{kg air}}{\text{m}^3} \cdot \left[(0.02 \frac{\text{mg O}_3}{\text{mg O}_2}) (0.21 \frac{\text{mg O}_2}{\text{mg air}}) \right] \cdot (10^6 \frac{\text{mg air}}{\text{kg air}})} = 0.19 \frac{\text{m}^3}{\text{s}}$$

2. Find the volume of the tank, V .

$$V = \tau \cdot Q = (15 \text{ min}) \left(0.32 \frac{\text{m}^3}{\text{s}} \times \frac{60 \text{ s}}{\text{min}} \right) = 288 \text{ m}^3$$

3. Find the oxygen mass transfer coefficient, $K_L a_{\text{O}_2}$.
(See Steps 2a through 2e in previous problem.)

- a. Find $K_L a_{\text{O}_2}$.

$$K_L a_{\text{O}_2} = K_L a_{20}^* (1.024)^{T-20} = 0.00408 \frac{1}{\text{s}} (1.024)^{23-20} = 0.00438 \frac{1}{\text{s}}$$

4. Find the liquid diffusivities of oxygen and ozone.

- a. Calculate the liquid diffusivity of oxygen using the correlation of Holmén and Liss (1984).

$$D_i(\text{O}_2) = 10^{\left(3.15 - \frac{831}{296 \text{ K}}\right)} \times \left(1.0 \times 10^{-9} \frac{\text{m}^2}{\text{s}}\right) = 2.20 \times 10^{-9} \frac{\text{m}^2}{\text{s}}$$

5. Find the overall mass transfer coefficient for ozone, $K_L a_{\text{O}_3}$.

$$\begin{aligned} K_L a_{\text{O}_3} &= K_L a_{\text{O}_2} \left(\frac{D_{L,\text{O}_3}}{D_{L,\text{O}_2}} \right)^{0.6} \left[1 + \frac{1}{H_i(100)} \right]^{-1} \\ &= 0.00438 \frac{1}{\text{s}} \left(\frac{1.7 \times 10^{-9}}{2.2 \times 10^{-9}} \right)^{0.6} \left[1 + \frac{1}{3.77(100)} \right]^{-1} = 3.7 \times 10^{-3} \frac{1}{\text{s}} \end{aligned}$$

6. Calculate y_e .

$$y_e = \frac{y_0}{1 + \left[\frac{1}{H \frac{\dot{V}}{Q} (1 - e^{-\phi})} \right]} = \frac{3 \frac{\text{mg}}{\text{L}}}{1 + \left\{ 1 / \left[3.77 \left(\frac{0.189}{0.315} \right) \left(1 - e^{-\frac{0.0037 \frac{1}{\text{s}} \cdot 284 \text{ m}^3}{3.77 \cdot 0.189 \frac{\text{m}^3}{\text{s}}}} \right) \right] \right\}} = 1.75 \frac{\text{mg}}{\text{L}}$$

7. Calculate C_e assuming no ozone reaction.

$$C_e = \frac{\dot{V}}{Q} (y_0 - y_e) = \left(\frac{0.19}{0.32} \right) (3 - 1.90) \frac{\text{mg}}{\text{L}} = 0.65 \frac{\text{mg}}{\text{L}} \quad \blacktriangle$$

SURFACE AERATION

Surface aeration has been used primarily for oxygen absorption and the stripping of gases and volatile contaminants when the required removals are less than about 90 percent. Surface aeration devices consist of the brush or turbine types shown in Fig. 6-16. The brush-type aerator consists of several brushes attached to a rotary drum that is half submerged in water in the center of the tank. As the drum rotates it disperses the water into the surrounding air, providing reasonable contact between the air and water for mass transfer to take place. The turbine-type aerator consists of a submerged propeller system located in the center of the tank and surrounded by a draft tube. As the submerged propeller rotates it draws water from outside the draft tube through the inner section and into the air, creating contact between the air and water. These types of systems have been extensively used in the aeration of wastewater, and their design and operation have been well documented (WEF-ASCE, 1991).

FIGURE 6-16 Schematic of various surface aeration devices.

Governing Equations

Figure 6-17 displays a schematic of a surface aeration system for a single tank. Model development for air stripping using surface aeration has been described in the literature (Matter-Müller, Gujer, and Giger, 1981; Roberts and Dändliker, 1983; Roberts, Munz, and Dändliker, 1984; Roberts and Levy, 1985; Munz and Roberts, 1989). The development of the process design equations incorporate the following assumptions: (1) the tank is completely mixed in the liquid phase, (2) the gas-phase concentration of the contaminant in the tank equals zero, (3) the process is at steady state, and (4) Henry's constant applies. Incorporating these assumptions into an overall mass balance around the tank shown in Fig. 6-17 yields the following expression (Hokanson, 1996):

$$QC_o - QC_e - K_L a C_e V = 0 \quad (6-82)$$

FIGURE 6-17 Schematic of a mechanical surface aerator used for the development of the design equation for a single tank.

Solving Eq. 6-82 for V results in the minimum tank volume required for a single tank to meet the treatment objective, C_e :

$$V = \frac{Q(C_o - C_e)}{K_L a C_e} \quad (6-83)$$

Alternatively, Eq. 6-83 can be expressed in terms of the hydraulic retention time, τ , where τ is equal to V/Q . Substituting this relationship into Eq. 6-83 gives:

$$\tau = \frac{(C_o - C_e)}{K_L a C_e} \quad (6-84)$$

If the removal of a given contaminant is required for an existing tank, Eq. 6-83 or Eq. 6-84 can be solved for C_e to yield:

$$C_e = \frac{C_o}{1 + K_L a \left(\frac{V}{Q}\right)} = \frac{C_o}{1 + K_L a \tau} \quad (6-85)$$

The process performance can be improved significantly with less total volume requirement by configuring the surface aeration system as tanks in series. Figure 6-18 shows a schematic of a surface aeration system operated with a tanks-in-series configuration. From the tanks-in-series development presented in Chap. 4, if it is assumed that all the tanks are equally sized and the assumptions for a single-tank system are also valid here, the effluent concentration for n tanks in series using surface aeration is expressed as:

$$C_n = \frac{C_{n-1}}{1 + K_L a \left(\frac{V}{Q}\right)} = \frac{C_o}{\left[1 + K_L a \left(\frac{V}{Q}\right)\right]^n} \quad (6-86)$$

FIGURE 6-18 Schematic of tanks in a series surface aeration system.

in which C_n is the effluent contaminant concentration from tank n and C_{n-1} is the effluent concentration from tank $n - 1$.

Equation 6-86 is the general expression for the effluent concentration for a surface aeration system consisting of tanks in series. Solving Eq. 6-86 in terms of the volume for each individual tank yields:

$$V = \frac{Q}{K_L a} \left[\left(\frac{C_o}{C_n} \right)^{1/n} - 1 \right] \quad (6-87)$$

Substitution of τQ for V into Eq. 6-87 yields the hydraulic retention time, τ , for each tank in series:

$$\tau = \frac{1}{K_L a} \left[\left(\frac{C_o}{C_n} \right)^{1/n} - 1 \right] \quad (6-88)$$

The total volume for all tanks, V_n , can be obtained by multiplying both sides of Eq. 6-88 by n :

$$V_n = V \times n = \frac{nQ}{K_L a} \left[\left(\frac{C_o}{C_n} \right)^{1/n} - 1 \right] \quad (6-89)$$

Likewise, the total hydraulic retention time, τ_n , for all tanks can be obtained by multiplying both sides of Eq. 6-89 by n :

$$\tau_n = \tau \times n = \frac{n}{K_L a} \left[\left(\frac{C_o}{C_n} \right)^{1/n} - 1 \right] \quad (6-90)$$

Because the quantities V , V_n , τ , and τ_n are not independent, calculation of one of these variables from the above equations allows for determination of the other three parameters because the flow rate, Q , and the number of tanks are specified.

The $K_L a$ for surface aeration can be calculated using Eq. 6-74. A value of 0.5 is recommended for the diffusivity exponent, m , and a value of 40 is recommended for the ratio k_s/k_l (Munz and Roberts, 1989). The overall mass transfer coefficient for oxygen can be estimated using the following correlation (Roberts and Dändliker, 1983):

$$K_L a_{O_2} = 2.9 \times 10^{-5} \left(\frac{P}{V} \right)^{0.95} \quad (6-91)$$

where P/V is the power input per unit tank volume (W/m^3). Equation 6-91 is valid for P/V values between 10 and $200 W/m^3$, and it is assumed the reactor is completely mixed. The liquid diffusivity of oxygen can be calculated using the correlation of Hayduk and Laudie (1974).

The total power required for surface aeration is estimated based on the power supplied to the aerators. The following equation can be used to calculate the power requirements:

$$P_{\text{surface}} = \left(\frac{P}{V}\right) \frac{V \times n_{\text{tanks}}}{1000 \text{Eff}_s} \tag{6-92}$$

in which Eff_s is the surface aerator motor efficiency.

Example 6-6 Surface Aeration

An existing clearwell is to be modified to include a surface aeration system capable of reducing radon concentration from 3000 pCi/L to less than 300 pCi/L. The total volume of the clearwell is $3785 m^3$ (1 Mgal) (depth = 5.0 m, length = 30 m, width = 25 m). The average plant flow rate is $0.22 m^3/s$ (5 mgd) and the water temperature is $20^\circ C$. The chemical and physical properties of radon are summarized below.

Determine the power input per unit tank volume and the total power input for aeration of the whole clearwell. Assuming the clearwell can be modified into individual tanks in series, determine the power input per unit tank volume and the total power input for aeration assuming a total retention time of 1.5 hours. Assume the blower efficiency is 30 percent.

Chemical and Physical Properties of Radon at $20^\circ C$.

Property	Value
Molecular weight (g/mole)	222
D_g (m^2/s)	2.0×10^{-5}
D_l (m^2/s)	1.4×10^{-9}
H (-)	4.08

Solution

1. Determine the overall mass transfer coefficients for radon by first assuming a power input per unit volume of $35 W/m^3$.

a. Calculate the liquid diffusivity of oxygen using the correlation of Holmén and Liss (1984).

$$D_l(O_2) = 10^{\left(3.15 - \frac{831}{293^2 K}\right)} \times \left(1.0 \times 10^{-9} \frac{m^2}{s}\right) = 22 \text{ } 0 \times 10^{-9} \frac{m^2}{s}$$

b. Calculate $K_L a$ (O_2) using Eq. 6-91,

$$K_L a(O_2) = 2.9 \times 10^{-5} \times \left(\frac{P}{V}\right)^{0.95} = 2.9 \times 10^{-5} \times \left(35 \frac{W}{m^3}\right)^{0.95} = 8.5 \times 10^{-4} s^{-1}$$

c. Calculate $K_L a$ for radon using Eq. 6-90.

$$K_L a(\text{radon}) = 8.5 \times 10^{-4} s^{-1} \left(\frac{1.4 \times 10^{-9} \frac{m^2}{s}}{2.07 \times 10^{-9} \frac{m^2}{s}}\right)^{0.6} \left[1 + \frac{1}{(4.08)(40)}\right]^{-1} = 6.7 \times 10^{-4} s^{-1}$$

2. Calculate the surface aeration removal efficiency using Eq. 6-85.
 Volume of clearwell = 3785 m³
 Average flow = 0.22 m³/s

$$C_e(\text{radon}) = \frac{3000 \frac{\text{pCi}}{\text{L}}}{1 + (6.7 \times 10^{-4} \text{ s}^{-1}) \left(\frac{3785 \text{ m}^3}{0.22 \frac{\text{m}^3}{\text{s}}} \right)} = 239 \frac{\text{pCi}}{\text{L}}$$

For a P/V of 35 W/m³, the radon effluent concentration is less than the treatment objective of 300 pCi/L. The above calculation can be repeated using a slightly lower P/V value, but the solution is conservative.

3. Calculate the total power requirements for one tank using Eq. 6-92.

$$P = \left(35 \frac{\text{W}}{\text{m}^3} \right) \left(\frac{3,785 \text{ m}^3}{0.30} \right) \left(\frac{1 \text{ kW}}{1000 \text{ W}} \right) = 442 \text{ kW}$$

4. Calculate the P/V requirement for the system of three tanks in series using Eq. 6-92 and assuming a total retention time of 1.5 hours (90 minutes).

$$\text{Assume } \frac{P}{V} = 35 \frac{\text{W}}{\text{m}^3}$$

$$C_e(\text{radon}) = \frac{3000 \frac{\text{pCi}}{\text{L}}}{\left[1 + 6.7 \times 10^{-4} (30 \text{ min}) \left(\frac{60 \text{ s}}{\text{min}} \right) \right]^3} = 279 \frac{\text{pCi}}{\text{L}}$$

5. Converting a portion of the clearwell volume into three tanks of equal size in series yields an effluent radon concentration equal to 279 pCi/L. The total power requirement can be calculated as:

$$\left\{ \begin{array}{l} \text{Total volume of} \\ \text{the 3 tank system} \end{array} \right\} = \left(0.22 \frac{\text{m}^3}{\text{s}} \right) \left(\frac{33600 \text{ s}}{\text{hr}} \right) (1.5 \text{ hr}) = 1188 \text{ m}^3$$

$$\left\{ \begin{array}{l} \text{Total power requirement} \\ \text{for the 3 tank system} \end{array} \right\} = \left(35 \frac{\text{W}}{\text{m}^3} \right) \left(\frac{1188 \text{ m}^3}{0.3} \right) \left(\frac{1 \text{ kW}}{1000 \text{ W}} \right) = 139 \text{ kW}$$

A modification of a small portion of the clearwell to incorporate the three tanks in series system as opposed to aeration of the whole clearwell could reduce the power costs by about 69 percent. ▲

SPRAY AERATORS

Spray aerators have been used in water treatment for many years to oxygenate groundwater in order to remove iron and manganese and for air stripping of gases (i.e., carbon dioxide, hydrogen sulfide) and VOCs. Effective iron oxidation by aeration usually requires at least 1 hour of retention time after aeration. Manganese oxidation by aeration is slow and not practical for waters with pH values below 9.5. Manganese removal usually requires a stronger oxidant. Carbon dioxide and hydrogen sulfide removals have ranged from 50 to 90 percent depending upon the water's pH. Chapter 7 discusses oxidation processes in more detail. VOC removals have been as high as 90 percent depending upon the Henry's law constant.

Spray aerator systems consist of a series of fixed nozzles on a pipe grid. The grids can be placed in towers, commonly known as spray towers or fountains, that spray onto the surface of raw water reservoirs. Pressurized nozzles disperse fine water droplets into the surrounding air, creating a large air-to-water surface for mass transfer. Two types of pressurized spray nozzles, hollow and full cone, are commonly used in water treatment. Full-cone nozzles deliver a uniform spray pattern of droplets. The hollow-cone nozzle delivers a circular spray pattern with most of the droplets concentrated at the circumference. The hollow-cone nozzle is generally preferred over the full-cone type because it provides smaller droplets for better mass transfer, even though it has a larger pressure-drop requirement. Hollow-cone spray droplets are around 5 mm and are prone to plugging. It is recommended that in-line strainers be installed in the spray nozzle manifold to prevent plugging.

The fountain-type spray aerators have been used more widely in water treatment because they can be easily adapted to existing water treatment systems. The design approach and application of the fountain type is presented below. The design approach and application for spray towers is covered elsewhere (Crittenden et al., 2005).

Governing Equations

Figure 6-19 displays a schematic of a single fountain-type spray aerator. A design equation can be derived for estimating the removal of a volatile contaminant by performing a mass balance on a water drop while it is exposed to the air. If it is assumed that all the water drops are the same size and have the same exposure time in the air, the following mass balance can be performed:

$$\left. \begin{matrix} \text{Mass lost from} \\ \text{the water drop} \\ \text{per unit time} \end{matrix} \right\} = \left. \begin{matrix} \text{Mass transferred across} \\ \text{the air/water interface} \\ \text{of a water drop} \\ \text{per unit time} \end{matrix} \right\} \tag{6-93}$$

$$V_d \frac{dC}{dt} = K_L a [C(t) - C_s(t)] V_d \tag{6-94}$$

FIGURE 6-19 Schematic of a single fountain spray aerator.

in which V_d is equal to the volume of the drop (m^3). In spray aeration, it is assumed that the gas-phase contaminant concentration in the open air is zero. As a result of this assumption, C_s is also assumed to be zero because it is in equilibrium with the contaminant gas-phase concentration. Rearranging Eq. 6-94 and integrating over the time the drop is exposed to the air yields the following expression for the final contaminant concentration of the water drop after being exposed to the air:

$$C_e = C_o e^{-K_L a t} \quad (6-95)$$

in which C_o is the initial contaminant liquid-phase concentration ($\mu\text{g/L}$) of the drop before being exposed to the air and t is the time of contact between the water drops and the air and is dependent upon the water drop exiting velocity and trajectory. t is estimated from the following equations:

$$t = \frac{2v_d \sin \alpha}{g} \quad (6-96)$$

where α is the angle of spray measured from the horizontal (degrees), g is the acceleration due to gravity (m/s^2), and v_d is the exit velocity of the water drop from the nozzle (m/s):

$$v_d = C_v \sqrt{2gh} \quad (6-97)$$

where C_v is the velocity coefficient of the nozzle (–) and h is the total head of the nozzle (m). C_v varies from 0.4 to 0.95 and can be obtained from the nozzle manufacturer. The flow rate Q through a given nozzle is estimated from the following equation:

$$Q = C_d A \sqrt{2gh} \quad (6-98)$$

where A is the area of the nozzle opening (m^2) and C_d is the coefficient of discharge from the nozzle (dimensionless).

The overall mass transfer coefficient, K_L , is estimated from the following correlations (Higbie, 1935; Jury, 1967):

$$\text{For } \frac{2D_l t^{1/2}}{d_p} < 0.22 \quad K_L = 2 \left(\frac{D_l}{\pi t} \right)^{1/2} \quad (6-99)$$

$$\text{For } \frac{2D_l t^{1/2}}{d_p} > 0.22 \quad K_L = \frac{10D_l}{d_p} \quad (6-100)$$

where d_p is the sauter mean diameter (SMD) of the water drop (in.) (SMD is obtained by dividing the total volume of the spray by the total surface area), D_l is the contaminant liquid diffusivity (m^2/s), and t is the contact time of the water drop with the air (s).

The interfacial surface area available for mass transfer for the water drop is obtained from the following equation:

$$a = \frac{6}{d_p} \quad (6-101)$$

Example 6-7 Spray Aeration

Well water contains 1.0 mg/L of total sulfide at a pH of 6.2. The well pumps 0.063 m^3/s (1000 gpm) and the pump has the capacity to provide 28 m (91.8 ft) of head. Determine the number of nozzles required and the expected H_2S removal efficiency. It is assumed

that the water has sufficient buffer capacity to maintain the pH at 6.2 during aeration. The following information was obtained from the nozzle manufacturer: SMD = 0.10 cm, $\alpha = 90^\circ$, $C_v = 0.45$, $C_d = 0.1$, nozzle diameter = 1.25 cm.

Solution

1. Determine the number of nozzles required.

$$A_{\text{nozzle}} = \frac{\pi \left(\frac{1.25 \text{ cm}}{100 \frac{\text{cm}}{\text{m}}} \right)^2}{4} = 1.23 \times 10^{-4} \text{ m}^2$$

The flow rate through one nozzle, Q_{nozzle} , can be calculated using Eq. (6-98):

$$Q_{\text{nozzle}} = C_d A_{\text{nozzle}} \sqrt{2gh} = 0.25 (1.23 \times 10^{-4} \text{ m}^2) \sqrt{2 \left(9.81 \frac{\text{m}}{\text{s}^2} \right) (28 \text{ m})} = 7.21 \times 10^{-4} \frac{\text{m}^3}{\text{s}}$$

The number of nozzles can be calculated by dividing the total flow by the flow through each nozzle.

$$\left\{ \begin{array}{l} \text{Number of} \\ \text{nozzles} \\ \text{required} \end{array} \right\} = \frac{Q}{Q_{\text{nozzle}}} = \frac{0.063 \frac{\text{m}^3}{\text{s}}}{7.21 \times 10^{-4} \frac{\text{m}^3}{\text{s}}} = 88$$

$$K_L = 2 \left(\frac{D_t}{\pi t} \right)^{1/2} = 2 \left(\frac{1.5 \times 10^{-5} \frac{\text{cm}^2}{\text{s}}}{\pi (2.14 \text{ s})} \right)^{1/2} = 0.0031 \frac{\text{cm}}{\text{s}}$$

2. Determine the H₂S removal efficiency.

Equation 6-97 is used to calculate the velocity of the water exiting the nozzle.

$$v_d = C_v \sqrt{2gh} = 0.45 \sqrt{2 \left(9.81 \frac{\text{m}}{\text{s}^2} \right) (28 \text{ m})} = 10.6 \frac{\text{m}}{\text{s}}$$

The contact time of the water drop with the air can be calculated using Eq. 6-96.

$$t = \frac{2v_d \sin \alpha}{g} = \frac{2(10.6 \frac{\text{m}}{\text{s}}) \sin(90^\circ)}{9.81 \frac{\text{m}}{\text{s}^2}} = 2.16 \text{ s}$$

The overall liquid-phase mass transfer coefficient is calculated using Eq. 6-99.

$$\frac{2D_t t^{1/2}}{d_p} = \frac{2(1.6 \times 10^{-5} \frac{\text{cm}^2}{\text{s}})(2.14 \text{ s})^{1/2}}{0.10 \text{ cm}} = 4.68 \times 10^{-4}$$

$$4.68 \times 10^{-4} \ll 0.22$$

The interfacial area for mass transfer is calculated using Eq. 6-101.

$$a = \frac{6}{d_p} = \frac{6}{0.1 \text{ cm}} = 60 \text{ cm}^{-1}$$

Calculate $K_L a$.

$$K_L a = \left(0.0031 \frac{\text{cm}}{\text{s}} \right) (60 \text{ cm}^{-1}) = 0.19 \text{ s}^{-1}$$

The H_2S reacts with water to form both HS^- and S^{2-} , as shown by the following equations:

On the gas side, the only sulfide species is hydrogen sulfide, H_2S . On the liquid side, sulfide can exist as two species: H_2S or HS^- . Therefore, the following general relationship applies on the liquid side:

$$C_s = C_{\text{H}_2\text{S}} + C_{\text{HS}^-}$$

in which C_s is the total sulfide concentration in the liquid phase ($\mu\text{g}/\text{L}$) and is equal to the sum of $C_{\text{H}_2\text{S}}$ and C_{HS^-} . Conveniently, $C_{\text{H}_2\text{S}}$ can be related to C_s by making use of the ionization fraction, α_0 (see Chap. 3 for details), which is defined as

$$\alpha_0 = \frac{C_{\text{H}_2\text{S}}}{C_s} = \left(1 + \frac{K_{a1}}{[\text{H}^+]} + \frac{K_{a1}K_{a2}}{[\text{H}^+]^2} \right)^{-1}$$

If Eq. 6-98 is rewritten in terms of total sulfide and integrated using the same assumptions, the following expression to the effluent liquid-phase concentration of hydrogen sulfide can be written as

$$C_{se} = C_{so} e^{(-\alpha_o K_L a_{\text{H}_2\text{S}} t)}$$

in which C_{se} is the effluent liquid-phase concentration of total sulfide after spray aeration, C_{so} is the influent total liquid-phase sulfide concentration, and $K_L a_{\text{H}_2\text{S}}$ is the overall mass transfer coefficient for hydrogen sulfide. The first ionization constant, α_o , is calculated as

$$\alpha_o = \frac{C_{\text{H}_2\text{S}}}{C_s} = \left(1 + \frac{10^{-6.99}}{[10^{-6.2}]} + \frac{(10^{-6.99})(10^{-18.2})}{[110^{6.2}]^2} \right)^{-1} = 0.860$$

If the influent H_2S concentration is $1.0 \text{ mg}/\text{L}$, then the total initial sulfide concentration is

$$C_{so} = \frac{C_{(\text{H}_2\text{S})_o}}{\alpha_o} = \frac{1.0 \frac{\text{mg}}{\text{L}}}{0.860} = 1.16 \frac{\text{mg}}{\text{L}}$$

The effluent total liquid-phase sulfide concentration after stripping is calculated as:

$$C_{se} = 1.16 \frac{\text{mg}}{\text{L}} e^{(-0.860 \times 0.19 \text{ s}^{-1} \times 2.14 \text{ s})} = 0.818 \frac{\text{mg}}{\text{L}}$$

The effluent liquid-phase hydrogen sulfide concentration is:

$$C_{e,\text{H}_2\text{S}} = \alpha_o \times C_{se} = (0.860) \times \left(0.818 \frac{\text{mg}}{\text{L}} \right) = 0.703 \frac{\text{mg}}{\text{L}}$$

The H_2S removal due to stripping is calculated as

$$\left\{ \begin{array}{l} \text{H}_2\text{S removal} \\ \text{due to stripping} \end{array} \right\} = \frac{1.0 \frac{\text{mg}}{\text{L}} - 0.703 \frac{\text{mg}}{\text{L}}}{0.1.0 \frac{\text{mg}}{\text{L}}} \times 100 = 29.7\% \quad \blacktriangle$$

NOTATION FOR EQUATIONS

a	interfacial area available for mass transfer (m^2/m^3)
a_{air}	activity of component A in the gas-phase (dimensionless)
a_{aq}	activity of component A in the aqueous phase (dimensionless)
a_t	total specific surface area of the packing material (m^2/m^3)
a_w	wetted surface area of the packing material (m^2/m^3)
a_0 a_1 a_2	calculated empirical parameters (dimensionless)
A	cross sectional area (m^2)
B	microporosity constant (cm^6/cal^2)
C_b	bulk aqueous phase concentration (mg/L or mole/L)
C_e	effluent aqueous phase concentration (mg/L or mole/L)
C_f	packing factor ($1/\text{m}$)
C_i	aqueous phase concentration (mg/L or mole/L)
C_s	aqueous phase concentration at the air/water interface (mg/L or mole/L)
$C_{s,A}$	aqueous solubility of component A (mg/L)
C_s^*	aqueous phase concentration of A at the air/water interface assuming no concentration gradient in the gas-phase (mg/L or mole/L)
C_o^*	liquid phase concentration at the air/water interface in equilibrium with the exiting gas-phase concentration at the top of the tower (mg/L or mole/L)
D	tower diameter (m)
d_e	effective depth at saturation (m)
D_g	gas-phase diffusivity (m^2/s)
D_l	liquid-phase diffusivity (m^2/s)
d_p	nominal diameter of the packing material (m)
E	calculated empirical parameter (dimensionless)
Eff_b	blower efficiency (dimensionless)
F	calculated empirical parameter (dimensionless)
g	gravitational constant (9.81 m/s^2)
G_m	air mass loading rate ($\text{kg}/\text{m}^2\cdot\text{s}$)
H	Henry's law constant of component A ($\text{atm}\cdot\text{L}/\text{mole}$)
H_o	Henry's law constant for oxygen ($\text{atm}\cdot\text{mole}/\text{L}$)
H_{app}	apparent Henry's law constant ($\text{atm}\cdot\text{L}/\text{mole}$)
HTU	height of transfer unit (dimensionless)
I	ionic strength (mole/L or mg/L)
J_A	mass flux of component A ($\text{kg}/\text{m}^2\cdot\text{s}$)
k_l	liquid-phase mass transfer coefficient (m/s)
k_g	gas-phase mass transfer coefficient (m/s)
k_p	constant ($275 \text{ N}\cdot\text{s}/\text{m}^4$)
K	Boltzmann's constant, (joule/K)

K_{eq}	equilibrium constant (dimensionless)
K_G	overall mass transfer coefficient (m/s)
$K_{G,a}$	overall mass transfer coefficient (1/s)
K_L	overall mass transfer coefficient (m/s)
$K_{L,a}$	overall mass transfer coefficient (1/s)
$K_L a_{O_2}$	overall mass transfer coefficient for oxygen (1/s)
K_s	Setschenow constant (L/mole)
L	depth of packing in tower (m)
L_m	water mass loading rate (kg/m ² ·s)
m	diffusivity exponent (dimensionless)
M	molecular weight of the VOC (gm/mole)
M_a	molecular weight of air (gm/mole)
M_o	molecular weight of oxygen (gm/mole)
n_a	constant in determining blower brake power (dimensionless)
NTU	number of transfer units (dimensionless)
P	partial pressure (N/m ²)
$P_{ambient}$	ambient air pressure (N/m ²)
P_A	pressure A exerts in the gas-phase (atm)
P_b	barometric pressure (atm)
P_{blower}	blower brake power (kW)
P_{in}	inlet air pressure to packed tower (N/m ²)
P_{out}	outlet air pressure from packed tower (N/m ²)
P_{pump}	pump power requirement (kW)
P_s	saturation vapor pressure (N/m ²)
P_s	barometric pressure under standard conditions (1 atm)
$P_{v,A}$	vapor pressure of pure component A (atm)
q	solid-phase VOC concentration (mg/gm or μ mole/gm)
Q	water flow rate (m ³ /s)
r_A	radius of a molecule A (nm)
r_B	characteristic radius of the gas medium (nm)
r_{AB}	molecular separation at collision (nm)
R	universal gas constant 1.987 kcal/mole·K
R_g	universal gas constant (0.08205 L · atm/mole·K)
R_G	gas-phase mass transfer resistance (dimensionless)
R_L	liquid-phase mass transfer resistance (dimensionless)
R_T	overall resistance due to mass transfer (dimensionless)
S	stripping factor (dimensionless)
T	temperature (°C)
T_b	boiling temperature of molecule (K)
V	volume of bed or tank (m ³)

\dot{V}	gas flow rate (m ³ /s)
V_b	molar volume of a compound at the boiling point (cm ³ /mole)
W	adsorption space or pore volume occupied by the adsorbate (cm ³ /gm)
W_o	maximum adsorption space (cm ³ /gm)
y_b	bulk gas phase concentration (mg/L or mole/L)
y_s	gas phase concentration at the air/water interface (mg/L or mole/L)
γ_A	activity coefficient of component A in the aqueous phase (dimensionless)
y_s^*	gas-phase concentration at the air/water interface in equilibrium with the with the bulk aqueous phase concentration (mg/L or mole/L)
z	packing depth (m)
Z_i	charge of species i (dimensionless)
α	polarizability of the VOC (m ³ /kg)
ΔH°	standard enthalpy change in water due (kcal/kmole)
ΔP	gas pressure drop (N/m ²)
μ_L	viscosity of water (N·s/m ²)
μ_g	viscosity of air (N·s/m ²)
ρ_l	density of water (kg/m ³)
ρ_g	density of air (kg/m ³)
σ	surface tension of water (kg/s ²)
σ_c	critical surface tension of the packing material (kg/s ²)
ϵ_A	force constant of molecule (Joule)
ϵ	adsorption potential (cal/mole)
ρ_L	liquid density of VOC (gm/L)
η	refractive index of the VOC (dimensionless)
ρ_a	density of air at 20°C
ϕ	Stanton number (dimensionless)

INTRODUCTION

Chemical oxidation processes play several important roles in the treatment of drinking water. Chemical oxidants are used for the oxidation of: reduced inorganic species, such as ferrous iron [Fe(II)], manganous manganese [Mn(II)], and sulfide [S(-II)]; hazardous synthetic organic compounds, such as trichloroethene (TCE) and atrazine; and other emerging contaminants, such as methyl-*tert*-butyl-ether (MTBE), pharmaceutically active compounds and personal care products (PPCPs), endocrine disrupting chemicals (EDCs) and

algal toxins. Oxidants can also be used to destroy taste and odor-causing compounds and eliminate color. In addition, in some cases, they may improve the performance of, or reduce the required amount of coagulants. Because many oxidants also have biocidal properties, these oxidants can be used to control nuisance aquatic growths, for example, algae, in pre-treatment basins and may be used as primary disinfectants to meet $C \times T$ (disinfectant concentration times contact time) requirements (see Chap. 17). Oxidants are often added at the head of the treatment plant, prior to or at the rapid mix basin, but they can also be employed after clarification, prior to filtration, after a substantial portion of oxidant-demanding natural organic matter (NOM) has been removed.

The most common chemical oxidants used in water treatment are chlorine, ozone, chlorine dioxide, and permanganate. Ozone is sometimes used in conjunction with hydrogen peroxide or ultraviolet irradiation in what are called advanced oxidation processes (AOPs) to produce radicals that have powerful oxidative properties. Mixed oxidant technologies are also available.

Free chlorine has traditionally been the oxidant (and disinfectant) of choice in the United States, but concerns about the formation of potentially harmful halogenated disinfection by-products (DBPs; see Chap. 19) produced by reactions between free chlorine and NOM (exacerbated in some cases by the presence of bromide) have caused many water systems to adopt alternative chemical oxidants (and disinfectants) to lower halogenated DBP formation.

These other oxidants may also react with NOM and bromide to various degrees, depending on the properties of the oxidant, to form oxidation by-products, some of which also have adverse public health effects or result in downstream operational problems in the treatment plant or distribution system.

This chapter reviews thermodynamic and kinetic principles associated with the use of chemical oxidants in general, the types and properties of the chemical oxidants used in water treatment, and specific applications of oxidation processes for the treatment of drinking water. Comparisons among the different oxidant choices are presented where information is available.

PRINCIPLES OF OXIDATION

Thermodynamic Considerations

Thermodynamics establishes the feasibility or constraints of chemical reactions such as oxidation reactions. Chemical kinetics describes the rate of the reactions and pathways or mechanisms by which the reactions occur. Thermodynamic properties of the reactants, such as free energies, enthalpies, and entropies, provide a starting point for characterizing and understanding oxidation reactions. In this section, basic thermodynamic concepts relating to oxidation reactions are presented. Additional background is provided in Chap. 3. For a more comprehensive treatment of the subject, there are many excellent physical chemistry textbooks that can be consulted, for example, Atkins (1994).

Electrochemical Potentials. Oxidation reactions are often viewed as reactions involving the exchange of electrons. While it is sometimes convenient to think of oxidants as electron acceptors and reductants as electron donors, many oxidants actually donate an electron-poor element or chemical group, rather than simply accept a lone electron. Nevertheless, it is useful to treat all oxidation reactions as simple electron transfers for the purpose of balancing equations and performing thermodynamic calculations.

Thermodynamic principles can be used to determine if specific oxidation reactions are possible. This generally involves the calculation of some form of reaction potential. Although in most cases oxidation equilibria lie far to one side or the other, it is sometimes instructive to calculate equilibrium concentrations of the reactants and products.

The first step is to identify the species being reduced and those being oxidized. Appropriate half-reactions and their standard reduction and oxidation potentials (E_{red}° and E_{ox}° , respectively) are available in tables of thermodynamic constants. Important reduction and oxidation half-reactions in water treatment are listed, respectively, in Tables 7-1 and 7-2. Table 7-1 lists common oxidants that accept electrons from reducing agents, while Table 7-2 gives illustrative reducing agents that donate electrons and are subsequently oxidized. Oxidation and reduction half-reactions may be combined to get the overall standard reaction potential E_{net}° .

$$E_{\text{net}}^{\circ} = E_{\text{ox}}^{\circ} + E_{\text{red}}^{\circ} \tag{7-1}$$

Much as an acidity constant describes the tendency of an acid to give up a proton, the reduction and oxidation potentials (E_{red}° and E_{ox}° , respectively) describe the tendency of an

TABLE 7-1 Standard Half-Cell Potentials for Chemical Oxidants Used in Water Treatment at 25°C

Oxidant	Reduction half-reaction	E_{red}° , volts
Ozone	$\frac{1}{2}\text{O}_{3(\text{aq})} + \text{H}^+ + e^- \rightarrow \frac{1}{2}\text{O}_{2(\text{aq})} + \frac{1}{2}\text{H}_2\text{O}$	2.04
Hydrogen peroxide	$\frac{1}{2}\text{H}_2\text{O}_2 + \text{H}^+ + e^- \rightarrow \text{H}_2\text{O}$	1.78
Hydroxyl radical	$\text{OH} + \text{H}^+ + e^- \rightarrow \text{H}_2\text{O}$	2.59
Permanganate	$\frac{1}{5}\text{MnO}_4^- + \frac{1}{5}\text{H}^+ + e^- \rightarrow \frac{1}{5}\text{MnO}_{2(\text{s})} + \frac{1}{5}\text{H}_2\text{O}$	1.68
Ferrate	$\frac{1}{6}\text{FeO}_4^{2-} + \frac{1}{6}\text{H}^+ + e^- \rightarrow \frac{1}{6}\text{Fe}(\text{OH})_{3(\text{s})} + \frac{1}{6}\text{H}_2\text{O}$	2.07
Chlorine dioxide	$\text{ClO}_2 + e^- \rightarrow \text{ClO}_2^-$	1.15
Hypochlorous acid	$\frac{1}{2}\text{HOCl} + \frac{1}{2}\text{H}^+ + e^- \rightarrow \frac{1}{2}\text{Cl}^- + \frac{1}{2}\text{H}_2\text{O}$	1.49
Hypochlorite ion	$\frac{1}{2}\text{OCl}^- + \text{H}^+ + e^- \rightarrow \frac{1}{2}\text{Cl}^- + \frac{1}{2}\text{H}_2\text{O}$	0.90
Hypobromous acid	$\frac{1}{2}\text{HOBr} + \frac{1}{2}\text{H}^+ + e^- \rightarrow \frac{1}{2}\text{Br}^- + \frac{1}{2}\text{H}_2\text{O}$	1.33
Hypoiodous acid	$\frac{1}{2}\text{HOI} + \frac{1}{2}\text{H}^+ + e^- \rightarrow \frac{1}{2}\text{I}^- + \frac{1}{2}\text{H}_2\text{O}$	0.98
Monochloramine	$\frac{1}{2}\text{NH}_2\text{Cl} + \text{H}^+ + e^- \rightarrow \frac{1}{2}\text{Cl}^- + \frac{1}{2}\text{NH}_4^+$	1.40
Dichloramine	$\frac{1}{4}\text{NHCl}_2 + \frac{3}{4}\text{H}^+ + e^- \rightarrow \frac{1}{2}\text{Cl}^- + \frac{1}{4}\text{NH}_4^+$	1.34
Oxygen	$\frac{1}{4}\text{O}_{2(\text{aq})} + \text{H}^+ + e^- \rightarrow \frac{1}{2}\text{H}_2\text{O}$	1.27

oxidant to take up an electron (Table 7-1) or a reductant to give one up (Table 7-2). The standard Gibbs free energy of a reaction (ΔG°) is related to the standard electrochemical potential by Faraday's constant ($F = 96.5 \text{ kJ/coul}$) and the number n of electrons transferred.

$$\Delta G^\circ = -nFE_{\text{net}}^\circ \quad (7-2)$$

For one-electron transfer reactions such as those shown in Tables 7-1 and 7-2, this becomes

$$\Delta G^\circ (\text{kJ}) = -96.5 E_{\text{net}}^\circ (\text{V}) \quad (7-3)$$

Classical thermodynamics indicates that reactions with a negative Gibbs free energy (or a positive E_{net}°) are feasible and will spontaneously proceed in the direction as written (i.e., from left to right), and those with a positive Gibbs free energy (or negative E_{net}°) are not feasible and will proceed in the reverse direction.

Consider a generic oxidation reaction

where substance A (an oxidant) accepts electrons from substance B (a reductant). The coefficients a and b are stoichiometric coefficients that are required to balance the reaction. In order to determine which substance is being reduced and which is being oxidized, one must calculate and compare oxidation states of the reactant atoms and product atoms (see Chap. 3 and below).

The equilibrium constant K for this reaction defines the relative concentrations of the reactants and products at equilibrium.

$$K = \frac{(A_{\text{red}})^a (B_{\text{ox}})^b}{(A_{\text{ox}})^a (B_{\text{red}})^b} \quad (7-5)$$

The overall standard electrochemical potential for the reaction is then directly related to this equilibrium constant by

$$E_{\text{net}}^\circ = \frac{RT}{nF} \ln K \quad (7-6)$$

For a one-electron transfer reaction at 25°C, this simplifies to

$$\log K = \frac{1}{0.059} E_{\text{net}}^\circ \quad (7-7)$$

Oxidation-Reduction Reactions

Oxidation state. An oxidation state is characterized by an oxidation number, which is the charge one would expect for an atom if it were to dissociate from the surrounding molecule or ion (assigning any shared electrons to the more electronegative atom). Oxidation number may be either a positive or negative number, usually an integer between $-VII$ and $+VII$, although in their elemental forms, for example, $S(s)$ and $O_2(aq)$, atoms have an oxidation number of zero. This concept is useful in balancing chemical equations and performing certain calculations.

Balancing equations. The first step in working with oxidation reactions is to identify the roles of the reacting species. At least one reactant must be the oxidizing agent (i.e., contain an atom or atoms that accept electrons and get chemically reduced), and at least

one must be a reducing agent (i.e., contain an atom or atoms that lose electrons and become oxidized). The second step is to balance the gain of electrons by the oxidizing agent with the loss of electrons from the reducing agent. Next, oxygen atoms are balanced by adding water molecules to one side of the reaction or the other as needed, and hydrogen atoms are balanced with H⁺ ions. For a more detailed treatment of oxidation reactions, the reader is referred to a general textbook on aquatic chemistry (e.g., Jensen, 2003; Benjamin, 2002; Stumm and Morgan, 1996).

Example 7-1 Oxidation of Reduced Manganese by Ozone

Write a balance stoichiometric reaction for the oxidation of reduced (manganous) manganese by ozone and determine if the reaction is thermodynamically feasible under typical water treatment conditions.

Solution Equation 7-8 shows the species involved in the reaction. The substance being oxidized (losing electrons) is manganese (i.e., the reducing agent), and the one doing the oxidizing (i.e., gaining electrons and being reduced) is ozone.

Next, the products formed need to be evaluated. It might be known from experience that soluble manganous manganese (i.e., Mn²⁺) can be oxidized in water to the relatively insoluble manganese dioxide. It might also be known that ozone ultimately forms hydroxide and oxygen after it becomes reduced.

The next step is to determine the oxidation state of all atoms involved.

From this analysis, it is clear that manganese is oxidized from +II to +IV, which involves a loss of two electrons per atom. On the other side of the ledger, the ozone undergoes a gain of two electrons per molecule, as one of the three oxygen atoms goes from an oxidation state of 0 to -II. The two separate half-reactions can be written as single electron transfers, as shown in Tables 7-1 and 7-2. Each half-reaction is balanced by adding water molecules and/or H⁺ ions as needed to balance oxygen and hydrogen, respectively. For the oxidation half-reaction:

By convention, when hydroxide appears in a half-reaction, additional H⁺ ions are added until all of the hydroxide is converted to water. This is done for the reduction half-reaction as follows:

From this point, it is a simple matter of combining the equations and canceling out terms or portions of terms that appear on both sides. At the same time, the standard

electrode potentials from Tables 7-1 and 7-2 can be combined to get the overall standard potential for the net reaction:

The balanced reaction indicates that 1 mole of soluble manganous manganese requires 1 mole of ozone to oxidize it to insoluble manganese dioxide. Further, the oxidation reaction produces two protons for each mole of manganous manganese oxidized, resulting in a reduction in pH and the consumption of two equivalents of alkalinity.

It can also be seen that the reaction is thermodynamically feasible and will proceed toward the right (the E_{net}° is positive). But how far to the right will the reaction proceed? To answer this, Eq. 7-7 is rearranged to get

$$K = e^{16.95E_{\text{net}}^{\circ}} \quad (7-14)$$

So for this reaction,

$$K = e^{16.95(0.83)} = 1.29 \times 10^6 \quad (7-15)$$

Using the concentration quotient (see Eq. 7-5) and the reaction stoichiometry:

$$1.29 \times 10^6 = \frac{[\text{O}_{2(\text{aq})}]^{0.5} [\text{MnO}_{2(s)}]^{0.5} [\text{H}^+]}{[\text{O}_{3(\text{aq})}]^{0.5} [\text{Mn}^{2+}]^{0.5} [\text{H}_2\text{O}]^{0.5}} \quad (7-16)$$

Because the activity of solvents (i.e., water) and solid phases are, by convention, equal to 1, Eq. 7-16 reduces to

$$1.29 \times 10^6 = \frac{[\text{O}_{2(\text{aq})}]^{0.5} [\text{H}^+]}{[\text{O}_{3(\text{aq})}]^{0.5} [\text{Mn}^{2+}]^{0.5}} \quad (7-17)$$

If the pH is 7.0 and a dissolved oxygen concentration of 10 mg/L and an ozone concentration of 0.5 mg/L is achieved in the ozonated water, an equilibrium Mn^{2+} concentration of 1.8×10^{-25} M, or about 10^{-27} mg/L can be calculated. Thermodynamic principles therefore indicate that this reaction essentially goes to completion.

Knowing that the Mn^{2+} should react completely to form manganese dioxide, it might be informative to determine if ozone can oxidize the manganese dioxide to a higher oxidation state, i.e. permanganate. To examine this possibility, the reduction equation for ozone must be combined with the reverse of the permanganate reduction equation (from Table 7-1) to get the net reaction

This allows the net potential to be calculated.

$$E_{\text{net}}^{\circ} = E_{\text{ox}}^{\circ} + E_{\text{red}}^{\circ} = (-1.68 \text{ V}) + (+2.04 \text{ V}) = +0.36 \text{ V} \quad (7-19)$$

Again, this is a thermodynamically favorable reaction. The equilibrium constant is

$$\log K = \frac{1}{0.059} E_{\text{net}}^{\circ} = \frac{1}{0.059} (+0.36 \text{ V}) = 6.1$$

$$K = 10^{6.1} \quad (7-20)$$

The equilibrium quotient can now be formulated directly from the balanced equation and the equilibrium constant calculated.

$$K = \frac{[A_{\text{red}}]^a [B_{\text{ox}}]^b}{[A_{\text{ox}}]^a [B_{\text{red}}]^b}$$

$$K = \frac{[\text{MnO}_4^-]^{0.33} [\text{H}^+]^{0.33} [\text{O}_2]^{0.5}}{[\text{O}_3]^{0.5}} = 10^{6.1} \quad (7-21)$$

Note that neither manganese dioxide (MnO_2) nor water (H_2O) appears in this quotient because both are presumed present at unit activity. Manganese dioxide is a solid and is considered to be in a pure, undiluted state as long as it remains in the system. The same may be said for water. As long as the solutes remain dilute, the concentration of water remains constant.

So, under typical conditions where the pH is near neutrality (i.e., $[\text{H}^+] = 10^{-7}$), dissolved oxygen is near saturation (i.e., $[\text{O}_{2(\text{aq})}] = 3 \times 10^{-4} \text{ M}$), and the ozone residual is 0.25 mg/L (i.e., $[\text{O}_{3(\text{aq})}] = 5 \times 10^{-6} \text{ M}$), the expected equilibrium permanganate concentration can be calculated:

$$K = \frac{[\text{MnO}_4^-]^{0.33} [10^{-7}]^{0.33} [3 \times 10^{-4}]^{0.5}}{[5 \times 10^{-6}]^{0.5}} = 10^{6.1} \quad (7-22)$$

Solving for permanganate,

$$[\text{MnO}_4^-]^{0.33} = 3.5 \times 10^7$$

$$[\text{MnO}_4^-] = 327 \quad (7-23)$$

Obviously one cannot have 327 moles/L of permanganate. The example illustrates that the reaction will proceed in this direction so that all of the manganese dioxide would be converted to permanganate. Once the manganese dioxide is depleted, the reaction must stop. This simple example explains why permanganate is produced when water containing dissolved manganous manganese is subjected to ozonation during water treatment (see applications below). ▲

Some other examples illustrating the balancing of oxidation/reduction equations that are relevant to water treatment, using the half-reactions in Tables 7-1 and 7-2 and their corresponding oxidation and reduction potentials, include:

1. The reduction of free chlorine by sulfite, which is the common method of dechlorinating water:

2. The oxidation of ferrous iron by oxygen leading to the formation and precipitation of insoluble ferric hydroxide, which is the net reaction resulting from the aeration of water for iron removal

3. The oxidation of sulfide by chlorine, a common method for eliminating odorous sulfide from water

4. The formation of hypiodous acid from monochloramine, an important reaction in iodide containing waters associated with the formation of iodinated disinfection byproducts (see the following and Chap. 19)

In all cases, the value of the redox potential for the net reaction is positive, indicating that the reaction proceeds from left to right as written.

As already mentioned, the preceding thermodynamic analysis is useful in establishing which reactions are feasible and the relative concentrations of oxidized and reduced species when the system reaches equilibrium. However, many oxidation reactions are quite slow or, in some cases, kinetically unfavorable, so that the actual concentrations of reactants and products observed during water treatment are far from those predicted by classical thermodynamics. For this reason, kinetic considerations are extremely important in understanding which oxidation reactions occur and the extents to which they occur in water treatment.

Kinetic Considerations

Reaction Kinetics. Thermodynamics indicates whether a reaction will proceed as written. However, it does not indicate whether this reaction will produce significant change within milliseconds, hours, days, or thousands of years. For this, chemical kinetics must be considered. As an example, consider the reaction between hypochlorous acid and bromide ion:

In order for a molecule of hypochlorous acid and a molecule of bromide to react to form products, the two molecules must come into contact with each other (contact meaning approach within a certain distance so that bonding forces can take effect). The probability that a single $\text{HOCl}:\text{Br}^-$ molecular encounter will occur within any fixed time period is directly proportional to the number of molecules of each of the reactants in the system. It will also depend on the rate of movement and energy of each of the reactant molecules. As a consequence, the rate of formation of products, for example, HOBr , will be dependent on

a number of factors including the concentration of hypochlorous acid and the concentration of bromide in the reacting solution. This is in accordance with the kinetic law of mass action which is expressed mathematically in Eq. 7-29.

$$\frac{d[\text{HOBr}]}{dt} = k_f [\text{HOCl}][\text{Br}^-] \quad (7-29)$$

The reactants and products are expressed in molar units of concentration, and k_f is called the forward reaction rate constant. The units for k_f are liters/mole per unit time. The reaction rate constant is going to be a function of such factors as temperature, the rate of movement of the molecules, and the probability of HOBr formation given that a collision between hypochlorous acid and bromide has already occurred. Because the concentrations of HOCl and Br^- that appear in Eq. 7-29 are raised to the first power, it is said that this rate law is first order in both reactants. The overall order of the reaction is the sum of the individual orders (i.e., second order in this case).

A more careful examination of this reaction reveals that it probably occurs in three separate steps (Kumar and Margerum, 1987) as follows:

Since the first step is the slow one (called the *rate-limiting step*), it defines the overall rate of the three-step sequential reaction. As a result, the rate law in Eq. 7-29 is still valid even though it is not strictly speaking an elementary reaction. Like many reactions, this one can be catalyzed by the presence of proton-donating acidic solutes in solution (e.g., acetic acid, bicarbonate, dihydrogen phosphate). These are generically represented by HA in the following alternative first step of the reaction sequence. In this case, the value k_3 is a third-order constant, and dependent on the type of proton-donating species in solution.

In a more general sense, Eq. 7-30 is the rate law for any elementary reaction of the type described by Eq. 7-31.

$$-\frac{d[A]}{dt} = k_{fa} [A]^a [B]^b \quad (7-30)$$

$$aA + bB = cC + dD \quad (7-31)$$

where the capital letters represent chemical species participating in the reaction and the small letters are the stoichiometric coefficients (i.e., the numbers of each molecule or ion required for the balanced reaction). The overall order describes the extent of dependence of the reaction rate on reactant concentrations. For the reaction in Eq. 7-31, the overall order is equal to $(a + b)$. The order with respect to species A is a , and the order with respect to species B is b . Thus, the reaction in Eq. 7-28 is first order in both reactants and second order overall.

Chemical reactions may be either elementary or non-elementary. Elementary reactions are those reactions that occur exactly as they are written, without any intermediate steps. These reactions almost always involve just one or two reactants. The number of molecules or ions involved in elementary reactions is called the *molecularity* of the reaction. Thus, for all elementary reactions, the overall order equals the molecularity, as in Eqs. 7-28 and 7-31.

Nonelementary reactions involve a series of two or more elementary reactions and involve complex reaction pathways. Many environmental reactions are nonelementary in nature. In general, reactions with an overall reaction order greater than two, or reactions with a noninteger reaction order for one or more of the reactants are nonelementary.

Reaction rate constants for various oxidants with similar solutes are often positively correlated. In other words, a compound favored for oxidation by one oxidant is generally favored by others as well. Those that are relatively resistant to oxidation by one will likewise be unreactive with others. A good example is found in the extensive research done on the oxidation of phenolic compounds by Tratnyek and Hoigne (1994). These data highlight the similarities between the chemical structure of a reactant and its reactivity with various oxidants. Chemists have used such relationships to develop quantitative structure-activity relationships (QSARs). The Hammett equations are some of the most widely used QSARs. (See Brezonik, 1994, for more detail on this subject.)

Temperature Dependence. As mentioned previously, the reaction rate constant k is a function of temperature. The Arrhenius equation (Eq. 7-32) is the classic model that describes this relationship.

$$k = A e^{-E_a/RT} \quad (7-32)$$

where A is called the frequency factor or the pre-exponential factor, E_a is the activation energy, R is the universal gas constant (8.314 J/K-mole), and T is the temperature in K. The values for k and E_a may be found in the literature or determined from experimental measurements.

pH Dependence. The degree of protonation or deprotonation of reacting species is determined by the solution pH. If one form of an oxidant or reduced substance is the sole or preferred reactive form, then changes in pH can profoundly affect the overall rate of reaction. Consider the reaction of aqueous chlorine and phenol. In this case, it has been determined that only the fully protonated, hypochlorous acid (HOCl) and the deprotonated phenate ($C_6H_5O^-$) react to any appreciable degree.

Consequently, the fundamental rate equation should only include these two species. This is not very convenient, as analytical methods to measure the reactants are not species-specific and only tell us how much total free chlorine ($[\text{chlorine}]_{\text{tot}} = [\text{HOCl}] + [\text{OCl}^-]$) and total phenol ($[\text{phenol}]_{\text{tot}} = [C_6H_5OH] + [C_6H_5O^-]$) we have at any given time. Nevertheless, the ratio of a protonated form or a deprotonated form to its total concentration can be readily calculated from the pH and the acidity constant (K_a). Hence, we can reformulate the rate law as follows:

$$\begin{aligned} -\frac{d[\text{phenol}]_{\text{tot}}}{dt} &= k_2[\text{HOCl}][C_6H_5O^-] \\ &= k_2[\text{chlorine}]_{\text{tot}} \frac{[H^+]}{K_{a,Cl_2} + [H^+]} [\text{phenol}]_{\text{tot}} \frac{K_{a,phenol}}{K_{a,phenol} + [H^+]} \end{aligned} \quad (7-34)$$

The apparent or observed rate constant (k_{obs}) is equal to the product of the fundamental second-order rate constant (k_2) times the total analytical concentrations of the reactants times two pH-dependent distribution coefficient, referred to as alpha-values (α).

$$k_{\text{obs}} = k_2[\text{chlorine}]_{\text{tot}}[\text{phenol}]_{\text{tot}} \alpha_{0,Cl_2} \alpha_{1,phenol} \quad (7-35)$$

FIGURE 7-1 Illustration of the pH-dependency of the reacting species on the rate constant for the oxidation of phenol by chlorine.

The rate, therefore, takes on a pH dependence that makes the rate increase with pH until a maximum (at a pH halfway between the pK_{a, Cl_2} and the $pK_{a, phenol}$) and then declines at higher pH, as shown in Fig. 7-1.

Types of Reactions

Oxidation reactions can generally be categorized as those involving electron transfer and those involving transfer of atoms and groups of atoms. They may also be characterized as reactions involving species with paired electrons (ionic) and those involving unpaired electrons (radical). Aqueous chlorine offers a wide array of ionic reactions (e.g., Morris 1975) that will serve as illustrative examples for this discussion.

Table 7-3 presents a summary of the major types of ionic reactions of interest in drinking water. Chlorine or bromine can be added to olefinic bonds (i.e., carbon-carbon double bonds) forming halohydrins when hypochlorous acid or hypobromous acid, respectively, is added to water. This is an electrophilic reaction where the initial attack is by the halogen atom (on the positive side of the hypohalous acid (HOX) dipole). The most stable configuration places the halogen on the carbon with the most hydrogen atoms (producing the most stable carbonium ion in accordance with Markovnikov's rule). The other carbon becomes a carbanion ion, which subsequently reacts with the HO portion of the HOX species or with water.

Activated ionic substitution can occur with chlorine and bromine and both aromatic and aliphatic compounds. As with the addition reactions, this type of reaction will also lead to the formation of organohalide compounds. Aromatic substitution reactions occur readily when an electron-donating substituent is bound to the ring. Functional groups on the aromatic ring, such as OH and NH_2 , can be thought of as creating a partial negative charge on the ortho and para positions (second closest and furthest carbon atoms from the functional group, respectively). The halogen end of the HOX molecule attacks one of these carbons. Next there is a loss of the OH end of the molecule, and displacement of the H atom from

TABLE 7-3 Major Types of Ionic Reactions

Reaction type	Example
1. Addition to an olefinic bond	$\begin{array}{c} \text{H} & & \text{H} \\ & \backslash & / \\ & \text{C} = \text{C} \\ & / & \backslash \\ \text{R}_1 & & \text{R}_2 \end{array} \xrightarrow{\text{HOCl}} \begin{array}{c} \text{H} & \text{H} \\ & \\ \text{R}_1 - \text{C} - & \text{C} - \text{R}_2 \\ & \\ \text{OH} & \text{Cl} \end{array}$
2. Activated aromatic substitution	$\text{C}_6\text{H}_5\text{OH} \xrightarrow{\text{HOCl}} \text{C}_6\text{H}_4\text{OHCl} + \text{H}_2\text{O}$
3. Substitution onto nitrogen	$\text{H}-\text{N}(\text{R}_1)(\text{R}_2) \xrightarrow{\text{HOCl}} \text{Cl}-\text{N}(\text{R}_1)(\text{R}_2) + \text{H}_2\text{O}$
4. Oxidation with oxygen transfer	$\text{R}-\text{C}(=\text{O})\text{H} \xrightarrow{\text{HOCl}} \text{R}-\text{C}(=\text{O})\text{OH} + \text{H}^+ \text{Cl}^-$
5. Oxidation with electron transfer	$2 \text{Fe}^{+2} \xrightarrow{\text{HOCl}} 2 \text{Fe}^{+3} + \text{OH}^- \text{Cl}^-$

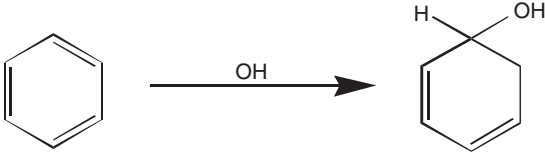

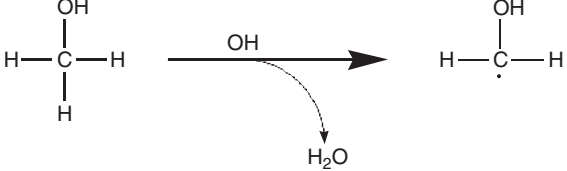

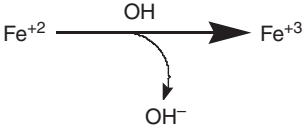

the carbon under attack. Substitution on aliphatic species is also a multi-step reaction as exemplified by the haloform reaction (see next section on pathways).

When substitution (or transfer) of a halogen occurs onto a nitrogen atom, a relatively reactive N-halo organic compound results. These compounds retain some of the oxidizing capabilities of their corresponding hypohalous acid and, consequently, the reactions are not considered to cause an oxidant demand. The rates of substitution reactions with nitrogenous organic compounds generally increase as the basicity of the nitrogen atom increases.

Oxidation reactions involving halogens are characterized by the formation of the corresponding inorganic halide ion and an oxidized (non-halogenated) form of the reacting compound. With organic compounds, it is quite common to observe addition of an oxygen atom. For example, oxidation reactions transform unsaturated hydrocarbons into alcohols, then to aldehydes and ketones, and finally to carboxylic acids. Some oxidations do not result in a net transfer of atoms. For these electron transfer reactions, it is common to form free radical intermediates. When this happens, chain reactions can occur, sometimes leading to the types of reactions in Table 7-4.

There are several types of reactions involving free-radical species that can occur following the addition of oxidants to drinking water. Free radicals are atoms, molecules, or ions

TABLE 7-4 Major Types of Radical Reactions

Reaction type	Example
6. Radical addition reaction	 <p>The reaction shows a benzene ring (a hexagon with three alternating double bonds) reacting with a hydroxyl radical (OH with a dot above it). An arrow points to the right, leading to a cyclohexadienyl radical (a hexagon with two double bonds and a carbon atom bonded to both a hydrogen atom and a hydroxyl group, with a dot on that carbon).</p>
7. Hydrogen abstraction reaction	 <p>The reaction shows a methyl radical (a central carbon atom bonded to three hydrogen atoms and a hydroxyl group, with a dot on the carbon) reacting with a hydroxyl radical (OH with a dot above it). An arrow points to the right, leading to a methanol molecule (a central carbon atom bonded to three hydrogen atoms and a hydroxyl group) and a water molecule (H₂O). A dashed arrow indicates the transfer of a hydrogen atom from the methyl radical to the hydroxyl radical.</p>
8. Radical oxidation reaction with single-electron transfer	 <p>The reaction shows Fe⁺² reacting with a hydroxyl radical (OH with a dot above it). An arrow points to the right, leading to Fe⁺³ and a hydroxide ion (OH⁻). A dashed arrow indicates the transfer of an electron from Fe⁺² to the hydroxyl radical.</p>

with unpaired electrons that cause them to be highly reactive. These types of reactions are commonly encountered with ozone, chlorine dioxide, and especially *advanced oxidation processes (AOPs)*; see below). For example, the addition of ozone will always lead to some ozone decomposition and subsequent formation of hydroxyl radicals (OH). These reactive hydroxyl radical species engage in reactions that generally lead to the formation of new free-radical species. The most common types of radical reactions are addition reactions, hydrogen abstractions, and single-electron transfers (see Table 7-4).

Catalysis. Many types of oxidation reactions are strongly affected by the presence of catalysts. Catalysts are agents that alter reaction rates without being formed or consumed in the reaction. They typically participate in some key, rate-limiting step and are regenerated during some later step. Catalysts generally provide an alternative pathway with lower activation energy so that the reaction proceeds faster.

Probably the most important catalytic processes in water treatment involve the participation of acids and bases. Specific acid and specific base catalysis involve H⁺ and OH⁻, respectively. General acid and base catalysis involves any electron acceptor (e.g., a proton donor) and electron donor (e.g., a proton acceptor), respectively. A good example of general base catalysis is the classic haloform reaction (see the next section).

Another type of catalysis that is important in oxidation processes involves the catalytic initiation of a free-radical chain reaction. Examples include the decomposition of ozone by hydroxide and the decomposition of chlorine by iron (e.g., Brezonik, 1994). In either case, the original oxidant will not react appreciably with recalcitrant compounds such as oxalate. However, in the presence of sufficient catalyst, decomposition is initiated, leading to a series of chain propagation reactions whereby oxalate can be readily converted to carbon dioxide.

Sometimes oxidation reactions are catalyzed by the presence of solid phases in the system which have the ability to adsorb one or more of the reacting species. Manganese dioxide (MnO₂(s)) is a common catalyst in the oxidation of dissolved manganous manganese (see below).

FIGURE 7-2 Ozonation of atrazine. (Source: Acero et al., 2000; reprinted with permission from the American Chemical Society, Copyright 2000.)

Reaction Pathways. Oxidation reactions in drinking water can be very complex. They may begin with one of the mechanisms just discussed, but then may be followed by a wide range of non-oxidation processes, such as elimination reactions, hydrolysis reactions, radical chain reactions, and rearrangement reactions.

The ozonation of atrazine, a commonly occurring pesticide found in many raw water sources, provides a good example of the complex reaction pathways associated with ozonation (Acero et al., 2000; see Fig. 7-2). The percentages shown represent the formation of products due to reaction with molecular ozone (O_3 ; solid lines) or with the hydroxyl radical (OH ; dashed lines). Reaction begins primarily with the attack by ozone on the nitrogen group that is in the α -position to the ethyl group, leading to the formation of an atrazine-imine (ATRA-imin) that slowly hydrolyzes to diethylatrazine (DEA) and acetaldehyde. ATRA-imin is also formed by hydroxyl radicals through hydrogen abstraction on the carbon in the α -position to the ethyl-nitrogen. The attack by ozone on the nitrogen group that is in the α -position to the isopropyl group leads to the formation of diisopropyl atrazine (DIA). DIA is also formed by hydrogen abstraction on the isopropyl side of atrazine by the hydroxyl radical, producing an imine, which readily hydrolyzes to DIA and acetone. Another major product is 4-acetamido-2-chloro-6-isopropylamino-s-triazine. At typical ozone doses, atrazine is not mineralized, and although the parent compound atrazine may be eliminated, the triazine ring persists in the daughter products. The lack of mineralization and the formation of daughter products is true for the oxidation of many organic contaminants in water (see below).

Another important reaction is the formation of trihalomethanes (see Chap. 19) which may occur through many different reaction pathways. One of the most widely discussed is the haloform reaction (Fig. 7-3), which involves the stepwise chlorine substitution of the enolate form of a methyl ketone. The rate-limiting step is the loss of a proton leading to the formation of the enol. This classic reaction begins with base-catalyzed halogenations, ultimately leading to a carboxylic acid and chloroform. It is base-catalyzed because the species that reacts with hypochlorous acid is the enol form of the methyl ketone. Although Fig. 7-3 shows the reaction being catalyzed by hydroxide, any strong base will participate. The base (or hydroxide) consumed in the first step is regenerated in the second. The enol undergoes electrophilic substitution forming a mono-halogenated intermediate. The presence of halogens on this carbon speeds subsequent enolization, which leads to complete halogenation of the α -carbon. The resulting intermediate (a trihalogenated acetyl compound) is subject to base-catalyzed hydrolysis, giving a trihalomethane and a carboxylic acid. If hypochlorous acid is the only halogenating species, chloroform is the result.

FIGURE 7-3 The haloform reaction.

Many early studies with acetone (or propanone) indicated that the rate-limiting step was the initial enolization. Once the enolate was formed, the molecule quickly proceeded through the entire reaction pathway. Thus, the reaction rate expression often cited in the chemical literature was

$$\frac{-d[\text{CH}_3\text{COCH}_3]}{dt} = k[\text{CH}_3\text{COCH}_3] \quad (7-36)$$

However, under drinking water treatment conditions (i.e., neutral pH, low chlorine residual), other steps may be rate limiting. This changes the rate law and complicates attempts to characterize it. In addition, a competing pathway exists that leads to the formation of dichloroacetic acid (Reckhow and Singer, 1985). Trichloropropanone may undergo further base-catalyzed chlorine substitution to form pentachloropropanone. This compound will rapidly hydrolyze to form chloroform and dichloroacetic acid. The rate law proposed for the loss of trichloropropanone is

$$\frac{-d[\text{CH}_3\text{COCCl}_3]}{dt} = \left\{ \frac{k_1 k_2 [\text{HOCl}][\text{P}_T]}{k_{-1}[\text{P}_T] + k_2 [\text{HOCl}]} + k_3 [\text{OCl}^-] + k_4 [\text{OH}^-] \right\} [\text{CH}_3\text{COCCl}_3] \quad (7-37)$$

This complicated rate law reflects catalysis by hypochlorite (OCl^-), hydroxide (OH^-), and phosphate (P_T).

OXIDANTS USED IN WATER TREATMENT

Chlorine

Chlorine is the most widely used oxidant (and disinfectant; see Chap. 17) in water treatment practice. Chlorine is available in gaseous form (as Cl_2), as a concentrated aqueous solution

(sodium hypochlorite, NaOCl, i.e., bleach), or as a solid (calcium hypochlorite, Ca(OCl)₂), or it can be electrolytically generated on-site.

When chlorine gas is added to water, the chlorine rapidly disproportionates to form hypochlorous acid (HOCl) and the chloride ion (Cl⁻).

The equilibrium constant for Eq. 7-38 is 5×10^{-4} at 25°C, indicating that the reaction goes relatively far to the right, as shown. The residual concentration of molecular Cl₂ in solution will represent only a small fraction of the total chlorine concentration, except at very low pH conditions or at high chloride concentrations. For example, even in water at pH 2 with a 10⁻³ M chloride concentration, only 2 percent of the total chlorine will exist as molecular Cl₂. The chlorine produced by Eq. 7-38 is essentially inert with respect to its oxidizing and disinfecting properties.

Hypochlorous acid is a weak acid (pK_a = 7.6 at 25°C) that can transfer a proton to form the hypochlorite ion (OCl⁻).

The ratio of hypochlorous acid to hypochlorite may be calculated from the expression

$$\log \left(\frac{[\text{HOCl}]}{[\text{OCl}^-]} \right) = 7.6 - \text{pH} \quad (7-40)$$

The sum of the three species, Cl₂, HOCl, and OCl⁻, is commonly referred to as *free available chlorine (FAC)*, and the concentrations of the individual species and their sum are usually expressed in units of mg/L as Cl₂.

Equations 7-38 and 7-39 show that the species of chlorine present in water depends on the total concentration of chlorine, pH, and temperature. Figure 7-4 is a diagram of the relative amounts of hypochlorous acid and hypochlorite as a function of pH. At 20°C, hypochlorous acid is the predominant species below pH 7.6, and hypochlorite ion is predominant at pH values greater than 7.6. The concentrations of the two species are equal

FIGURE 7-4 Distribution of hypochlorous acid and hypochlorite ion in water as a function of pH.

at pH 7.6 (the pK_a value). The distribution shifts somewhat with changing temperature because the equilibrium constants for Eqs. 7-38 and 7-39 are temperature dependent.

If chlorine is added to water as liquid sodium hypochlorite, the following reactions occur.

If calcium hypochlorite granules are dissolved in water, they also form the hypochlorite ion

which, like the hypochlorite formed from the addition of NaOCl, reacts with water to form hypochlorous acid.

Just as in the case of the species formed by the addition of chlorine gas, the relative distribution of HOCl and OCl^- that results from the addition of sodium hypochlorite or calcium hypochlorite will be determined by pH, temperature, and the total chlorine concentration. Again, this distribution will be in accordance with Eq. 7-40 and Fig. 7-4. Regardless of the form in which the chlorine is added to water (Cl_2 , NaOCl, or $\text{Ca}(\text{OCl})_2$), hypochlorite, hypochlorous acid, and molecular chlorine will be formed as described by the chemical equilibria represented by the previous reactions. The only difference is that chlorine gas produces an acidic reaction which lowers the pH of the solution, whereas sodium hypochlorite and calcium hypochlorite are both bases which will raise the pH of the water. The extent of the pH change will depend on the alkalinity of the water, but is likely to be relatively small because of the low doses of chlorine typically used.

As shown in Table 7-1, hypochlorous acid and the hypochlorite ion are both strong oxidizing agents, but HOCl is the stronger of the two. Hence, oxidation reactions of chlorine, in general, tend to be more effective at low pH values unless the reactant exhibits pH-dependent behavior as in the case of phenol (see Fig. 7-1).

Gaseous chlorine is typically provided for water treatment applications in pressurized tanks so that the chlorine exists as a liquid under pressure. The chlorine is then added to water by reducing the pressure in the tank and releasing the chlorine as a gas. Handling of the chlorine gas is extremely dangerous, and caution must be exercised in working with chlorine feeding equipment. This is discussed further in Chap. 17.

Alternatively, if liquid sodium hypochlorite solution is used, it is usually added from a concentrated NaOCl bulk solution directly to the main plant flow with the help of a liquid metering pump. Solid granules of calcium hypochlorite can be added to the water directly, or a concentrated solution of calcium hypochlorite can be prepared from which the hypochlorite is metered into the main flow as in the case of sodium hypochlorite. Calcium hypochlorite is not widely used at municipal water treatment plants.

Historically, gaseous chlorine in pressurized tanks has been the most common method of applying chlorine in municipal water treatment practice, but more recently, because of concerns about transport and handling of hazardous chemicals, the use of liquid sodium hypochlorite is becoming more widely practiced despite its higher cost. A potential concern involving the use of sodium hypochlorite is its stability. The hypochlorite tends to degrade over time, particularly when it is stored at high temperatures and/or exposed to sunlight (Bolyard et al., 1992, 1993; Adam and Gordon, 1999). One of the degradation products is chlorate (ClO_3^-), a potential health concern (see the discussion of chlorine dioxide below). Common practice is to limit on-site storage of sodium hypochlorite feedstocks to 90 days. Research also indicates the possible presence of bromate, another inorganic disinfection by-product usually associated with ozonation, in sodium hypochlorite feedstocks at levels

which could exceed regulatory limits when the hypochlorite is fed at typical doses used in practice (Chlorine Institute, 1999; Weinberg et al., 2003). Appropriate specifications need to be provided when ordering sodium hypochlorite to minimize the presence of bromate.

Free chlorine can also be generated electrolytically on-site from brine (sodium chloride, NaCl) solutions (see Fig. 7-5). The molecular chlorine generated at the anode can

FIGURE 7-5 Electrolysis cell illustrating on-site generation of sodium hypochlorite. (Source: Boal, 2009; reprinted with permission from the National Environmental Services Center, West Virginia University, Copyright 2009.)

be dissolved in sodium hydroxide (NaOH), which is also a by-product of the electrolysis reaction, to produce a concentrated sodium hypochlorite solution.

Again, while the use of electrolysis cells to produce chlorine gas on-site tends to be more costly than purchasing chlorine gas directly in pressurized tanks, the hazards associated with the transport and handling of pressurized chlorine containers is avoided. Also, although more expensive than purchasing bulk sodium hypochlorite, electrolytically generated chlorine production can be paced to match the need for chlorine during treatment, thereby eliminating the need for storage of sodium hypochlorite and its associated degradation over time.

Reactions of Chlorine with Organic Compounds. Chlorine reacts with organic material by a combination of oxidation and substitution reactions. For example, chlorine reacts with amino acids to produce non-halogenated oxidation by-products, such as aldehydes and organic acids. Conversely, chlorine reacts with phenol to produce chlorinated phenolic compounds, such as ortho- and parachlorophenol. Formation of the latter contributes to an enhancement of taste and odor in chlorinated water containing phenol (see below). In the case of aromatic compounds, the presence of electron-donating substituents on the aromatic ring facilitates both substitution reactions and oxidative ring cleavage reactions.

Chlorine reacts with NOM (e.g., humic substances) to produce a variety of chlorine-substituted halogenated disinfection by-products, such as chloroform, di- and trichloroacetic acid, dichloroacetonitrile, and chloropicrin. In view of the importance of these reactions to water quality and treatment, the subject of disinfection by-product formation and control is presented separately, in Chap. 19. The rates of reactions between chlorine and NOM or chlorine and trace organic contaminants are dependent on the structure of the organic compounds and on other factors such as pH, temperature, and chlorine residual concentration. See the critical review by Deborde and von Gunten (2008) for a more complete discussion of chlorine reactions and a compilation of rate constants.

Reactions of Chlorine with Ammonia. Ammonia in water exerts a chlorine demand in accordance with Eq. 7-46.

One mole of ammonia consumes 1.5 moles of chlorine, or 1 mg of ammonia as N consumes 7.6 mg of chlorine as Cl_2 . Hence if chlorine is used for the oxidation of reduced iron and manganese, sulfide, or organic micropollutants (see below) or for disinfection (see Chap. 17), more than 7.6 mg of chlorine must be applied to overcome the chlorine demand of 1 mg of ammonia as N.

If lesser amounts of chlorine are applied per mg N, inorganic chloramines are produced in accordance with Eqs. 7-47 to 7-49.

The mixture of monochloramine (NH_2Cl), dichloramine (NHCl_2), and trichloramine or nitrogen trichloride (NCl_3) that results depends on pH, temperature, and the ratio of chlorine to ammonia. At a chlorine:ammonia molar ratio less than 1:1 or a weight ratio ($\text{Cl}_2:\text{N}$) less than 5:1 and a pH of about 8, the principal chloramine species formed is monochloramine. At higher chlorine:ammonia ratios and lower pH values, dichloramine formation becomes important, and at mildly acidic pH values in the range of 6 to 6.5, nitrogen trichloride can be formed. The sum of the concentrations of the three chloramine species is typically referred to as *combined chlorine* and is often expressed in units of mg/L as Cl_2 . Combined chlorine is analytically distinguishable from free chlorine (*Standard Methods*, 2005). The sum of the free and combined chlorine concentrations is referred to as *total chlorine*.

Chloramine formation may be done purposefully by adding ammonia to water containing free available chlorine if it is desired to form monochloramine for maintenance of a stable disinfectant residual in the distribution system (see Chap. 17) and for limiting the formation of regulated disinfection by-products (see Chap. 19). Monochloramine, being a weaker oxidant, is a more stable and persistent, albeit weaker, disinfectant species than free chlorine and does not contribute appreciably to the formation of the regulated disinfection by-products. For these reasons, monochloramine is an attractive secondary disinfectant in water distribution systems. Because of its important role in disinfection, chloramine chemistry is discussed in greater detail in Chap. 17. From the standpoint of its oxidation potential, monochloramine is too weak to oxidize reduced iron and manganese and most taste and odor-causing organics, and it is too weak to eliminate natural organic color. While monochloramine will oxidize NOM to some degree and produce some halogenated organic material, it does not generally produce trihalomethanes (see Chap. 19).

Part of the oxidation capacity of the chloramines derives from monochloramine hydrolysis represented by the reverse reaction of Eq. 7-47. The free chlorine liberated, although

often in small amounts, may be responsible in part for the formation of some halogenated by-products associated with chloramines. Likewise, the free ammonia liberated may contribute to nitrification problems in water distribution systems.

In general, the principal value of monochloramine in water treatment is not as an oxidant but as a secondary disinfectant (see Chap. 17).

Reactions of Chlorine with Bromide. In drinking waters containing bromide, chlorine will oxidize the bromide to produce hypobromous acid (HOBr).

This reaction is very fast, with a second-order rate constant of $2.95 \times 10^3 \text{ M}^{-1}\text{s}^{-1}$. Hence bromide represents another source of chlorine demand, albeit a minor one, and the presence of bromide contributes somewhat to the depletion of free chlorine.

The resulting hypobromous acid, like hypochlorous acid, is a weak acid ($\text{pK}_a = 8.7$ at 25°C) and will dissociate to some degree to form the hypobromite ion (OBr^-), depending on pH.

As noted in Table 7-1, hypobromous acid is a somewhat weaker oxidant than hypochlorous acid. The formation of hypobromous acid is important, however, because hypobromous acid is capable of reacting with NOM to produce undesirable brominated disinfection by-products, such as bromoform and dibromoacetic acid. The presence of bromide and its subsequent oxidation to hypobromous acid is what contributes, along with hypochlorous acid, to the formation of mixed brominated and chlorinated disinfection by-products such as bromodichloromethane and bromochloroacetic acid (see Chap. 19). Because of their relative acidity constants, more hypobromous acid remains in the undissociated HOBr form than hypochlorous acid under most pH conditions encountered in practice. Accordingly, because the undissociated forms of these species are stronger oxidants than their deprotonated counterparts, hypobromous acid behaves as a stronger substituting agent than hypochlorous acid, which results in the formation of greater amounts of halogenated disinfection by-products in bromide-containing waters.

Reactions of Chlorine with Iodide. Chlorine reacts quickly with iodide, leading to the formation of hypiodous acid (HOI).

The second-order rate constant for the reaction between HOCl and iodide is $4.3 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$. The resultant HOI is rapidly oxidized to iodate, with OCl^- being the primary oxidant at typical drinking water treatment conditions (Bichsel and von Gunten, 1999).

The reaction is first order with respect to both OCl^- and HOI, and the rate constant is $52 \text{ M}^{-1}\text{s}^{-1}$ at 25°C . Because the rate constant for the oxidation of HOI by chlorine to produce iodate is so fast, HOI does not persist long enough to react with NOM to produce iodinated disinfection by-products to any appreciable degree. This is not the case with monochloramine, which will rapidly oxidize iodide to HOI (second-order rate constant of $2.4 \times 10^{10} \times [\text{H}^+] \text{ M}^{-2}\text{s}^{-1}$), but the subsequent oxidation of HOI by monochloramine is so slow ($< 2 \times 10^{-3} \text{ M}^{-1}\text{s}^{-1}$) that HOI persists and will react with NOM to produce iodinated disinfection by-products. This is the reason why higher levels of iodinated disinfection by-products are found in chloraminated waters containing iodide than in chlorinated waters (Weinberg, et al., 2002; Bichsel and von Gunten, 1999).

Chlorine Dioxide

Chlorine dioxide (ClO_2) is unstable at high concentrations and can explode on exposure to heat, light, electrical sparks, or shocks. Accordingly, it is never shipped in bulk, but instead is generated on-site. Aqueous solutions are usually prepared from the gaseous chlorine dioxide generated, as chlorine dioxide is very soluble in water. It does not hydrolyze in water as chlorine does and remains in its molecular form as ClO_2 . It is much more volatile than chlorine and can easily be stripped from aqueous solution if not properly handled. Chlorine dioxide is usually generated by reacting sodium chlorite (NaClO_2) with either gaseous chlorine (Cl_2) or hypochlorous acid (HOCl) under acidic conditions, in accordance with the following reactions:

In order to drive the reaction to completion and avoid the presence of unreacted chlorite (ClO_2^-) in the product stream, some generators use excess chlorine, although several variations in generator design have been developed which allow for the sodium chlorite to be completely converted to chlorine dioxide without using excess chlorine. Additionally, to overcome the basicity of sodium chlorite and the hydroxide produced by Eq. 7-55, acid is sometimes added along with the hypochlorous acid to maintain the optimal pH for chlorine dioxide generation. Typically, pH values in the range of 3.5 to 5.5 are preferred; more acidic pH values lead to the formation of chlorate (ClO_3^-).

Chlorine dioxide may also be prepared by acidification of a sodium chlorite solution.

Once generated, chlorine dioxide can be dissolved in water and is stable in the absence of light and elevated temperatures. At high pH values or in the presence of light or at elevated temperatures, chlorine dioxide disproportionates to form both chlorite and chlorate (Bowen and Cheung, 1932), both of which are undesirable in drinking water (see below and Chap. 19):

The primary application of chlorine dioxide in the past has been for taste and odor control, although it is also an effective oxidant for reduced iron and manganese and is a good primary disinfectant (see Chap. 17). Hoigne and Bader (1994) and Tratnyek and Hoigne (1994) provide a listing and discussion of the rate constants for reactions between chlorine dioxide and a variety of organic and inorganic compounds, a number of which are of relevance to the treatment of drinking water (see Table 7-5). The rate constants are shown for pH 8 because many of the reactions are pH dependent due to acid/base behavior of the reactant, for example, amines and phenols. For the phenols and amines, the deprotonated forms are generally more reactive than the protonated forms, and the rates tend to increase 10-fold for every unit increase in pH.

One of the principal advantages of chlorine dioxide is that it does not react with ammonia (see the low rate constant in Table 7-5). Hence, much lower doses of chlorine dioxide are required for most oxidative applications compared to chlorine dosage requirements. Another advantage is that chlorine dioxide does not enter into substitution reactions with NOM to the same degree that free chlorine does and, accordingly, does not form trihalomethanes, haloacetic

TABLE 7-5 Second-Order Reaction Rate Constants for Chlorine Dioxide and Several Organic and Inorganic Compounds Found in Water (after Hoigne and Bader, 1994)

Reactant	Rate constant at pH 8, M ⁻¹ s ⁻¹
Br ⁻	<0.05
I ⁻	1.4 × 10 ³
Ammonia	<10 ⁻⁶
Ferrous iron	3 × 10 ³
Manganous manganese	5 × 10 ⁴
Phenol	5 × 10 ⁵
Catechol	1.58 × 10 ⁸
Resorcinol	3 × 10 ⁶
2-chlorophenol	1.1 × 10 ⁷
2,4-dichlorophenol	1 × 10 ⁶
2,4,6-trichlorophenol	5.3 × 10 ⁶
Pentachlorophenol	1.4 × 10 ³
o-cresol	2.2 × 10 ⁶
m-cresol	0.8 × 10 ⁶
4-nitrophenol	1.4 × 10 ⁸
Glycine	<10 ⁻⁵
Dimethylamine	<1
Trimethylamine	10 ²
Anasole	<2 × 10 ⁻³
Naphthalene	<0.3
Phthalic acid	<10 ⁻³

acids, or most other commonly observed halogenated disinfection by-products that result from chlorination, at least not to any appreciable extent. Richardson et al. (1994) and others have identified a number of disinfection/oxidation by-products of chlorine dioxide treatment, for example, aldehydes, carboxylic acids, and some halogenated compounds, but most of the latter were present at extremely low concentrations. Because it does not tend to form halogenated disinfection by-products to any significant degree, chlorine dioxide has enjoyed renewed interest as a water treatment oxidant. An additional benefit is that chlorine dioxide reacts only very slowly with bromide (see Table 7-5). Hence, brominated by-products, either organic or inorganic (e.g., bromate), are not a concern following treatment with chlorine dioxide.

Chlorine dioxide typically reacts with most reducing agents (e.g., taste and odor compounds, NOM) through a one-electron transfer (see Table 7-1).

As a result, chlorite is considered to be the principal oxidation by-product of chlorine dioxide usage. Most researchers (e.g., Werdehoff and Singer, 1987) have reported that approximately 50 to 70 percent (by mass) of the chlorine dioxide applied during the course of drinking water treatment ends up as chlorite.

Chlorite has been demonstrated to exhibit a number of potential adverse health effects based on studies with laboratory animals (see Chap. 2). Because of this, the Stage 1 and Stage 2 Disinfectants/Disinfection By-Products rules (USEPA, 1998, 2006) establish a maximum contaminant level (MCL) of 1.0 mg/L for chlorite in the distribution system

and a maximum residual disinfectant level (MRDL) of 0.8 mg/L for chlorine dioxide at the point of entry to the distribution system. No regulations exist for chlorate at this time. Given the observations that chlorine dioxide is rapidly consumed during the course of water treatment and that up to 70 percent of the applied chlorine dioxide is reduced to chlorite, the practical upper limit for chlorine dioxide doses would be approximately 1.4 to 1.5 mg/L, unless chlorite is removed (see below).

A second concern associated with residual chlorite in the distribution system is that it reacts with free chlorine, producing low levels of chlorine dioxide and/or chlorate.

If present in tap water, the chlorine dioxide, being volatile, can be released into the home or office environment when customers open their water taps. This can lead to offensive chlorinous odors, or if new carpeting has recently been installed, the escaping chlorine dioxide can react with organic compounds released from the carpeting to produce other offensive odors (Hoehn et al., 1990).

Chlorite, whether it is present as a result of incomplete oxidation of sodium chlorite in the chlorine dioxide generator (Eqs. 7-54 and 7-55) or by chemical reduction of the chlorine dioxide during the course of treatment (Eq. 7-59), can be removed from water by the application of ferrous iron salts (Iatrou and Knocke, 1992) or reduced sulfur compounds such as bisulfite.

No practical method for the removal of chlorate is available; hence, its formation during chlorine dioxide generation should be minimized.

Ozone and Advanced Oxidation Processes

Ozone is an unstable gas that must be generated on-site. A simplified representation of the chemistry involved in the formation of ozone (O_3) is as follows:

Figure 7-6 shows an illustrative picture of an ozone generator. The energy required to produce nascent or elemental oxygen (O) from molecular oxygen (O_2) is usually supplied by an electric discharge with a peak voltage from 8 to 20 kV depending on the apparatus used. Dry, refrigerated, particle-free air, oxygen, or oxygen-enriched air is passed through a narrow gap between two electrodes and a high energy discharge is generated across the gap between the electrodes. This corona or cold plasma discharge is induced by an alternating current that creates a voltage cycle between the two electrodes. The yield of ozone depends on the voltage, the frequency, the design of the ozone generator, and the type and quality of the feed gas used. Ozone streams containing up to 14 percent ozone by volume can be produced. Current ozone generators are available as low-frequency (50–60 Hz), medium-frequency (400–1000 Hz), and high-frequency (2000–3000 Hz) systems.

Once generated, the ozone-enriched air or oxygen gas is passed through a gas absorption device to transfer ozone into solution. This can be achieved through either a countercurrent multistage bubble contactor (see Fig. 7-7) using gaseous diffusers such as those shown on the left side of Fig. 7-8 or an in-line gas injection system using Venturi-type injectors such as those shown on the right side of Fig. 7-8.

Ozone is unstable in aqueous solution. It is very reactive with a number of common constituents in drinking water (e.g., NOM), and it also undergoes a spontaneous decomposition process, sometimes referred to as *auto-decomposition*. The auto-decomposition of ozone is a complex chain reaction process involving several free-radical species. Decomposition may be initiated by a number of different water constituents, such as hydroxide ion (e.g., high pH values), NOM, and ferrous iron, or it may be initiated by the addition of hydrogen peroxide or by irradiation with ultraviolet light. The reactions shown in Eqs. 7-66 through 7-71 illustrate the auto-decomposition scheme when hydroxide ion is the initiator.

Because the OH radical reacts rapidly with molecular ozone (Eq. 7-71), the decomposition of ozone is an autocatalytic reaction.

These reactions constitute a chain mechanism because the hydroperoxyl radical (HO_2) produced by Eq. 7-71 generates additional superoxide (O_2^- ; Eq. 7-67) that further contributes to ozone decomposition. In pure water, the chain may be very long; for example, hundreds of ozone molecules may be decomposed by a single initiation step. In natural waters, the lifetime of ozone depends on several variables, including pH, temperature, total organic carbon (TOC) concentration, and bicarbonate and carbonate concentrations. Bicarbonate and carbonate increase the lifetime of ozone by reacting with the hydroxyl radical (OH), thereby slowing down the chain reaction mechanism shown in Eqs. 7-66 to 7-71.

The bicarbonate and carbonate radicals (HCO_3 and CO_3^- , respectively) are relatively unreactive intermediates that cannot propagate the chain. Thus, waters high in bicarbonate and carbonate alkalinity will retain an ozone residual for longer periods of time than low-alkalinity waters. This is especially important when ozone is used as a disinfectant (see Chap. 17). Additionally, the radical-scavenging activity of the carbonate species increases with increasing pH because carbonate is a more effective scavenger than bicarbonate. This partially offsets the more rapid rate of the hydroxide-induced initiation reaction (Eq. 7-66) at higher pH values (higher hydroxide ion concentrations).

The hydroxyl radical, one of the intermediates produced by the decomposition of ozone, is one of the strongest chemical oxidants known (see Table 7-1), and is capable of rapidly reacting with a myriad of organic and inorganic impurities in water (see below). Accordingly, the oxidative properties of ozone depend significantly on the oxidative characteristics of this free-radical species.

Figure 7-9 is an illustrative schematic of the behavior of ozone in aqueous solution based on the fundamental work of Hoigne and his coworkers (e.g., Hoigne and Bader, 1976; Staehelin and Hoigne, 1982). Figure 7-9 shows that ozone reacts by two distinct types of pathways: a direct pathway involving molecular ozone (O_3) and an indirect pathway originating with the decomposition of ozone to produce the hydroxyl radical (OH). Direct reactions involving molecular ozone are selective; ozone reacts rapidly with some species (M_d in the figure), but only slowly with other species. The kinetics of reactions of

FIGURE 7-9 Illustrative direct and indirect reaction pathways of ozone.

molecular ozone with various impurities in water have been studied extensively. The most comprehensive listings of reaction rate constants are those provided by Hoigne and co-workers (e.g. Hoigne and Bader, 1983a, 1983b; Hoigne et al., 1985) and von Gunten (2003). Illustrative second-order rate constants for molecular ozone with a number of potential drinking water contaminants are shown in Table 7-6. As indicated, some solutes react quickly with molecular ozone whereas others react more slowly. The rate constants vary over ten orders of magnitude. For example, the oxidation of sulfide (S^{2-}) by molecular ozone is

TABLE 7-6 Second-Order Rate Constants for the Oxidation of Selected Drinking Water Contaminants by Molecular Ozone and the Hydroxyl Free Radical (after von Gunten, 2003)

Reactant	Second-order rate constant for O_3 , $M^{-1}s^{-1}$	Second-order rate constant for OH , $M^{-1}s^{-1}$
Ammonia, NH_3	20	9.7×10^7
Ferrous iron, $Fe(II)$	8.2×10^5	3.5×10^8
Manganese, $Mn(II)$	1.5×10^3	2.6×10^7
Hydrogen sulfide, H_2S	$\sim 3 \times 10^4$	1.5×10^{10}
Sulfide, S^{2-}	3×10^9	9×10^9
Bromide, Br^-	160	1.1×10^9
Geosmin	<10	8.2×10^9
2-methylisoborneol	<10	$\sim 3 \times 10^9$
Microcystin-LR	3.4×10^4	—
Atrazine	6	3×10^9
Alachlor	3.8	7×10^9
Carbofuran	620	7×10^9
Endrin	<0.02	1×10^9
Methoxychlor	270	2×10^{10}
Chloroethene (vinyl chloride)	1.4×10^4	1.2×10^{10}
Cis-1, 2-dichloroethene	540	3.8×10^9
Trichloroethene	17	2.9×10^9
Tetrachloroethene	<0.1	2×10^9
Chlorobenzene	0.75	5.6×10^9
Benzene	2	7.9×10^9
Toluene	14	5.1×10^9
o-Xylene	90	6.7×10^9
MTBE	0.14	1.9×10^9
Chloroform	<0.1	5×10^7
Bromoform	<0.2	1.3×10^8
Diclofenac	$\sim 1 \times 10^6$	7.5×10^9
Carbamazepine	$\sim 3 \times 10^5$	8.8×10^9
Sulfamethoxazole	$\sim 2.5 \times 10^6$	5.5×10^9
17 α -ethinylestradiol	$\sim 7 \times 10^9$	9.8×10^9

extremely rapid, with a second-order rate constant of $3 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$. The second-order rate constants for the oxidation of the solvent vinyl chloride (chloroethene) and the pesticide carbofuran by molecular ozone are also relatively high at 1.4×10^4 and $620 \text{ M}^{-1}\text{s}^{-1}$, respectively. Conversely, the second-order rate constants for the oxidation of benzene and tetrachloroethene, two common groundwater contaminants, are 2 and $<0.1 \text{ M}^{-1}\text{s}^{-1}$, respectively. The oxidation of trichloroethene and atrazine, two other common contaminants of drinking water, are also relatively low, at 6 and $17 \text{ M}^{-1}\text{s}^{-1}$. Additionally, ammonia reacts very slowly with molecular ozone in the pH range of interest in drinking water treatment.

The second-order rate constant for the reaction of olefins with molecular ozone decreases by a factor of more than 10 for each additional chlorine substituent. Also, while benzene itself is relatively unreactive toward molecular ozone, derivatives of benzene tend to be much more reactive, especially with the addition of electron-withdrawing substituents on the aromatic ring. Compounds that dissociate in water react with molecular ozone at rates that depend on the individual species present. Amines and amino acids react quickly when the amino group is deprotonated, that is, with increasing pH. The same is true for phenols; phenolate ($\text{C}_6\text{H}_5\text{O}^-$) reacts 10^6 times faster than molecular phenol ($\text{C}_6\text{H}_5\text{OH}$; Hoigne and Bader, 1981b). Saturated compounds, such as aldehydes, ketones, and organic acids react very slowly with molecular ozone, although deprotonation of the organic acids increases their reactivity. Methyl and other alkyl ethers also react slowly.

Conversely, the OH radical is relatively nonselective in its behavior, reacting rapidly with a large number of species (illustrated by M_i in Fig. 7-9). Table 7-6 presents illustrative second-order rate constants for the hydroxyl radical with a number of potential drinking water contaminants. Whereas the rate constants for molecular ozone range over ten orders of magnitude, the rate constants for the hydroxyl radical range over only three orders of magnitude, from 10^7 to $10^{10} \text{ M}^{-1}\text{s}^{-1}$. It is for this reason that the hydroxyl radical is often called *nonselective* with respect to its reactivity. Atrazine, benzene, geosmin, trichloroethene, and tetrachloroethene, all relatively inert toward molecular ozone, are oxidized at appreciable rates by the hydroxyl radical. Because of the large magnitude of the rate constants for oxidation reactions involving the hydroxyl radical, the rate-determining step in these reactions is the rate at which the radicals are generated either by ozone decomposition or by other advanced oxidation processes (see below). Hence, in many cases, the oxidation of these solutes is enhanced at elevated pH values because of the more rapid generation of hydroxyl radicals by hydroxide-induced ozone decomposition.

Hydroxyl free radicals can be produced through a number of other pathways in addition to the hydroxide-induced ozone decomposition chain reaction described previously. For example, the addition of both hydrogen peroxide and ozone to water accelerates the decomposition of ozone and enhances production of the hydroxyl radical. The hydrogen peroxide (H_2O_2) dissociates into the hydroperoxide ion (HO_2^-).

The hydroperoxide ion then reacts with molecular ozone to produce the superoxide ion (O_2^-) and the hydroxyl radical, plus molecular oxygen.

The hydroxyl radical and the superoxide ion then participate in the ozone decomposition chain depicted by Eqs. 7-68 to 7-71; this leads to an accelerated production of more hydroxyl radicals. Because reactions 7-74 and 7-75 tend to be appreciably faster than reaction 7-66 under most conditions, the conjunctive use of O_3 and H_2O_2 tends to be a more effective method of generating the highly reactive, nonselective hydroxyl radicals for chemical oxidation reactions.

Another method for generating hydroxyl radicals is by ultraviolet (UV) irradiation of hydrogen peroxide. The UV irradiation provides the energy needed to split the hydrogen peroxide into two hydroxyl radicals.

This process tends to be slower than reactions 7-74 and 7-75 and is therefore a less effective method of generating hydroxyl radicals.

Additionally, ultraviolet irradiation of waters containing dissolved molecular ozone leads directly to the formation of hydrogen peroxide. The hydrogen peroxide then reacts with molecular ozone in the same manner as it does in reactions 7-74 and 7-75, which produces the hydroxyl radical and other species that enter the ozone decomposition chain depicted by Eqs. 7-68 to 7-71.

The preceding reactions, all of which involve the accelerated production of the hydroxyl free radical, are termed advanced oxidation processes. Often, when applying ozone to natural waters containing impurities, it is difficult to distinguish between reactions that are attributable to molecular ozone and those which are attributable to the hydroxyl radical, although there are analytical techniques that can be used in the laboratory to distinguish between the indirect and direct reaction pathways (Hoigne and Bader, 1983a; Elovitz and von Gunten, 1999; Elovitz et al., 2000). It is believed that hydroxyl radical reactions are at the heart of all reactions involving molecular ozone, except perhaps for disinfection reactions, reactions with some solutes that have very high reaction rate constants with molecular ozone (see Table 7-6), and reactions that take place in the presence of high concentrations of hydroxyl radical scavengers.

Formation of Biodegradable Organic Material. When ozone reacts with organic contaminants in water, including NOM, it partially oxidizes them to lower molecular weight and more polar species, including a variety of aldehydes and organic acids. These oxidation by-products, while not believed to be harmful in themselves, tend to be biodegradable and may contribute to biofouling problems in the water distribution system if not properly controlled. Often, ozonation is followed by a biologically active filtration process to remove these biodegradable organic materials (see Chaps. 10 and 14) to produce a biologically stable finished water. Ozonation by-products are discussed in greater detail in Chap. 19.

Reactions of Ozone with Bromide. Ozone is capable of oxidizing bromide to hypobromous acid in the same manner that chlorine does.

This is a fast reaction, with a second-order reaction rate constant of $160 \text{ M}^{-1}\text{s}^{-1}$ (see Table 7-6). The hypobromous acid can then react with NOM to produce brominated DBPs, such as bromoform, dibromoacetic acid and bromopicrin. This is discussed in greater detail in Chap. 19.

A particular concern associated with the ozonation of bromide-containing waters is the formation of bromate (BrO_3^-). Bromate is a possible human carcinogen and is currently regulated at $10 \mu\text{g/L}$, the *practical quantitation limit (PQL)* for bromate, although it is expected that this level will decrease in the future with the development of more sensitive and robust analytical techniques for measuring bromate. Bromate is produced by a number of possible pathways involving molecular ozone and the hydroxyl radical (von Gunten and Oliveras, 1998; see Fig. 7-10).

FIGURE 7-10 Pathways illustrating the reaction of ozone and bromide to form bromate and brominated organic compounds. (Source: Sulzberger et al., 1997, reprinted with permission from *Chimia*, Copyright 1997.)

One such pathway proceeds through the formation of hypobromite (OBr^-) and bromite (BrO_2^-) and involves only molecular ozone.

In the pH range of most natural waters, a large portion of the OBr^- is protonated as HOBr (the pK_a for hypobromous acid is 8.7 at 25°C), so that the rate of formation of bromite by reaction 7-79 is slowed considerably with decreasing pH.

If the rate of formation of hydroxyl radicals in the water is high, bromate may also be formed through the hypobromite radical (BrO) as follows:

Techniques for controlling bromate formation most often involve ozonation at slightly acidic pH values, multistage ozonation in which the ozone is added at several different application points, and the use of ammonia or chlorine and ammonia together to convert the hypobromous acid produced to bromamine (see Chap. 19).

Once formed, bromate is somewhat difficult to remove, although it can be removed by chemical reduction using reduced sulfur compounds, such as bisulfite (HSO_3^-) or ferrous iron. Granular activated carbon is also capable of adsorbing bromate, albeit to a limited degree, and medium pressure ultraviolet irradiation decomposes bromate to bromide. Bromate control is discussed further in Chap. 19.

Potassium Permanganate

Potassium permanganate (KMnO_4) has been used as a water treatment oxidant for decades. It is commercially available in crystalline form and is either fed into solution directly using a dry chemical feeder or a concentrated solution is prepared on-site from which the desired dose is metered into the water. Sodium permanganate is also commercially available.

Permanganate contains manganese in the +VII oxidation state. Under most treatment applications, oxidation by permanganate involves a three-electron transfer, with the permanganate (MnO_4^-) being reduced (see Table 7-1) to insoluble manganese dioxide ($\text{MnO}_2(\text{s})$).

The manganese dioxide produced is a black precipitate which, if not properly removed by a suitable solid-liquid separation process, will create black particulate deposits in the distribution system and in household plumbing fixtures. Most often, removal of manganese dioxide is achieved by conventional clarification and/or filtration processes. Because most operators are fearful of seeing pink water (reflecting unreacted permanganate) coming through their filters, permanganate is commonly added at the head of the treatment plant, as close to the intake as possible. This allows sufficient time for the permanganate to perform its oxidative function and to be reduced completely to solid manganese dioxide prior to filtration.

The kinetics of oxidation reactions involving permanganate tend to be more rapid with increasing pH values. Hence, in some cases, addition of a base prior to filtration may be desirable to hasten the reduction of permanganate.

The manganese dioxide that results from permanganate reduction (Eq. 7-83) has some beneficial attributes. Manganese dioxide is an effective adsorbent for ferrous iron (Fe^{2+}), manganous manganese (Mn^{2+}), radium (Ra^{2+}), and other trace inorganic cationic species. Accordingly, some additional removal of Fe^{2+} and Mn^{2+} occurs as a result of permanganate treatment beyond that achieved simply through oxidation by permanganate. In fact, the adsorptive behavior of $\text{MnO}_2(\text{s})$ is the principle underlying the historic manganese greensand process in which the filter media is coated with manganese dioxide which serves as an adsorbent for Fe^{2+} , Mn^{2+} , and Ra^{2+} in the filter influent. The filter backwash water is treated with permanganate, or low doses of permanganate are applied to the filter influent to oxidize adsorbed Fe^{2+} and Mn^{2+} , thereby creating additional adsorption sites.

Solid manganese dioxide is also capable of adsorbing NOM that serves as DBP precursors. This benefit is particularly pronounced in hard waters (Colthurst and Singer, 1982), presumably because of the bridging action of calcium and magnesium which facilitates the adsorption of NOM to the negatively charged MnO_2 surface.

Potassium Ferrate

Potassium ferrate (K_2FeO_4) is a strong oxidant that is relatively new to the water treatment field (Sharma, 2002; Jiang and Lloyd, 2002). Ferrate, which contains iron in the +VI oxidation state, has a standard half-cell potential of 2.07 V (see Table 7-1); this makes it a powerful oxidant. One of the attractive features is that when the Fe(VI) is reduced, it produces Fe(III) which can serve a coagulation function, or an adsorptive function with respect to the removal of arsenic.

Ferrate is unstable under acidic conditions but is stable in alkaline solutions. It can be produced in the laboratory by oxidizing an Fe(III) solution with concentrated sodium hypochlorite under alkaline conditions, or it can be produced electrochemically from metallic iron under strongly alkaline conditions. Recent studies by a number of researchers have shown that ferrate rapidly oxidizes many trace organic contaminants in water, including pharmaceutically active compounds and endocrine disruptors (Lee et al., 2009). Ferrate also has good disinfecting properties.

Mixed Oxidants

Electrolysis of brine has been used since the nineteenth century to produce chlorine on an industrial scale (see Fig. 7-5). This technology has recently been modified and adapted to electrochemically produce a mixture of free chlorine and other powerful oxidants and disinfectants for drinking water applications for small, rural water supplies. Both liquid- and gas-phase generators are available.

The underlying principle is based on fundamental electrochemical theory. At the anode of the electrochemical cell, chloride is oxidized to chlorine, which subsequently hydrolyzes to hypochlorous acid.

The pH of the anodic stream tends to be on the order of 3 to 5. At the cathode, water is reduced to hydrogen gas, producing a strongly alkaline solution with a pH of about 10 to 11.

The anodic and cathodic streams are separated by a semipermeable barrier. While free chlorine is the primary oxidant produced by these mixed oxidant generators, other reactions occur at the anode, purportedly resulting in the formation of ozone, chlorine dioxide, hydrogen peroxide, other short-lived reactive oxidant species, and a number of inorganic by-products, such as chlorite, chlorate, and bromate. However, the composition of the oxidant streams from these mixed oxidant generators has not been fully characterized. More research is needed to characterize these product streams before widespread use of these generators is recommended.

APPLICATIONS OF OXIDATION PROCESSES TO WATER TREATMENT

This section describes typical applications of oxidants and the role they play in overall water treatment practice. These oxidants are most often used for the oxidation of reduced iron and manganese, destruction of taste- and odor-causing organic contaminants, elimination of color, and the oxidation of organic chemicals (micropollutants) of public health concern. Additionally, many of these oxidants act as coagulant aids, and are also employed as part of an overall program for the control of potentially harmful disinfection by-products. The formation and control of oxidation and disinfection by-products is discussed separately in Chap. 19. Many of these oxidants are also powerful disinfectants and therefore serve the dual purposes of oxidation and disinfection. Disinfection is discussed in detail in Chap. 17.

Control of Iron and Manganese

Iron and manganese are relatively soluble under reducing conditions, for example, in groundwaters, stagnant surface waters, and hypolimnetic waters of eutrophic lakes, reservoirs, and impoundments (see Chap. 3 for a discussion of the occurrence of Fe and Mn in source waters). Correspondingly, they are quite insoluble under oxidizing conditions, e.g., in flowing streams and in the epilimnetic waters of lakes or impoundments, at pe values

greater than 9 for manganese and at pe values greater than zero for iron (see Fig. 3-5). Accordingly, dissolved iron and manganese are rarely found at appreciable concentrations under oxidizing conditions. This is the basis of hypolimnetic aeration, which introduces oxygen into the bottom waters of impoundments to maintain oxidizing conditions, which keep iron and manganese immobilized in their insoluble oxidized forms. It is also the basis of in-situ control of iron and manganese in groundwaters, where oxygen-enriched water is injected into aquifers to create an oxidized zone around the well point that limits iron and manganese mobility (Braester and Martinell, 1988).

The reduced forms of iron and manganese, ferrous iron [Fe(II)] and manganous manganese [Mn(II)], respectively, may occur as the free metal ions, Fe²⁺ and Mn²⁺, as is often the case in most groundwaters, or they may be found complexed to various degrees with NOM, as is often the case in surface waters and highly colored groundwaters. During and immediately following lake overturn, that is, when iron- and manganese-rich hypolimnetic water is mixed with the remainder of the lake water, dissolved iron and manganese levels in the upper portions of the lake can increase appreciably. The duration of this increase may be days or weeks, depending on a number of factors, for example, temperature, pH, dissolved oxygen concentration, and the presence of microorganisms capable of catalyzing the oxidation of ferrous iron and manganous manganese to their insoluble oxidized forms. The primary concern with elevated levels of dissolved iron and manganese in water is that, if they are not removed, insoluble ferric hydroxide (Fe(OH)₃(s)) and manganese dioxide (MnO₂(s)) precipitates are produced when the reduced forms of the metals are oxidized by dissolved oxygen or chlorine. These precipitates cause reddish-orange or black deposits, respectively, to appear on plumbing fixtures and to create stains during laundering operations. As a result, the secondary maximum contaminant levels for iron and manganese in finished drinking water in the United States have been set at 0.3 and 0.05 mg/L, respectively, although many utilities have established finished water goals for manganese of less than 0.02 mg/L.

Dissolved Fe(II) and Mn(II) are usually removed from water by oxidizing them under engineered conditions to their insoluble forms through the addition of an oxidant and then removing the precipitated ferric hydroxide and manganese dioxide by sedimentation and filtration. The oxidants used most often for this purpose are oxygen, chlorine, permanganate, chlorine dioxide, and ozone. Equations 7-88 and 7-89 show the balanced oxidation reactions with dissolved oxygen following aeration.

Table 7-7 shows balanced reactions for the oxidation of reduced iron and manganese with various strong oxidants, and the corresponding oxidant demands. It should be noted that, although manganese dioxide is the principal form of oxidized manganese shown

TABLE 7-7 Oxidant Demands of Reduced Iron and Manganese

Reaction	Oxidant demand
$2\text{Fe}^{2+} + \text{HOCl} + 5\text{H}_2\text{O} \rightarrow 2\text{Fe}(\text{OH})_3(\text{s}) + \text{Cl}^- + 5\text{H}^+$	0.64 mg of chlorine per mg Fe(II)
$5\text{Fe}^{2+} + \text{ClO}_2 + 13\text{H}_2\text{O} \rightarrow 5\text{Fe}(\text{OH})_3(\text{s}) + \text{Cl}^- + 11\text{H}^+$	0.24 mg of chlorine dioxide per mg Fe(II)
$3\text{Fe}^{2+} + \text{MnO}_4^- + 7\text{H}_2\text{O} \rightarrow 3\text{Fe}(\text{OH})_3(\text{s}) + \text{MnO}_2(\text{s}) + 5\text{H}^+$	0.71 mg of permanganate per mg Fe(II)
$2\text{Fe}^{2+} + \text{O}_3 + 5\text{H}_2\text{O} \rightarrow 2\text{Fe}(\text{OH})_3(\text{s}) + \text{O}_2 + 4\text{H}^+$	0.43 mg of ozone per mg Fe(II)
$\text{Mn}^{2+} + \text{HOCl} + \text{H}_2\text{O} \rightarrow \text{MnO}_2(\text{s}) + \text{Cl}^- + 3\text{H}^+$	1.29 mg of chlorine per mg Mn(II)
$\text{Mn}^{2+} + 2\text{ClO}_2 + 2\text{H}_2\text{O} \rightarrow \text{MnO}_2(\text{s}) + 2\text{ClO}_2^- + 4\text{H}^+$	2.46 mg of chlorine dioxide per mg Mn(II)
$3\text{Mn}^{2+} + 2\text{MnO}_4^- + 2\text{H}_2\text{O} \rightarrow 5\text{MnO}_2(\text{s}) + 4\text{H}^+$	1.45 mg of permanganate per mg Mn(II)
$\text{Mn}^{2+} + \text{O}_3 + \text{H}_2\text{O} \rightarrow \text{MnO}_2(\text{s}) + \text{O}_2 + 2\text{H}^+$	0.87 mg of ozone per mg Mn(II)

for these oxidants, various forms of solid manganese oxidation products exist, e.g., MnOOH(s) , $\text{Mn}_2\text{O}_3\text{(s)}$, $\text{Mn}_3\text{O}_4\text{(s)}$, and $\text{MnO}_2\text{(s)}$, such that the oxidized insoluble form of manganese is often expressed as $\text{MnO}_x\text{(s)}$, with values of x ranging from 1.3 to 1.9 (Stumm and Morgan, 1996).

The kinetics of oxidation of Fe(II) by oxygen are relatively rapid at pH values above 7 (Stumm and Morgan, 1996), provided that the ferrous iron is not complexed by organic material. This is often the case for the removal of iron from groundwater, where dissolved organic carbon concentrations tend to be relatively low. The rate expression for the oxygenation of ferrous iron is

$$\frac{-d[\text{Fe(II)}]}{dt} = k[\text{Fe(II)}][\text{OH}^-]^2 p_{\text{O}_2} \quad (7-90)$$

The kinetics are first-order with respect to the concentration of ferrous iron and the partial pressure of oxygen (p_{O_2}) and second-order with respect to the hydroxide ion concentration (Stumm and Morgan, 1996). The latter illustrates the strong pH dependency of Fe(II) oxidation by oxygen and is due to the pathway by which the ferrous iron is oxidized; that is, oxidation proceeds primarily via the oxidation of the zerovalent Fe(OH)_2 species. The rate increases tenfold for every 0.1 increase in pH. The rate constant k has a value of $8.0 \times 10^{13} \text{ L}^2\text{mole}^{-2}\text{atm}^{-1}\text{min}^{-1}$ at 20°C .

In the case of Mn(II), oxidation by oxygen has been shown to conform to the following kinetic expression:

$$\frac{-d[\text{Mn(II)}]}{dt} = k_0[\text{Mn(II)}] + k[\text{Mn(II)}][\text{MnO}_2\text{(s)}] \quad (7-91)$$

where the rate constants k_0 and k are dependent on pH and the oxygen concentration. This is an autocatalytic reaction whereby the by-product of the oxidation reaction, manganese dioxide ($\text{MnO}_2\text{(s)}$), catalyzes the oxidation of reduced manganese as shown by the second-term on the right (Stumm and Morgan, 1996).

Despite the close chemical relationship between iron and manganese, the physical-chemical conditions for the oxidation of the two metals require different treatment strategies. This is seen by the different oxidation potentials for Fe^{2+} and Mn^{2+} (see Table 7-2), the different kinetic relationships defining their oxidation rates, and the different oxidation states of their oxidized products.

The oxidation of Fe(II) by oxygen is relatively rapid at neutral pH values (pH 7 and above) whereas the initial oxidation step for the chemical oxidation of Mn(II) by oxygen, represented by the first term on the right side of Eq. 7-91, is orders of magnitude slower at neutral pH. Accordingly, whereas simple aeration is commonly used to provide oxygen for the oxidation of ferrous iron in groundwaters, aeration is not an effective means for the chemical oxidation of reduced manganese. If, however, the ferrous iron is complexed by organic material, the rate of oxidation by oxygen can be very slow (Theis and Singer, 1974) and a stronger oxidant, for example, chlorine, permanganate, chlorine dioxide, or ozone, may be needed. Likewise, because the oxidation of manganous manganese by oxygen is relatively slow at neutral pH values, a strong chemical oxidant is often used for the oxidation of manganese. Again, Table 7-7 gives the chemical requirements for the oxidation of reduced iron and manganese by a number of strong chemical oxidants, although higher doses are typically needed to overcome the oxidant demand of dissolved organic material (Knocke et al., 1994).

The rates of oxidation of manganous manganese by permanganate and chlorine dioxide are illustrated, respectively, in Figs. 7-11 and 7-12. The rates of Mn(II) oxidation with both oxidants increase with increasing pH, increase with increasing temperature, and decrease with increasing amounts of NOM. In all cases shown, the half-times for Mn(II) oxidation tend to be less than 60 sec, attesting to rapid oxidation kinetics with these strong

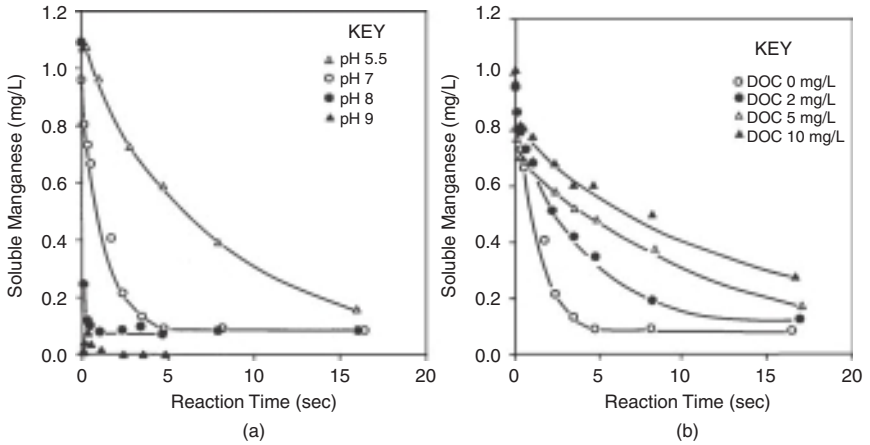

FIGURE 7-11 Rate of Mn(II) oxidation by permanganate under various conditions. (a) Effect of pH at 25°C, DOC < 1 mg/L; (b) Effect of DOC concentration at pH 7, 25°C. (Source: Knocke et al., 1991a; reprinted with permission from the American Water Works Association, Copyright 1991.)

oxidants. Gregory and Carlson (1993), however, showed that oxidation kinetics were highly dependent on the concentration of reduced manganese and that, at the low Mn(II) concentrations typically found in raw drinking waters, oxidation was appreciably slower, requiring up to 30 min to lower dissolved manganese concentrations to less than 0.01 mg/L. They found that the oxidation reaction was much faster for chlorine dioxide than for permanganate. In the case of ozone, selection of the proper ozone dose for oxidation of Mn(II) to its insoluble form is more challenging; sufficient ozone must be applied to overcome the oxidant demand of NOM in the water, but too much ozone will convert the Mn(II) to permanganate, as shown by Eq. 7-92 and Example 7-1 at the beginning of this

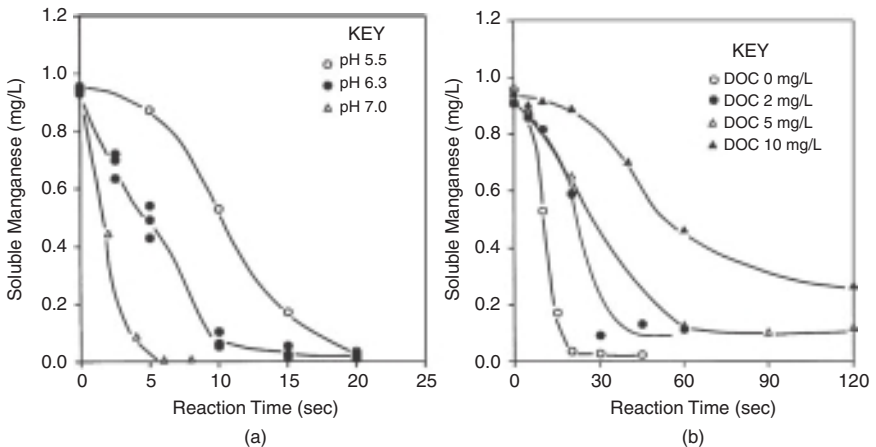

FIGURE 7-12 Rate of Mn(II) oxidation by chlorine dioxide under various conditions. (a) Effect of pH at 25°C, DOC < 1 mg/L; (b) Effect of DOC concentration at pH 7, 25°C. (Source: Knocke et al., 1991a; reprinted with permission from the American Water Works Association, Copyright 1991.)

chapter, necessitating additional contact time for the permanganate to be reduced to the insoluble manganese oxides.

For all of the strong oxidants, in the presence of NOM, higher doses beyond the stoichiometric amounts shown in Table 7-7 are required due to the oxidant demand of the organics. Figure 7-13a and b illustrates this for chlorine dioxide and permanganate, respectively. The stoichiometric requirements for the oxidation of 0.25 mg/L of Mn(II) are 0.62 mg/L for chlorine dioxide and 0.36 mg/L for permanganate so it is clear that appreciably higher oxidant doses are required to achieve effective manganese oxidation. Furthermore, the rates of Mn(II) oxidation tend to be much slower in the presence of NOM. The data shown in Fig. 7-13 are for a total oxidant contact time of 1 hr. A similar situation occurs with ferrous iron; that is, kinetics are slower in the presence of NOM, and greater amounts of the oxidants are needed beyond the stoichiometric requirements (Knocke et al., 1994). It should also be noted that the oxidized iron and manganese may be colloidal in nature and therefore difficult to remove by conventional solid-liquid separation techniques. This is especially true in the presence of NOM.

An alternative approach to removing manganese from water besides conventional oxidation, clarification and filtration is by adsorption/oxidation in a filter bed. Because the oxidation of Mn(II) is catalyzed by manganese dioxide (see the second term on the right side of Eq. 7-91) and manganese dioxide strongly adsorbs Mn²⁺, a common practice for manganese oxidation and removal is to allow the filter media to become coated by manganese dioxide and other insoluble oxides of manganese, MnO_x(s). Reduced manganese in the filter influent then adsorbs to these manganese oxide coatings and can be oxidized within the filter bed using chlorine or permanganate in the filter influent or during backwashing. This sequence of reactions can be represented as

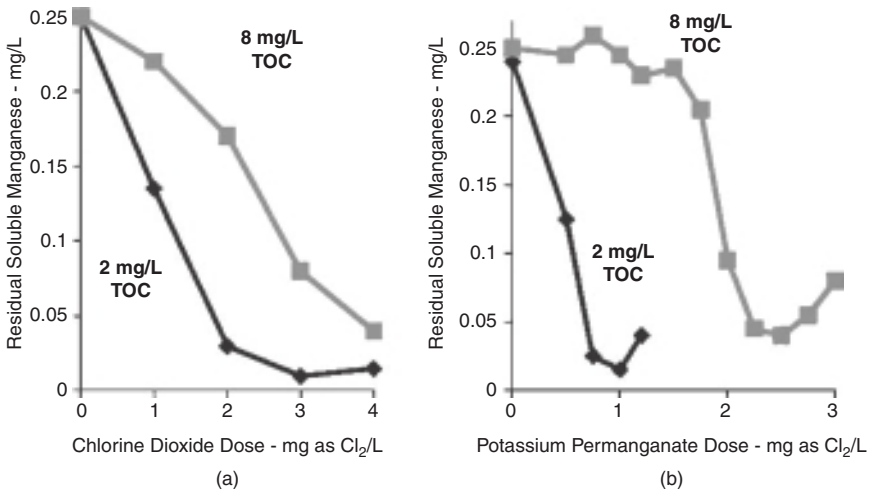

FIGURE 7-13 Effect of TOC on Mn(II) oxidation by (a) chlorine dioxide at pH 5.0 and 20°C, and (b) permanganate at pH 5.5 and 20°C. (After Knocke et al., 1987; reprinted with permission from the American Water Works Association, Copyright 1987.)

Commercially available glauconite (greensand), which has an affinity for the adsorption of Mn(II), can also be used as a filter media in the same manner. Other available proprietary products containing pyrolusite (β -MnO₂), such as Pyrolox[®] and Filox[®], are also commercially available. Such adsorbent media are also effective for the removal of reduced iron and arsenic (Ghurye and Clifford, 2004) and radium (Qureshi and Nelson, 2003).

When employing Mn oxide-coated filter media for Mn removal, care must be exercised with respect to maintaining optimal pH and oxidizing conditions in the filter bed (Knocke et al., 1988; Knocke et al., 1991b). Figure 7-14a shows that Mn removal increases with increasing pH. Tobiason et al. (2008) also demonstrated that both Mn uptake capacity and rate of Mn uptake increased as pH increased from 5.5 to 8.0. To ensure effective removal of manganese, a slightly alkaline pH value (7–8) is recommended.

Figure 7-14b illustrates the importance of the manganese oxide coating, with removal increasing as the extent of the Mn coating increases. The extent of the manganese oxide coating in several cores taken from a filter bed employing adsorption/oxidation for Mn removal is shown in Fig. 7-15. Effective Mn removal in full-scale filter media has been observed even with Mn coating levels as low as 1–2 mg Mn/g media as long as the proper pH is maintained.

Figures 7-16 and 7-17 show that it is important to maintain a free chlorine residual across the filter bed in order to retain manganese in the bed. Many utilities employ an operational target of 0.5 to 1 mg/L of free chlorine in the filter effluent for this purpose. Because MnO₂ is a moderately strong oxidant, it has the potential to undergo reductive dissolution within the filter bed to produce soluble Mn(II) in the absence of a strong oxidant residual, leading to manganese release from the bed. Again, pH is an important variable influencing the reductive dissolution of MnO₂.

An adaption of the oxide-coated media process for manganese removal involves the use of a post-filter, coarse media, manganese-coated adsorptive contactor (Tobiason et al., 2008). Because many utilities have had to (or would like to) eliminate free chlorine application to their conventional filters to reduce DBP production or employ biological filtration for dissolved organic carbon (DOC) removal, their ability to remove soluble Mn is compromised. The post-filter manganese oxide-coated adsorptive contactor concept offers the potential for controlling Mn in a separate bed under conditions that are different from those needed for optimal particle and NOM removal. For example, coagulation for NOM removal with alum is optimal at pH 6 to 6.5 whereas conditions for Mn uptake are better at pH values greater than 7.

Another approach for controlling manganese in water is through biological oxidation and filtration. Manganese biofiltration utilizes naturally occurring manganese-oxidizing bacteria in biofilms attached to the filter media to oxidize Mn(II). The resulting insoluble manganese oxides are retained within the filter bed and are available to adsorb additional Mn(II). Accordingly, the biological process cannot be considered in isolation and is dependent on the chemical behavior of Mn, i.e., the physical chemical factors and at the surface/water interface (e.g., pH, pe, temperature, solution-phase Mn(II) concentration, Mn coating on the filter media).

Microbial oxidation processes for Mn removal in drinking water treatment plants are widely used in Europe (Peitchev and Semov, 1988; Mouchet, 1992; Vandenabeele et al., 1992; Cameron, 1996; Katsoyiannis and Zouboulis, 2004; Pacini et al., 2005; Burger et al., 2008), and the subject is receiving increasing attention in the United States as more utilities move their application point for chlorine further downstream in the treatment train to avoid the formation of DBPs. Further research and development is required before it becomes acceptable for widespread incorporation into drinking water treatment practice in the United States.

Destruction of Tastes and Odors

Tastes and odors occur in water from a variety of sources, most notably algae, actinomycetes, organic and inorganic sulfides (e.g., mercaptans and hydrogen sulfide, respectively), and industrial contaminants, such as phenols (Mallevalle and Suffet, 1987). The presence of blue-green algae, in particular, is associated with a variety of specific chemical

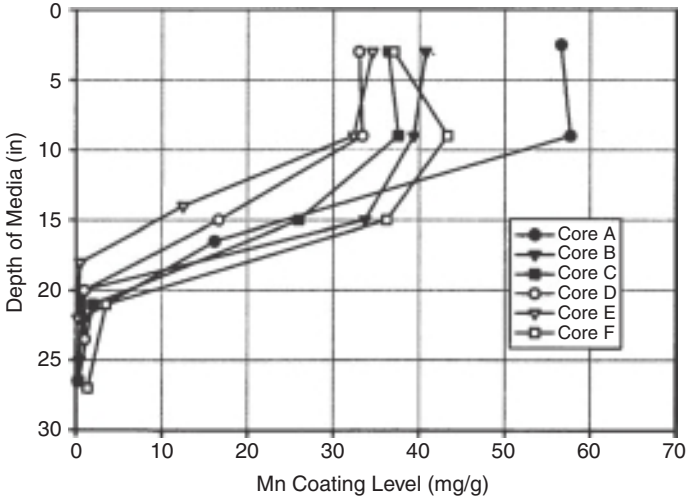

FIGURE 7-15 Manganese coatings on filter media in cores taken from a dual media filter using adsorption/oxidation for manganese removal. (Source: Tobiasson *et al.*, 2008; reprinted with permission from the Water Research Foundation, Copyright 2008.)

compounds that produce unpleasant odors at ng/L levels, for example, methylisoborneol (MIB) and geosmin, especially in waters drawn from impoundments. Because of the algal origin of these odorous compounds, they tend to occur on a seasonal basis (see Chap. 3 for additional coverage of the occurrence of algal-derived odors in source waters).

Chemical oxidation and activated carbon adsorption (see Chap. 14) are the two most common methods of eliminating taste and odor from drinking water. Free chlorine is an effective chemical oxidant for the destruction of odors associated with reduced sulfur compounds, but is less effective in destroying phenolic compounds and MIB and geosmin

FIGURE 7-16 Removal of dissolved manganese by MnO_2 -coated filter media in the presence and absence of 2 mg/L of free chlorine in the applied water at (a) pH (6-6.2), and (b) pH 7.8. (Lalezary et al., 1986). In the case of phenols, low doses of chlorine can produce chlorophenols by substitution reactions of the type shown earlier in this chapter. Some of these chlorophenols have stronger odors than the parent phenolic compounds themselves (Burttschell et al., 1959). Hence, the application of chlorine intensifies the odor. In some cases, the chlorinous odor associated with free chlorine itself simply masks the odor associated with the odor-causing contaminant.

Ozone (and AOPs), chlorine dioxide, and permanganate have all been used for oxidizing and eliminating odorous compounds in water, but their success varies and all are limited to some extent for different types of odor-producing compounds and in different types of waters (Glaze et al., 1990). Generally, all are effective for oxidizing phenolic compounds. A good summary of the kinetics of ozonation of a number of important taste and odor compounds is given by Peter and von Gunten (2007).

Lalezary et al., (1986) found that the order for oxidizing MIB and geosmin at low oxidant doses was $\text{ClO}_2 > \text{O}_3 > \text{Cl}_2 > \text{MnO}_4^-$. Other researchers (e.g., Glaze et al., 1990) have reported that ozone is the most effective agent for oxidizing MIB and geosmin, although when coupled with hydrogen peroxide or UV irradiation to produce the hydroxyl radical (see the earlier discussion), the resulting AOPs tend to be more effective in destroying MIB and geosmin than ozone alone (Ferguson et al., 1990; Ho et al., 2004; Westerhoff et al., 2006). pH has a significant effect on the ozonation of both compounds (see Fig. 7-18), with geosmin being more rapidly destroyed by ozonation than MIB (Liang et al., 2007). Dissolved organic matter in the water exerts an ozone demand, thereby decreasing the ozone concentration and resulting in lower removals of MIB and geosmin. On the other hand, the formation of OH radicals initiated by the organic matter can accelerate the oxidation of MIB and geosmin by ozone (Glaze et al., 1990; Liang et al., 2007).

Peter and von Gunten (2007) found that the oxidation of MIB and geosmin by molecular ozone is very slow (see Table 7-6). The ability of the OH radical in enhancing the oxidation of MIB and geosmin is shown in Figs. 7-19 and 7-20. Figure 7-19 shows a comparison between ozone and ozone/peroxide in oxidizing MIB and geosmin in Colorado River water. The AOP is clearly superior to molecular ozone by itself under these conditions. Figure 7-20 illustrates that both MIB and geosmin are oxidized rapidly, even in the presence of 2 mg/L

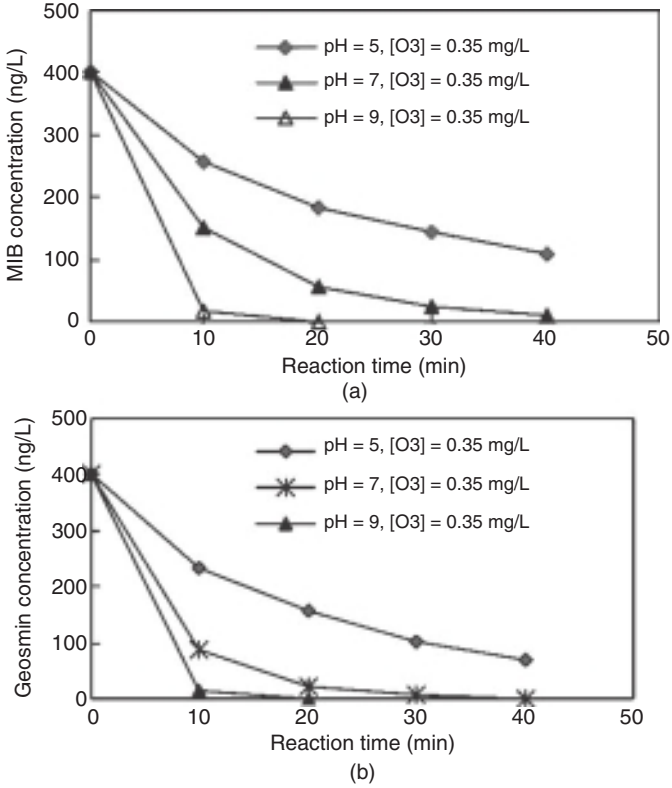

FIGURE 7-18 Effect of pH on the oxidation of (a) MIB and (b) geosmin by ozone. Conditions: 20°C, TOC = 2.91 mg/L, alkalinity = 120 mg/L as CaCO₃. (Source: Liang et al., 2007; reprinted with permission from *Ozone: Science and Engineering*, Copyright 2007.)

FIGURE 7-19 Removal of MIB and geosmin by ozone and peroxide plus ozone (“Peroxone”). H₂O₂/O₃ ratio = 0.2 mg/mg. Conditions: 12–13°C, pH 8.3–8.4, TOC = 2.6–2.8 mg/L, alkalinity 120–135 mg/L as CaCO₃, contact time = 6–12 min. (After Ferguson et al., 1990; reprinted with permission from the American Water Works Association, Copyright 1990.)

FIGURE 7-20 Oxidation of MIB and geosmin in the presence of dissolved hydrophobic organic material (S-HPO; DOC = 2 mg/L) and carbonate alkalinity. Ozone dose = 2 mg/L, temperature = 20°C, pH = 7.0). (Source: Ho et al., 2004; reprinted with permission from IWA Publishing, Copyright 2004.)

of hydrophobic organic carbon (represented here as S-HPO). Carbonate species (alkalinity), because they behave as OH radical scavengers, decrease the rate of oxidation. The relatively rapid rate shown here (seconds vs. minutes) is most likely due to the higher ozone dose used.

It should be noted that aldehydes are often formed from the reactions of ozone with NOM (see Chap. 19). These aldehydes will often impart a fruity odor to the water.

Lastly, as noted previously, the application of chlorine dioxide has been shown, in some cases, to produce noxious (kerosene-like and cat-urine-like) odors. This has been attributed to reactions between chlorite (the principal inorganic by-product of chlorine dioxide), free chlorine (which oxidizes the residual chlorite to chlorine dioxide, which is volatile), and volatile organic chemicals released from new carpeting (Hoehn et al., 1990). When chloramines are used as a secondary disinfectant in place of free chlorine, they are not strong enough to oxidize chlorite to chlorine dioxide, and there is no associated odor problem.

Sulfide Removal

Hydrogen sulfide is a common impurity in groundwater, giving rise to noxious odors. The presence of sulfide arises from the dissolution of sulfidic minerals and the reduction of sulfate under strongly reducing conditions. The most common method of eliminating sulfide from water is by aeration (see Chap. 6). Chemical oxidation can also be used to augment air-stripping or in place of air-stripping, although it tends to be a more expensive approach than air-stripping. The end products of sulfide oxidation are solid elemental sulfur, polysulfides, and sulfate, depending on the oxidant used and solution conditions, such as pH and temperature. Microorganisms can also play an important role in sulfide oxidation, as a number of species are capable of catalyzing sulfide oxidation by oxygen and are commonly found in air-stripping facilities.

Table 7-8 shows the chemical requirements for sulfide oxidation by oxygen and a number of strong oxidants. The stoichiometric requirements are shown for both elemental sulfur and sulfate as end products. Because of the different oxidation states of the sulfur, 4 times as much oxidant is required to convert sulfide to sulfate than to elemental sulfur.

TABLE 7-8 Oxidant Requirements for Sulfide Oxidation

Reaction	Oxidant demand, per mg S(-II)
$2\text{H}_2\text{S} + \text{O}_2 \rightarrow 2\text{S}(\text{s}) + 2\text{H}_2\text{O}$	0.5 mg oxygen
$\text{H}_2\text{S} + 2\text{O}_2 \rightarrow \text{SO}_4^{2-} + 2\text{H}^+$	2 mg oxygen
$\text{H}_2\text{S} + \text{HOCl} \rightarrow \text{S}(\text{s}) + \text{Cl}^- + \text{H}_2\text{O} + \text{H}^+$	2.21 mg chlorine
$\text{H}_2\text{S} + 4\text{HOCl} \rightarrow \text{SO}_4^{2-} + 4\text{Cl}^- + 6\text{H}^+$	8.86 mg chlorine
$\text{H}_2\text{S} + 2\text{ClO}_2 \rightarrow \text{S}(\text{s}) + 2\text{ClO}_2^- + 2\text{H}^+$	4.21 mg chlorine dioxide
$\text{H}_2\text{S} + 8\text{ClO}_2 + 4\text{H}_2\text{O} \rightarrow \text{SO}_4^{2-} + 8\text{ClO}_2^- + 10\text{H}^+$	16.8 mg chlorine dioxide
$3\text{H}_2\text{S} + 2\text{MnO}_4^- + 2\text{H}^+ \rightarrow 3\text{S}(\text{s}) + 2\text{MnO}_2(\text{s}) + 4\text{H}_2\text{O}$	2.47 mg permanganate
$3\text{H}_2\text{S} + 8\text{MnO}_4^- + 2\text{H}^+ \rightarrow 3\text{SO}_4^{2-} + 8\text{MnO}_2(\text{s}) + \text{H}_2\text{O}$	9.89 mg permanganate
$\text{H}_2\text{S} + \text{O}_3 \rightarrow \text{S}(\text{s}) + \text{O}_2 + \text{H}_2\text{O}$	1.50 mg ozone
$\text{H}_2\text{S} + 4\text{O}_3 \rightarrow \text{SO}_4^{2-} + 4\text{O}_2 + 2\text{H}^+$	5.99 mg ozone

The kinetics of sulfide oxidation by oxygen are strongly impacted by pH, as shown in Fig. 7-21. The oxidation reaction by oxygen is relatively slow and elemental sulfur and polysulfides are the primary products, but as noted previously, the reaction is readily catalyzed by sulfide-oxidizing bacteria. Lyn and Taylor (1992) found that the oxidation of sulfide by free chlorine was fast under typical water treatment conditions and that elemental sulfur is a major end product leading to elevated turbidity levels in the chlorinated water, requiring attention to sound solid-liquid separation processes to capture the sulfur precipitate. Sulfide oxidation by ozone and advanced oxidation processes is rapid, as illustrated in Table 7-6; sulfate is the principal end product, necessitating relatively high oxidant doses.

Color Removal

Color in water tends to be associated with the presence of polyaromatic compounds arising from natural vegetative decay processes. These compounds are often referred to as *humic acids* or *humic substances*. They impart a yellowish hue to the water, which can be quantified by the measurement of absorbance at 450 to 465 nm or by comparison to platinum-cobalt standards (*Standard Methods*, 2005). The nature of these substances and the molecular basis of the color varies with the source water. Color can also be correlated to the absorbance of UV radiation at 254 nm, a parameter that is often used to quantify the presence of NOM (see Chap. 3) that contributes to the formation of disinfection by-products (see Chap. 19). The

FIGURE 7-21 Effect of pH on the rate constant for the oxidation of sulfide by oxygen. (Source: Chen and Morris, 1972; reprinted with permission from the American Chemical Society, Copyright 1972.)

humic substances are frequently complexed with trace metals in the water, a phenomenon which contributes to the appearance and intensity of the color.

The most common processes for the removal of natural organic color from water are chemical oxidation and coagulation. In the case of coagulation, the color-causing organics are coagulated and physically removed from solution (see Chap. 8), whereas for chemical oxidation, the color-causing organics are chemically altered but the colorless products remain in solution. The oxidizing agent attacks the chromophoric portion of the molecules that are responsible for the absorption of visible light; these are usually the carbon-carbon double bonds, the groups that bind trace metals, and the polyaromatic structures themselves. Chlorine had been used historically for color removal, but it became apparent in the 1970s that the reactions between chlorine and the color-causing organic materials are the ones that lead to the formation of halogenated disinfection by-products that are of public health concern (see Chap. 19). Ozone and chlorine dioxide are also effective chemical oxidants for color removal, but these oxidants also produce by-products that can be problematic, for example, biodegradable organic material that, if not properly controlled, can lead to microbial growth in the distribution system (see Chap. 21). Accordingly, it may be more desirable to remove the color-causing organic materials by coagulation processes (see Chap. 8) first, thereby lowering the oxidant demand of the water, and then use chemical oxidation to polish any residual color that may remain after clarification and/or filtration.

Oxidation of Organic Micropollutants

Strong chemical oxidants are capable of reacting with a variety of organic micropollutants that may be present in water supplies, such as synthetic organic chemicals (e.g., pesticides), chlorinated solvents, fuel additives, pharmaceutically active compounds and personal care products, endocrine disruptors, and algal toxins. These reactions are highly dependent on the nature of

the organic compound, the specific oxidant in question, other constituents in the water that may interfere with or compete with the target contaminant, pH, and temperature. Some organic compounds are relatively easy to oxidize, whereas others are much more resistant to oxidation. Additionally, for any particular oxidant, the products of the reaction vary, depending on the oxidant, the ratio of the concentration of the oxidant to that of the contaminant, the pathway by which the reaction occurs, and general water quality characteristics. Rarely is the contaminant completely mineralized to carbon dioxide and water. In some cases, the oxidation products may be of greater concern than the parent compound.

For example, the oxidation of phenol by low doses of chlorine leads to the formation of mono-, di-, and trichlorophenols (Burttschell et al., 1959). At higher doses, the aromatic ring is cleaved to generate halogen-containing products. In the case of ozone, oxidation of phenol at low ozone doses results in the formation of primarily catechol and benzoquinone, before the aromatic ring is cleaved at higher doses to produce a variety of low-molecular-weight carboxylic acids such as *cis,cis*-muconic acid, maleic acid, and glyoxylic acid (Singer and Gurol, 1983; Ramseier and von Gunten, 2009). With chlorine dioxide, oxidation of phenol produces hydroxophenols, quinones, and several chlorophenols and chloroquinones at low oxidant doses (Wajon et al., 1982; Stevens, 1982). Subsequent ring cleavage at higher chlorine dioxide doses leads to the formation of carboxylic acids, as is the case with ozone. And, of course, chlorination of NOM leads to the formation of halogenated disinfection by-products (see Chap. 19).

As noted earlier, Hoigne and coworkers (1983a, 1983b, 1985) and von Gunten (2003) present rate constants for reactions of ozone with a variety of inorganic and organic compounds in water (e.g., see Table 7-6). The examples in Table 7-6 attest to the selectivity of molecular ozone for various types of contaminants. For example, the rate constants for the oxidation of pesticides span more than five orders of magnitude. Endrin has the lowest reactivity of the compounds shown because of the electron-withdrawing groups of the chloro-substituted double bond in this cyclic compound, whereas the rate constant for carbofuran is much higher because of the presence of a secondary amino group on the aromatic ring.

Phenol and naphthalene are rapidly oxidized by molecular ozone (Hoigne and Bader, 1983a), whereas atrazine, alachlor, benzene, methyl tertiary butyl ether (MTBE), trichloroethene, and tetrachloroethene are only slowly oxidized by molecular ozone (Table 7-6). On the other hand, these same micropollutants are rapidly oxidized by the hydroxyl radical generated from the decomposition of ozone. Hence, conditions that favor the formation of hydroxyl radicals are conducive to the elimination of these harmful contaminants. Such conditions include ozonation at elevated pH values or the use of ozone in conjunction with UV irradiation or hydrogen peroxide addition (AOPs). Conversely, conditions that favor the scavenging of hydroxyl radicals interfere with the effectiveness of these AOPs. This is true for high alkalinity waters that contain high concentrations of bicarbonate and carbonate, both of which are hydroxyl radical scavengers (see the discussion above). Additionally, because these micropollutants are usually present at relatively low concentrations ($\mu\text{g/L}$) compared to NOM which is present at milligram per liter concentrations, these advanced oxidation processes tend to be less effective in waters that contain high concentrations of NOM, although in some cases the presence of NOM can promote the formation of free radicals and accelerate the oxidation process.

Chlorine dioxide is also a highly selective chemical oxidant. Although little work has been done with pesticides and solvents, Hoigne and Bader (1994) present a summary of reaction rate constants for a variety of organic and inorganic species (see Table 7-5). Their work shows that olefins, aromatic hydrocarbons, primary and secondary amines, aldehydes, ketones, and carbohydrates are not very reactive with chlorine dioxide under water treatment conditions, whereas tertiary amines, thiols, and deprotonated phenols tend to have high reaction rate constants. Again, in waters with high concentrations of NOM, the oxidant demand of the NOM must be overcome before appreciable elimination of the target micropollutants can be achieved.

Given the growing interest in pharmaceutically active compounds, endocrine disruptors, and cyanotoxins, it is worth noting that many of these compounds are also readily oxidized by a number of the strong oxidants discussed in this chapter.

Cyanotoxins. Rositano et al. (2001) reported 100 percent destruction of the cyanotoxins microcystin-LR and -LA and anatoxin-a by ozonation of four treated waters with very different water qualities. The degree of destruction was related to the residual ozone concentration present after 5 min, which was, in turn, related to the water quality. They noted that direct reaction with molecular ozone could be responsible for cyanotoxin destruction.

Rodriguez et al. (2007) studied the oxidation of three cyanotoxins, microcystin-LR, cylindrospermopsin, and anatoxin-a, with ozone, chlorine, chlorine dioxide, and permanganate. Permanganate was found to oxidize anatoxin-a and microcystin-LR effectively, chlorine was found to oxidize cylindrospermopsin and microcystin-LR, and ozone was capable of oxidizing all three toxins with the highest rate constant among the three oxidants examined. Chlorine dioxide was not an effective oxidant for elimination of these cyanotoxins during drinking water treatment. Further, Onstad et al. (2007) found that hydroxyl radicals contributed significantly to toxin oxidation during the ozonation of natural waters. The order of reactivity, anatoxin-a > cylindrospermopsin > microcystin-LR, corresponds to the relative magnitudes of the second-order rate constants for their reaction with ozone and the hydroxyl radical. It was suggested that, because ozone primarily attacks the structural moieties responsible for the toxic effects of these algal toxins, ozone selectively detoxifies these compounds.

Pharmaceuticals, Personal Care Products, Endocrine Disruptors. Huber et al. (2003) determined second-order rate constants for the reactions of selected pharmaceuticals with ozone and OH radicals. Five of the pharmaceuticals (carbamazepine, diclofenac, 17 α -ethinylestradiol, sulfamethoxazole, and roxithromycin) exhibited rate constants $>5 \times 10^4 \text{ M}^{-1}\text{s}^{-1}$ with molecular ozone at pH 7, indicating that these compounds are completely transformed during ozonation processes. Diazepam, ibuprofen, and iopromide reacted orders of magnitude more slowly. In contrast, values for the rate constants with the OH radical ranged from 3.3 to $9.8 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$. Compared to other important micropollutants such as MTBE and atrazine, the selected pharmaceuticals reacted about 2 to 3 times faster with OH radicals. It was concluded that ozonation and AOPs are promising processes for an efficient removal of pharmaceuticals in drinking waters.

Westerhoff et al. (2005), in a study of 62 different endocrine disrupting compounds, pharmaceutically active compounds, and personal care products, reported that chlorine and ozone decreased the concentrations of these emerging contaminants by <10 to >90 percent. Ozone oxidized steroids containing phenolic moieties (estradiol, ethinylestradiol, and estrone) more efficiently than those without aromatic or phenolic moieties (androstenedione, progesterone, and testosterone). Six of the compounds studied (tri(2-chloroethyl) phosphate, BHC, chlor-dane, dieldrin, heptachlor epoxide, and musk ketone) were oxidized <20 percent by chlorine or ozone. Twenty-four of the compounds exhibited better removals with ozone than with chlorine. The remaining compounds were easily oxidized (>80 percent reacted) by chlorine, and were always oxidized at least as efficiently by ozone. Lei and Snyder (2007) used three-dimensional quantitative structure-property relationships as a screening tool to predict the removals of selected endocrine-disrupting compounds and pharmaceuticals and personal care products by ozone and free chlorine.

Broseus et al. (2009) investigated the oxidation of a number of pharmaceuticals, endocrine-disrupting compounds, and pesticides (including caffeine, trimethoprim, carbamazepine, naproxen, gemfibrozil, estrone, estriol, estradiol, 17 α -ethinylestradiol, progesterone, cyanazine, and diethylatrazine) and found that ozonation, at ozone doses and contact times typically applied in drinking water treatment, removed over 80 percent of caffeine, pharmaceuticals, and endocrine disruptors. The pesticides examined, some of which are metabolites of atrazine, were found to be the most recalcitrant compounds to oxidize.

In a review of the literature, Ikehata et al. (2008) found that, in most cases, ozonation and AOPs were effective for the degradation of a wide variety of pharmaceuticals, personal care products, endocrine-disrupting compounds, pesticides, and surfactants. Some compounds, such as carbamazepine, 17-estradiol, diclofenac, and pentachlorophenol, were reported to be extremely reactive toward ozone and hydroxyl radicals. On the other hand, it was found that halogenated pesticides, X-ray contrast agents, and surfactants were resistant to oxidative degradation by molecular ozone. UV-assisted advanced oxidation was found to be more effective in the degradation of halogenated organics compared with ozonation due to enhanced generation of hydroxyl radicals and photon-initiated cleavage of carbon-halogen bonds.

In an evaluation of chlorine dioxide for the oxidation of pharmaceutically active compounds, Huber et al. (2005) reported that sulfonamide and macrolide antibiotics, pyrazolone derivatives, and estrogens were rapidly oxidized by ClO_2 , but many other PhACs were refractory toward ClO_2 . Compared to ozone, ClO_2 reacted more slowly and with fewer compounds, but reacted faster with the compounds investigated than chlorine.

Methyl Tertiary Butyl Ether. Methyl-*tert*-butyl-ether (MTBE), a common oxygenated fuel additive found in reformulated gasoline and an oft-reported groundwater contaminant, was found to be rapidly oxidized by ozone and peroxide, but high doses of ozone and an ozone:peroxide ratio of 1:1 by weight were required (Liang et al., 2001). The products of the reaction were observed to be *t*-butyl formate, *t*-butyl alcohol, acetone, and a number of aldehydes, many of which are biodegradable. Acero et al. (2001) showed that MTBE reacts slowly with molecular ozone but rapidly with the hydroxyl radical, and found that the oxidation products reacted only slowly with molecular ozone. They proposed a pathway for the reaction between MTBE and the hydroxyl radical.

It is important to note again that, while the concentration of many of these organic micropollutants may be decreased appreciably by chemical oxidation reactions, the compounds are typically not completely mineralized. The oxidation reactions generate “daughter” products that also may be of public health concern. Hence it is important to understand the pathway by which the contaminants are oxidized and to identify the daughter products generated by the oxidation reactions before these processes are widely implemented for controlling organic micropollutants in drinking water.

Oxidation as an Aid to Coagulation and Flocculation

The application of oxidants to raw waters drawn from surface supplies is known to assist in subsequent coagulation and flocculation processes. While this has been reported to some degree for chlorine and chlorine dioxide, the use of ozone for this purpose has been widely touted (Langlais et al., 1991). The phenomenon appears to be associated with the facts that most particles in raw drinking water are negatively charged due to the adsorption of NOM to the particle surface and that NOM in bulk solution exerts an appreciable coagulant demand. Accordingly, mechanisms cited for the coagulation and flocculation benefits of oxidants include: oxidation of adsorbed organics to more polar forms which desorb from particles, thereby making the particles less stable and more amenable to aggregation; alteration of the configuration of the adsorbed organics so that they more effectively bind coagulants such as Al(III) and Fe(III) at the particle surface; oxidation of organics in bulk solution to form carboxylic acid functional groups that bind metals such as calcium and aluminum, resulting in direct precipitation of the organic material; and oxidation of organics causing them to release bound metals such as Fe(III) which can then assist in particle coagulation by conventional mechanisms (Reckhow et al., 1986). While the actual mechanisms are not entirely clear, there are a number of waters where these phenomena have been observed, although there are many other waters where no such benefits have been found (Reckhow et al., 1986).

Control of Biological Growths in Treatment Plants

One of the many benefits of chlorine is that it controls nuisance aquatic growths in water treatment plants. This includes growths in flocculation and sedimentation basins and on filter media. Maintenance of a free chlorine residual throughout the treatment plant minimizes the potential growth of microorganisms, especially in open basins exposed to sunlight, which encourages algal growth. Ozone, chlorine dioxide, and permanganate also exhibit biocidal attributes, but because of the doses typically employed and the relative chemical instability of these oxidants over time, it is not easy to maintain a residual with these oxidants across sedimentation basins and, in some cases, through filter beds.

In fact, because ozone, AOPs, chlorine dioxide, and permanganate oxidize NOM to produce low-molecular-weight biodegradable organic compounds, it can be anticipated that oxidative treatment will actually increase the potential for microbial growth in pretreatment basins and on filter media in the absence of a disinfectant (oxidant) residual. Accordingly, such growths must be controlled in order to minimize subsequent biofouling problems. This can include the use of free or combined chlorine following the application of these other oxidants, periodic shock treatment of the basins or filters with free chlorine, or engineering and operating the filters in a biological mode (see Chap. 21). Chlorine will also generate biodegradable organic compounds, but often the presence of a chlorine residual will control these biological growths.

Summary of Benefits of Oxidation to Water Treatment Processes

It is clear that chemical oxidants provide a variety of tangible benefits in drinking water treatment practice. Some are easy to define and quantify. Others are more diffuse and tend to be more difficult to delineate and assess. Ultimately, however, chemical oxidation is a multiobjective process that serves many useful purposes and helps to improve the overall quality of drinking water. The specific benefits of the process and of each candidate chemical oxidant need to be evaluated on a case-by-case basis.

ABBREVIATIONS

AOPs	advanced oxidation processes
ATRA-imin	atrazine-imine
CT	product of concentration and contact time
DBPs	disinfection by-products
DEA	diethylatrazine
DIA	diisopropyl atrazine
DOC	dissolved organic carbon
EDCs	endocrine disrupting chemicals
FAC	free available chlorine
HOX	hypohalous acid
MCL	maximum contaminant level
MIB	methylisoborneol
MRDL	maximum residual disinfectant level
MTBE	methyl- <i>tert</i> -butyl-ether

NOM	natural organic material
pe	negative log of electron activity
pH	negative log of hydrogen ion activity
PhACs	pharmaceutically active compounds
pK_a	negative log of acidity constant
PPCPs	pharmaceutically active compounds and personal care products
PQL	practical quantitation limit
QSARs	quantitative structure-activity relationships
S-HPO	hydrophobic organic carbon
TCE	trichloroethene
TOC	total organic carbon
USEPA	U.S. Environmental Protection Agency
UV	ultraviolet

NOTATIONS FOR EQUATIONS

α	pH-dependent distribution coefficient
ΔG°	standard Gibbs free energy change
A	arrhenius frequency factor or pre-exponential factor
E_a	activation energy
E_{net}°	net standard reaction potential
E_{ox}°	standard oxidation potential
E_{red}°	standard reduction potential
F	faraday's constant
K	equilibrium constant
$k, k_f, k_{\text{obs}}, k_2, k_3, \text{etc.}$	reaction rate constants
M_d	direct-reacting substrate
M_i	indirect-reacting substrate
n	number of electrons transferred
R	universal gas constant
T	absolute temperature

INTRODUCTION

Coagulation is a process that increases the tendency of small particles in an aqueous suspension to attach to one another and to surfaces such as the media in a filter bed. It is also used to affect the removal of certain soluble materials by adsorption or precipitation. The coagulation process typically includes promoting the interaction of particles to form larger aggregates. It is an essential component of conventional water treatment systems in which the processes of coagulation, clarification, filtration, and disinfection are combined to treat the water and remove and inactivate microbiological contaminants such as viruses, bacteria, and the cysts and oocysts of pathogenic protozoa. Facilitating the removal of microbiological contaminants is perhaps the key reason for using coagulation; however, other objectives such as the removal of natural organic matter (NOM) to reduce the formation of disinfection by-products (DBPs) and the adsorption of dissolved inorganic contaminants such as arsenic compounds are increasingly important. Coagulation and flocculation are pretreatment processes; they do not actually remove contaminants but rather promote changes that facilitate their efficient removal in subsequent separation processes.

Coagulation has been an important component of granular bed (rapid sand and multimedia) filtration plants in the United States since the 1880s. Alum and iron (III) salts have been used as coagulant chemicals since that time, with alum having the most widespread use. In the 1930s, Baylis (1937) perfected activated silica as a coagulant aid. This material, formed on site, is an anionic polymer or a small, negatively charged colloid. Synthetic organic polymers were introduced in the 1960s, with cationic polymers having the greatest use. Natural starches were used before the synthetic compounds. Polymers have helped change pretreatment and filtration practice, including the use of multimedia filters and filters with deep, uniform grain-size media; high-rate filtration; direct filtration (rapid mixing, flocculation, and filtration, but no clarification); and inline filtration (rapid mixing and filtration only).

Coagulants are also used to enhance the performance of membrane microfiltration and ultrafiltration systems (Wiesner et al., 1989; Judd and Hillis, 2001; Howe and Clark, 2006) and in pretreatment to prolong the bed life of granular activated carbon contactors (Nowack and Cannon, 1996). The development of new coagulant chemicals, advances in floc removal processes and filter design, particularly membrane processes, and challenging particle removal performance standards and goals have stimulated substantial diversity in the design and operation of the coagulation process. Change can be expected to continue into the future.

In evaluating granular bed filtration plants that were producing high-quality filtered water, Cleasby et al. (1989) concluded, "Chemical pretreatment prior to filtration is more critical to success than the physical facilities at the plant." Their report recommends that plant staff use a well-defined coagulant chemical control strategy that considers variable raw-water quality. There is no question that high-rate (rapid sand and multimedia) filtration plants are coagulant-based systems that work only as well as the coagulants that are used.

This chapter begins with introductory sections on definitions and the types of contaminants removed by the coagulation and flocculation processes. The fundamentals of physics and chemistry that explain how particles interact in suspensions are then reviewed. The various types of hydrolyzing metal salt coagulants are described and methods for estimating required dosages and minimizing residual coagulant metal concentrations are explained using some example calculations. Organic polyelectrolyte coagulants and supplemental materials are then discussed. The final sections describe the flocculation process and how it is used with coagulants to produce flocs that can be removed by particle separation processes.

Definitions

Coagulation is a complex process, involving numerous interconnected chemical reactions and mass transfer steps. As practiced in water treatment, the process is essentially four separate and sequential steps: coagulant transformation, uptake of adsorbed species, particle destabilization, and interparticle collisions. Coagulant transformation, adsorbate-coagulant interaction, and particle destabilization typically occur during and immediately after chemical dispersal in rapid mixing; interparticle collisions that cause aggregate (floc) formation begin during rapid mixing but usually occur with greatest effect in the flocculation process. For example, when the aluminum sulfate salt known as alum ($\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$) is used in coagulation, the assortment of chemical species, called *aluminum hydrolysis products*, that causes coagulation is formed during and after the alum is mixed with the water to be treated. Coagulants are sometimes formed (or partially formed) prior to their addition to the rapid-mixing units. Examples include activated silica and synthetic organic polymers and the prehydrolyzed metal salts such as polyaluminum chloride (PACl) and polyiron chloride (PICl).

The terminology of coagulation has not been standardized. However, in most of the water treatment literature, coagulation refers to all the reactions and mechanisms that result in particle aggregation in the water being treated, including coagulant transformations (where applicable), particle destabilization, adsorbate uptake, and physical interparticle contacts. The physical process of producing interparticle contacts and particle aggregates (flocs) is termed *flocculation*.

These definitions of coagulation and flocculation are based on the terminology used by early practitioners such as Camp (1955). However, in the colloid science literature, LaMer (1964) considered only chemical mechanisms in particle destabilization and used the terms *coagulation* and *flocculation* to distinguish between two of them. LaMer defined destabilization by simple salts such as NaCl (a so-called indifferent electrolyte) as coagulation.

The water treatment literature sometimes makes a distinction between the terms *coagulant* and *flocculant*. When this distinction is made, a coagulant is a chemical used to initially destabilize the suspension and is typically added in the rapid-mix process. In most cases a flocculant is used after the addition of a coagulant; its purpose is to enhance floc formation and to increase the strength of the floc structure. It has awkwardly been called a *coagulant aid*. Flocculants are often used to increase filter performance (they may be called *filter aids* in this context) and to increase the efficiency of a sludge dewatering process. In this chapter, no distinction is made between coagulants and flocculants. The term *coagulant* is used exclusively.

CONTAMINANTS

Particles

As discussed in Chap. 3 particles in natural water vary widely in origin, concentration, size, and surface chemistry. Some are derived from land-based or atmospheric sources (e.g., clays and other products of weathering, silts, pathogenic microorganisms, asbestos fibers, and other terrestrial detritus and waste discharge constituents), and some are produced by chemical and biological processes within the water source (e.g., algae, precipitates of CaCO_3 , $\text{Fe}(\text{OH})_3$, MnO_2 , and the organic exudates of aquatic organisms). Certain toxic metals and synthetic organic chemicals (SOCs) are associated with solid particles, so coagulation for particle aggregation can be important in the removal of soluble, health-related pollutants.

Particle size may vary by several orders of magnitude, from a few tens of nanometers (e.g., viruses and high molecular weight NOM) to a few hundred micrometers (e.g., zooplankton). The important cysts and oocysts of pathogenic protozoa (e.g., *Giardia* and

Cryptosporidium) are ovoid particles with overall dimensions in the 3- to 12- μm (micrometer) range. All can be effectively removed by properly designed and operated coagulation, flocculation, and filtration facilities.

The smallest particles, those with one dimension less than 1 μm , are usually called *colloidal* and those which are larger than this limit are said to be suspended. The operational definition of dissolved and suspended impurities is frequently established by a 0.45- μm -pore-size membrane filter but colloidal particles can be smaller than this dimension. The effect of gravity on the transport of colloidal particles tends to be negligible compared to the diffusional motion caused by interaction with the fluid (Brownian motion) and, compared to suspended particles, colloidal particles have significantly more external surface area per unit mass.

Measuring Particle Concentration. The principal methods for measuring the performance of particle removal processes in water treatment systems are turbidity and particle counting. Both techniques have limitations, and, consequently, a single method may not provide all the information needed to successfully monitor and control process performance.

Turbidity is measured using an instrument, called a *turbidimeter* or *nephelometer*, that detects the intensity of light scattered at one or more angles to an incident beam of light. Light scattering by particles is a complex process and the angular distribution of scattered light depends on a number of conditions including the wavelength of the incident light and the particle's size, shape, and composition (Sethi et al., 1997). Consequently, it is difficult to correlate the turbidity with the amount, number, or mass concentration of particles in suspensions.

When the turbidity measurement is used for regulatory purposes, it should theoretically be possible to take a given suspension and measure its turbidity at any water treatment facility and obtain an unbiased result that is reasonably close to the average turbidity measured at all other facilities. To achieve reasonable agreement, three factors must be considered: the design of the instruments, the material used to calibrate the instrument, and the technique used to make the measurement. Given this need, turbidimeter design, calibration, and operation criteria have been developed by a number of organizations using the consensus process. However, standardization is a difficult and imperfect process, and it has been shown (Hart et al., 1992) that instruments designed and calibrated using the criteria of these standards can give significantly different responses.

Turbidity measurements were first used to maintain the aesthetic quality of treated water. In 1974, after the passage of the Safe Drinking Water Act, the USEPA lowered the limit for filtered water to 1 ntu (nephelometric turbidity unit) with the explanation that particles causing turbidity can interfere with the disinfection process by enmeshing and, therefore, protecting microbiological contaminants from chemical disinfectants such as chlorine. Today the turbidity measurement is also used to assess filter performance. It is viewed as an important indicator of the extent to which disinfectant-resistant pathogens have been removed by the filtration process. Filtered-water turbidity criteria must be met before the protozoan cyst/oocyst and virus removal credits allowed by the Surface Water Treatment Rule of the 1986 Amendments of the Surface Water Treatment Rule can be applied (see Chap. 2).

Particle-counting instruments are widely used in the drinking water industry, especially for monitoring and controlling clarification and filtration process performance. Plants use them to detect early filter breakthrough and to maintain plant performance at a high level. Online devices that continuously measure particle concentrations in preselected size ranges at various points in the treatment system are especially important. Occasionally batch-sampling devices are used. Two types of particle-counting/sizing sensors are important in water treatment applications: light-blocking (light-obscuration) devices and light-scattering devices (Hargesheimer et al., 1992; Lewis et al., 1992). At the present time instruments with light-blocking-type sensors are more common.

The types of particle-counting instruments used in water treatment plants have limitations (Hargesheimer et al., 1992; Letterman, et al. (2001). Most do not detect any particles smaller

than about 1 μm and do detect only a fraction of the particles larger than 1 μm . (Letterman et al., 2001). They should therefore be used in conjunction with turbidimeters that detect smaller particles. Differences in the optical characteristics of the sensors make achieving direct count and size agreement between instruments difficult. There are no industry-wide standards for sensor resolution or for particle-counting and -sizing accuracy and efficiency. For a given particle suspension it is not possible to make similar sensors yield identical particle counts and sizes. Until this is feasible, the regulatory use of particle count measurements will be limited.

The reader may find additional coverage of turbidity and particle measures in Chap. 3.

Natural Organic Material (NOM) and the USEPA's Enhanced Coagulation Requirement. Chapter 3 discusses the characteristics and significance of NOM in water treatment. NOM consists of various types of organic matter that are important precursors in the formation of disinfection and other types of by-products as discussed in Chap. 19. NOM imparts a yellow color to water, especially the humic substances fractions (humic and fulvic acids); causes aesthetic concerns; and can affect water quality in the distribution system. Coagulation and flocculation can be effective ways to remove a significant fraction of the NOM. The dosage required for effective NOM removal is typically greater than that needed for particle (turbidity) removal.

The USEPA's 1998 Stage 1 Disinfection By-Products Rule (Stage 1 DBPR) (USEPA, 1998) requires the use of a NOM removal strategy called *enhanced coagulation* to limit the formation of all disinfection by-products (DBPs). The requirement applies to conventional water treatment facilities that treat surface water or groundwater that is under the influence of surface water. The amount of TOC a plant must remove is based on the raw-water TOC and alkalinity.

Enhanced coagulation ties the TOC removal requirement to the raw water alkalinity to avoid forcing a utility to add high dosages of *hydrolyzing metal salt (HMS)* coagulants to reduce the pH to between 5 and 6, a range where HMS coagulants frequently appear to be most efficient. It also recognizes that higher TOC removal is usually possible when the raw-water TOC concentration is relatively high and the fraction of the NOM that is more readily removed by HMS coagulants is typically greater. The matrix in Table 8-1 gives Stage 1 DBPR's required TOC removal percentages.

TABLE 8-1 Required Percent Removals of Total Organic Carbon by Enhanced Coagulation in the 1998 Stage 1 Disinfection By-Products Rule

Source-water total organic carbon (mg C/L)	Source-water alkalinity (mg/L as CaCO_3)		
	0–60	60–120	> 120
> 2.0–4.0	35	25	15
> 4.0–8.0	45	35	25
> 8.0	50	40	30

Example 8-1 Application of the USEPA's Enhanced Coagulation Requirement for TOC

Problem Statement A plant's source water has a TOC of 3.5 mg C/L and an alkalinity of 85 mg/L as CaCO_3 . Determine the maximum allowable TOC of the combined filter effluent in mg C/L for this water.

Solution According to the table, the required TOC removal is 25 percent. The TOC of the filtered water (after the point where the filter effluents are combined) would have to be less than 2.6 mg C/L, calculated using the relationship $2.6 \text{ mg C/L} = 3.5 \text{ mg C/L} \times (1 - 0.25)$. ▲

The Stage 1 DBPR provides alternative compliance criteria for the enhanced coagulation, treatment technique requirement. The six criteria are

1. The system's source water TOC is < 2.0 mg C/L.
2. The system's treated water TOC is < 2.0 mg C/L.
3. The system's source water TOC is < 4.0 mg C/L, the source water alkalinity is > 60 mg/L as CaCO_3 , and the system is achieving TTHM < 40 $\mu\text{g/L}$ and HAA5 (haloacetic acids) < 30 $\mu\text{g/L}$.
4. The system's TTHM is < 40 $\mu\text{g/L}$, HAA5 is < 30 $\mu\text{g/L}$ and only chlorine is used for primary disinfection and maintaining a distribution system residual.
5. The system's source water SUVA prior to any treatment is ≤ 2.0 L/(mg-m).
6. The system's treated water SUVA is ≤ 2.0 L/(mg-m).

The measurements used to test compliance with criteria 1, 2, 5, and 6 are made monthly and a running annual average is calculated quarterly. Compliance with criteria 3 and 4 is based on monthly measurements of TOC and alkalinity and quarterly measurements of TTHMs and HAA5, and the running annual average is calculated quarterly.

The regulatory negotiators who formulated the enhanced coagulation requirement were concerned that coagulant chemical costs might be excessive for utilities that treat water with a high concentration of NOM that is not amenable to removal by coagulants. For these plants the removal requirements of Table 8-1 and the alternative compliance criteria may not be feasible. This is rare, but in that event the Stage 1 DBPR allows them to use a jar test procedure to determine an appropriate, alternative TOC removal requirement (White et al., 1997).

The alternative TOC removal requirement is determined by performing jar tests on at least a quarterly basis for 1 year. In these tests, alum or ferric coagulants are added in 10-mg/L increments until the pH is lowered to a target pH value that varies with the source water alkalinity. For the alkalinity ranges of 0–60, >60–120, >120–240, and >240 mg/L as CaCO_3 , the target pH values are 5.5, 6.3, 7.0, and 7.5, respectively. When the jar test is complete, the residual TOC concentration is plotted versus the coagulant dosage (in mg coagulant/L) and the alternative TOC percentage is found at the point called the *point of diminishing returns (PODR)*. The PODR is the coagulant dosage where the slope of the TOC-coagulant dosage plot changes from greater than 0.3 mg C/10 mg coagulant to less than 0.3 mg C/10 mg coagulant. If the plot does not yield a PODR, then the water is considered to be not amenable to enhanced coagulation and the primacy agency may grant the system a waiver from the enhanced coagulation requirement. Details of the jar test procedure are given in the USEPA's Guidance Manual for Enhanced Coagulation and Enhanced Precipitative Softening (USEPA, 1999).

STABILITY OF PARTICLE SUSPENSIONS

In water treatment, the coagulation process is used to increase the rate or kinetics of particle aggregation and floc formation. The objective is to transform a stable suspension, that is, one that is resistant to aggregation (or attachment to a filter grain), into an unstable one. Particles that may have been in lake water for months or years as stable, discrete units can be aggregated in an hour or less following successful destabilization. The design and operation of the coagulation process requires proper control of both the particle destabilization and the subsequent aggregation process.

The suspensions that must be aggregated and separated in water treatment may include particles formed in or added to the treatment system, in addition to the particles in the source water. For example, processes used to remove manganese and iron can produce suspensions of MnO_2 and $\text{Fe}(\text{OH})_3$ precipitates, and particles of finely divided activated carbon (powdered activated carbon) are often added before particle separation processes to adsorb organic compounds. In some cases, such as high-quality upland reservoirs and lakes, the quantity of particles formed or added in treatment may greatly exceed that of the particles in the source water.

As particles in a suspension approach one another or as a particle in a flowing fluid approaches a stationary surface such as a filter grain, forces arise that tend to keep the surfaces apart. Also, there are forces that tend to pull the interacting surfaces together. The most well known repulsive force is caused by the interaction of the electrical double layers of the surfaces (electrostatic stabilization). The most important attractive force is called the *London-van der Waals force*. It arises from spontaneous electrical and magnetic polarizations that create a fluctuating electromagnetic field within the particles and in the space between them. These two types of forces, repulsive and attractive, form the basis of the Derjaguin, Landau, Verwey, and Overbeek (DLVO) theory of colloid stability (Derjaguin and Landau, 1941; Verwey and Overbeek, 1948). Other forces include those associated with the hydration of ions at the surfaces (a repulsive force), hydrophobicity of surfaces (an attractive force), and the presence of adsorbed polymers, which can cause either repulsion (steric interaction) or attraction (polymer bridging). Additional forces may arise if external fields, such as magnetic fields, are utilized in aggregation processes. As particles approach one another on a collision course, the fluid between them must move out of the way. The repulsive force caused by this displacement of fluid is called *hydrodynamic retardation*. Details about these forces can be found in the text by Elimelech et al. (1995).

Electrostatic Stabilization

Origins of Surface Charge. Most particles in water, mineral and organic, have electrically charged surfaces, and the sign of the charge is usually negative (Niehof and Loeb, 1972; Hunter and Liss, 1979; Stumm, 1992). As described in Chap. 3, there are three important processes for producing this charge. First, surface groups on the solid may react with water and accept or donate protons. In these reactions, the surface charge on a solid particle depends on the pH in the solution. As the pH increases, the surface charge becomes increasingly negative. Silica is negatively charged in water with a pH above 2; proteins contain a mixture of carboxyl and amino groups and usually have a negative charge at a pH above about 4.

Second, surface groups can react in water with solutes other than protons. These surface complex formation reactions involve specific chemical reactions between chemical groups on the solid surface (e.g., silanol groups) and adsorbable solutes (e.g., calcium and phosphate ions). The surface charge is again related to solution chemistry.

Third, a surface charge may arise because of imperfections within the structure of the particle; this is called *isomorphic replacement* or *substitution*. It is responsible for a substantial part of the charge on many clay minerals. Clays are layered structures and in these structures sheets of silica tetrahedra are typically cross-linked with sheets of alumina octahedra. The silica tetrahedra have an average composition of SiO_2 and may be depicted as shown in Fig. 8-1a: If an Al atom is substituted for a Si atom during the formation of this lattice, a negatively charged framework results (Fig. 8-1b).

Similarly, a divalent cation such as Mg (II) or Fe (II) may substitute for an Al(III) atom in the aluminum oxide octahedral network, also producing a negative charge. The

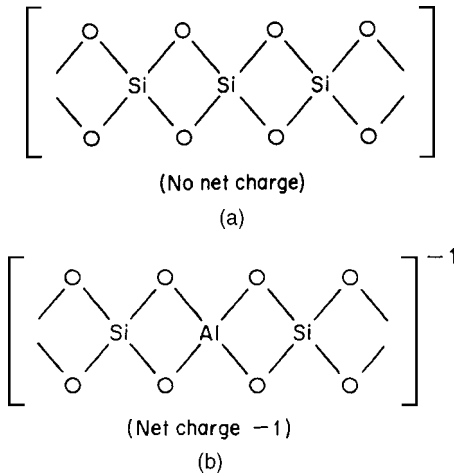

FIGURE 8-1 SiO_2 structure, (a) with no net charge and (b) with -1 net charge.

ical double layer. The diffuse layer results from electrostatic attraction of ions of opposite charge to the particle (*counterions*), electrostatic repulsion of ions of the same charge as the particle (*coions*), and thermal or molecular diffusion that acts against the concentration gradients produced by the electrostatic effects. Schematic representations of the diffuse layer are shown in Figs. 8-2 and 8-3a.

Because of the primary charge, an electrostatic potential (voltage) exists between the surface of the particle and the bulk of the solution. This electrical potential can be pictured as the electric pressure that must be applied to bring a unit charge having the same sign as the primary charge from the bulk of the solution to a given distance from the particle surface, shown schematically in Fig. 8-3b. The potential has a maximum value at the particle surface and decreases with distance from the surface. This decrease is affected by the characteristics of the diffuse layer and, thus, by the type and concentration of ions in the bulk solution.

Dynamic Aspects of the Electrical Double Layer. The interaction of two particles can be evaluated in terms of potential energy (i.e., the amount of energy needed to bring two particles from infinite separation up to a given separation distance). If the potential energy is positive, the overall interaction is unfavorable (repulsive) since energy must be provided to the system. If the potential energy is negative, the net effect is attractive.

When particles are forced to move in a fluid or when the fluid is forced to move past a stationary particle, some of the charge that balances the surface charge moves with the fluid and some of it does not. Thus, the electrical potential at the plane of shear (which is the boundary between the charge that remains with the particle and the charge that does not) is less than the electrostatic potential at the surface of the particle. The exact location of the slipping plane is not known, and, therefore, it is difficult to relate the potential measured at the plane of shear (by electrokinetic techniques such as electrophoresis or streaming current) to the surface potential. Lyklema (1978) locates the slipping plane at the outer border of the Stern layer as shown in Fig. 8-2.

The mathematical treatment of the double layer, shown schematically in Figs. 8-2 and 8-3a, was developed independently by Gouy and Chapman, and the result is called the *Gouy-Chapman model*. Details of the model can be found in several texts (e.g., Elimelech et al., 1995). In this model, electrostatic or coulombic attraction and diffusion are the

sign and magnitude of the charge produced by such isomorphous replacements are independent of the characteristics of the aqueous phase after the crystal is formed.

The Electrical Double Layer. In a colloidal suspension, there can be no net imbalance in the overall electrical charge; the primary charge on the particle must be counter balanced in the aqueous system. Figure 8-2 shows schematically a negatively charged particle with the counterbalancing cloud of ions (the diffuse layer) around the particle. Because the particle is negatively charged, excess ions of opposite charge (positive) accumulate in this interfacial region. Ions of opposite charge accumulating in the interfacial region, together with the primary charge, form an electrical

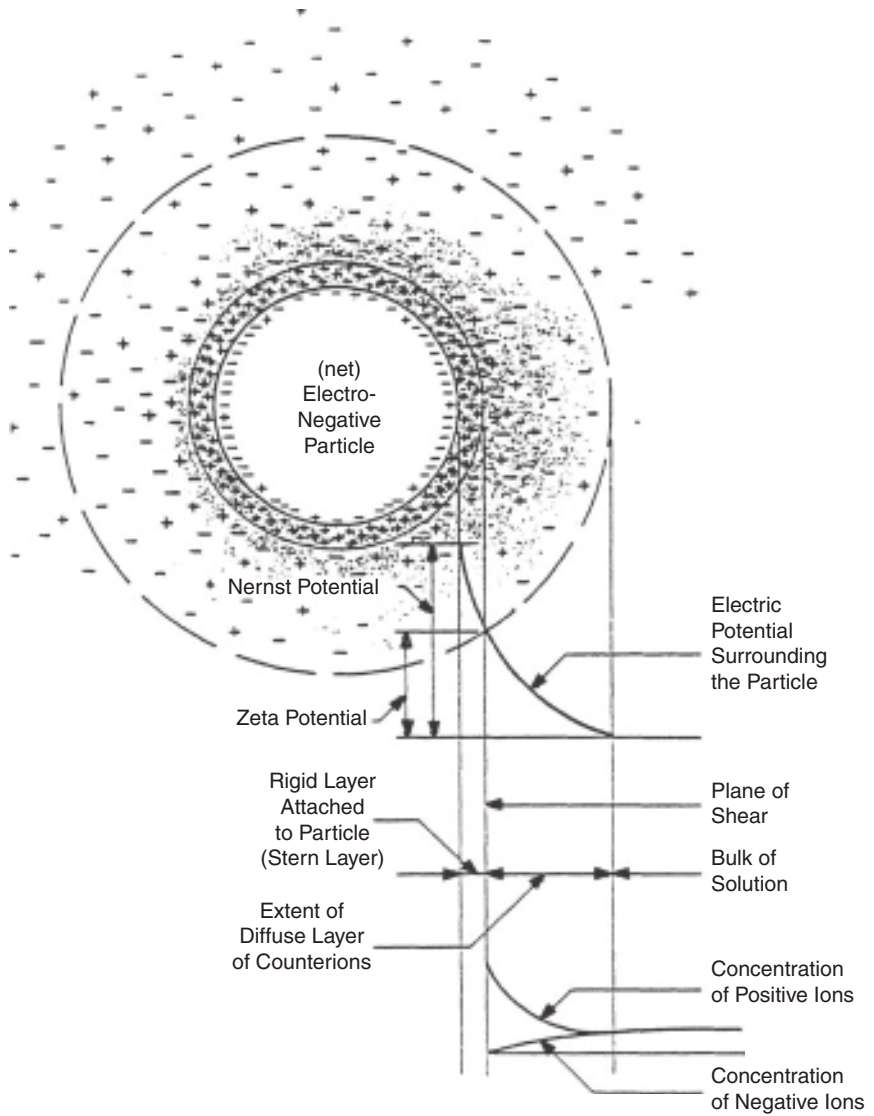

FIGURE 8-2 Negatively charged particle, the diffuse double layer, and the location of the zeta potential.

interacting processes responsible for the formation of the diffuse layer. Ions are treated as point (dimensionless) charges and have no other physical or chemical characteristics.

When two similar colloidal particles approach each other, their diffuse layers begin to overlap and to interact. This comingling of charge creates a repulsive potential energy ψ_R that increases in magnitude as the distance separating the particles decreases. Figure 8-3c and d plots the repulsive energy of interaction as a function of the distance between the interacting surfaces.

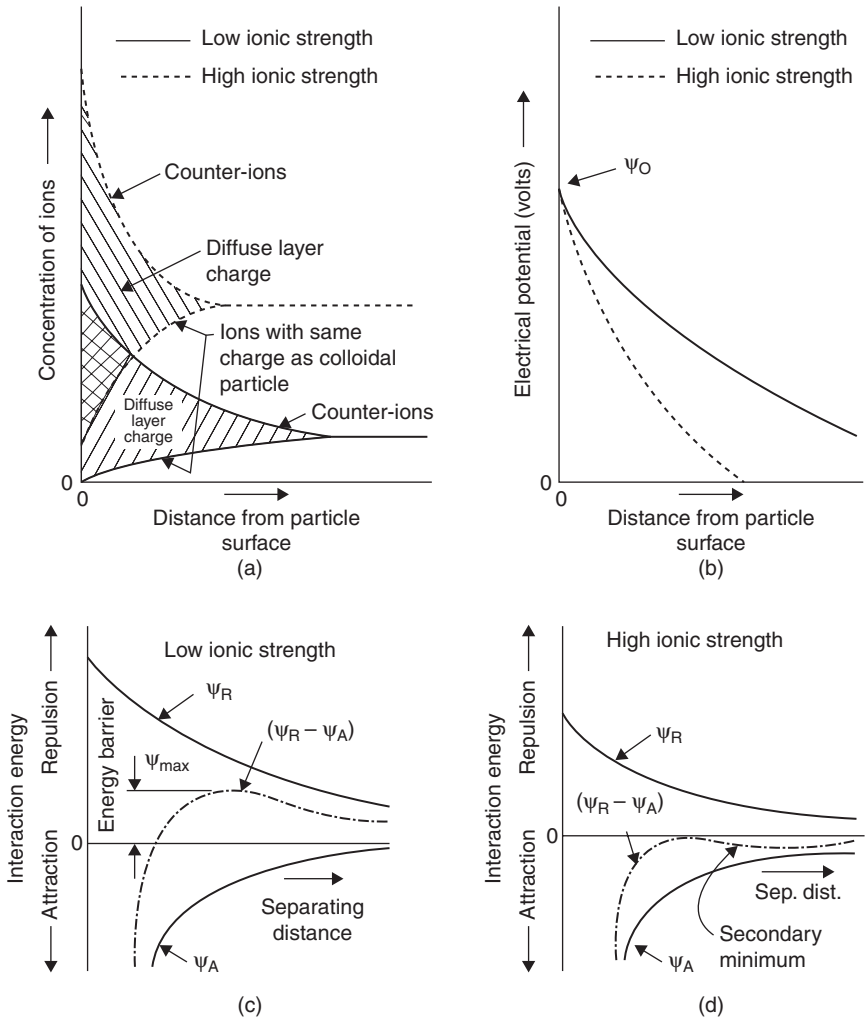

FIGURE 8-3 Schematic representations. (a) The diffuse double layer. (b) The diffuse layer potential. (c and d) Two cases of particle-particle interaction energies in electrostatically stabilized colloidal systems.

Attractive forces (van der Waals forces) exist between all types of particles, no matter how dissimilar they may be. These forces arise from interactions among dipoles, either permanent or induced, in the atoms composing the interacting surfaces and the water. The magnitude of the attractive energy of interaction ψ_A decreases with increasing separation distance. Schematic curves of the van der Waals attractive potential energy of interaction are shown in Fig. 8-3c and d. Unlike electrostatic repulsive forces, the van der Waals attractive forces are essentially independent of the composition of the solution; they depend on the kind and number of atoms in the colloidal particles and the continuous phase (water).

The net forces in a colloidal system are a superposition of electrostatic repulsive forces and attractive van der Waals interactions as explained by the DLVO theory. In other words,

summation of ψ_R and ψ_A yields the net interaction energy between two colloidal particles. This sum with the proper signs is $(\psi_R - \psi_A)$ and is shown schematically as a function of separation distance in Fig. 8-3c and d. The force acting on the particles is the derivative $d(\psi_R - \psi_A)/ds$ where s is the separation distance. When electrostatic repulsion dominates during particle-particle interactions, the suspension is said to be electrostatically stabilized and to undergo only *slow* coagulation. Electrostatic stabilization is fundamental to the current understanding of coagulation in water treatment. For additional insight into electrostatic stabilization, the mathematical treatment of Derjaquin and Landeau (1941) and Verwey and Overbeek (1948), as well as a summary by Lyklema (1978), should be consulted. Valuable summaries of the methods, mathematics, and meanings of models for electrostatic stabilization are also contained in books by Morel (1983), Stumm and Morgan (1996), and Elimelech et al. (1995).

The DLVO theory, which is based on the Gouy-Chapman model, provides a good qualitative picture of the origins of electrostatic stabilization. It can also describe the influence of ionic strength on particle stability as will be discussed later when double-layer compression is introduced as a destabilization mechanism. It does not provide, however, a quantitative predictive tool for such important characteristics as coagulant requirements and coagulation rates. Its principal drawback lies in its characterization of all ions as point charges. This allows for a physical description of electrostatics, but omits a description of chemical interactions. For example, the sodium ion (Na^+), the dodecylamine ion ($\text{C}_{12}\text{H}_{25}\text{NH}_3^+$), and the proton (H^+) have identical charges but are not identical coagulants. In addition, DLVO theory does not consider adsorption reactions at the surface although it can be used with surface complexation models to combine electrostatics and surface chemistry.

Quantitative models for the surface chemistry of oxides and other types of surfaces with ionizable surface sites are available. Some have been incorporated into computer programs such as MINEQL, allowing self-consistent calculations to be made simultaneously for surface and solution (Davis and Leckie, 1978). The most popular are the surface complexation models, which describe the formation of charge, potential, and the adsorption of ions at the particle-water interface. The fundamental concept on which all surface complexation models are based is that adsorption takes place at defined coordination sites (surface hydroxyl groups present in finite number) and that adsorption reactions can be described quantitatively by mass action expressions (Goldberg et al., 1996). The various models use different assumptions for the electrostatic interaction terms. For example, some use a simple linear relationship between charge and potential at the surface [the *constant capacitance model* of Schindler and Stumm (Stumm, 1992)] and others use more elaborate relationships such as the triple-layer model of Davis and Leckie (1978).

All the surface complexation models reduce to a similar set of simultaneous equations that are typically solved numerically: (1) mass action equations for all surface reactions, (2) mass balance equations for surface hydroxyl groups and other species, (3) equations for calculation of surface charge, and (4) a set of equations that describes the charge and potential relationships of the electrical double layer. Attempts have been made to use these models to predict the effects of solution and suspension variables on flocculation efficiency when aluminum salt coagulants are used (Letterman and Iyer, 1985) and on the rate of coagulation of iron-oxide particles (Liang and Morgan, 1990). Surface complexation models have also been extended to predict the kinetic behavior of particle-water interfaces (Yiacoumi and Tien, 1995), and electrostatic potentials as function of time have been calculated and compared with experimental data (Subramaniam and Yiacoumi, 2001). Such information could be useful in developing models for predicting particle flocculation kinetics.

Secondary Minimum Aggregation. In certain systems the kinetic energy and electrical double-layer characteristics of the interacting particles may be such that aggregation takes place in what is called a *secondary minimum* (see Fig. 8-3d). Under this condition, the particles are

held in proximity (at least momentarily) by van der Waals attraction but remain nanometers apart due to the repulsive force associated with the interacting electrical double layers. If the kinetic energy of the interacting particles is increased, the repulsive force may not be great enough to limit the close approach of the particles, and aggregation will tend to occur in the primary minimum, with the surfaces of the particles close together. In this case the separation distance in Fig. 8-3c is reduced until the quantity $(\Psi_R - \Psi_A)$ becomes less than Ψ_{\max} . Consideration of both primary and secondary minima in particle interactions may explain discrepancies between classical model predictions that consider only primary minimum aggregation and experimental deposition efficiencies of particles in porous media under unfavorable chemical conditions (Hahn and O'Melia, 2004).

Like-Charge Electrostatic Attraction of Colloids. As noted previously the principal drawback of the DLVO theory lies in the characterization of ions as point charges. As a consequence, the electrostatic factor in models of interparticle interaction does not consider interaction between the ions. Work in recent years has been focused on developing molecular modeling techniques that include ion-ion correlations or model ions as separate identities in predicting electrostatic interactions. Based on these studies, the presence of attractive electrostatic interactions between similarly charged surfaces in electrolyte solutions has been identified (Oasawa, 1971). In a study by Gulbrand et al. (1984), the osmotic pressure has been measured and attractive interaction has been observed in a system with two planar walls with divalent counterions. Taboada-Serrano et al. (2006) have studied the interactions between a colloidal particle and a planar surface in systems of symmetric and asymmetric electrolytes and like-charge electrostatic attraction has been observed in various systems. Similarly to the previous discussion of secondary minimum aggregation, like-charge electrostatic attraction of colloids may explain deposition of charged colloidal particles under unfavorable conditions or aggregation behavior that cannot be explained with classical theory. In the review article by Taboada-Serrano et al. (2005), aggregation modeling of colloidal particles is discussed on the basis of classical treatment and new molecular approaches.

Nanoparticles. Nanoparticles have received great interest in recent years. When studying nanoparticle fate and transport in aqueous media, the effect of diminishing particle size on the interaction energies has to be taken into account. For nanoparticles smaller than 20 nm, particle behavior resembles that of a molecular solute and intermolecular forces play a significant role in affecting the aggregation and deposition of these particles. At this scale, it is also important to characterize the heterogeneities of the surfaces with which nanoparticles interact. The transport of nanoparticles at mesoscopic scale is characterized by high diffusion coefficients due to their small size resulting in increased contact opportunities and resulting in fast aggregation even at low attachment efficiencies. Nanoparticles can often spontaneously aggregate to form clusters even in the absence of destabilizing agents (Brant et al., 2005).

Steric Stabilization

Steric stabilization can result from the adsorption of polymers at solid-water interfaces. Large polymers can form adsorbed segments on a solid surface with loops and tails extending into the solution (Lyklema, 1978) as illustrated in Fig. 8-4. Adsorbed polymers can be either stabilizing or destabilizing, depending on the relative amounts of polymer and solid particles, the affinities of the polymer for the solid and for water, electrolyte type and concentration, and other factors. A stabilizing polymer may contain two types of groups, one of which has a high affinity for the solid surface and a second, more hydrophilic group that

FIGURE 8-4 Illustration of adsorbed polymer configuration with loops, trains, and tails. (Source: Lyklema, 1978.)

extends into the solution (Gregory, 1978). The configuration of such an interfacial region is difficult to characterize either theoretically or experimentally. This, in turn, prevents quantitative formulation of the interaction forces between two such interfacial regions during a particle-particle encounter in coagulation. Some useful qualitative descriptions can, however, be made.

Gregory (1978) summarized two processes that can produce a repulsive force when two polymer-coated surfaces interact at close distances. These are illustrated in Fig. 8-5. First, the adsorbed layers can each be compressed by the collision; this reduces the volume available for the adsorbed molecules. This reduction in volume restricts the movement of the polymers (a reduction in entropy) and causes repulsion between the particles. Second, and more frequently, the adsorbed layers may interpenetrate on collision, increasing the concentration of polymer segments in the mixed region. If the extended polymer segments are strongly hydrophilic, they can prefer the solvent to reaction with other polymer segments. An overlap or mixing then leads to repulsion. These two processes are separate from and in addition to the effects of polymer adsorption on the charge of the particles and the van der Waals

FIGURE 8-5 Two possible repulsive interactions of adsorbed polymer layers in sterically stabilized colloidal systems. (Shaded areas are zones occupied by polymers. Zone thickness relative to particle size is arbitrary.) (Source: Gregory, 1978.)

interaction between particles. Charged polymers (polyelectrolytes) can alter particle charge; organic polymers can also reduce the van der Waals attractive interaction energy. Steric stabilization is widely used in the manufacture of industrial colloids such as paints and waxes. Natural organic matter such as humic substances is ubiquitous in water supplies. They are anionic polyelectrolytes, adsorb at interfaces, can be surface active, and may contribute to particle stability by affecting the particle negative charge and by steric effects (O'Melia, 1995).

DESTABILIZATION MECHANISMS

Destabilization is the process in which the particles in a stable suspension are modified to increase their tendency to attach to one another (or to a stationary surface like a filter grain or deposit). The aggregation of particles in a suspension after destabilization requires that they be transported toward one another. In flocculation, particles include those in the source water; those produced in treatment processes, such as oxidation and precipitation; and those added to the treatment system, such as powdered activated carbon. In dissolved air flotation following flocculation the aggregated particles must be transported to air bubbles; see Chap. 9. In filtration they must be transported to the stationary filter surface. Transport processes in suspensions are discussed in this chapter in the section on flocculation. Transport in filtration is discussed in Chap. 10.

Double-Layer Compression

The classical method of colloid destabilization is double-layer compression. To affect double-layer compression, a simple electrolyte such as NaCl is added to the suspension. The ions that are opposite in sign to the net charge on the surface of the particles enter the diffuse layer surrounding the particle. If enough of these counterions are added, the diffuse layer is compressed, reducing the energy required to move two particles of like surface charge into close contact. Destabilization by double-layer compression is not a practical method for water treatment because the salt concentrations required for destabilization may approach that of seawater and, in any case, the rate of particle aggregation would still be relatively slow in all but the most concentrated suspensions. Double-layer compression, however, is an important destabilization mechanism in certain natural systems, for example, estuaries (Edzwald et al., 1974).

Surface Charge Neutralization

Destabilization by surface charge neutralization involves reducing the net surface charge of the particles in the suspension. As the net surface charge is decreased the thickness of the diffuse layer surrounding the particles is reduced and the energy required to move the particles into contact is minimized.

Two processes are used to accomplish surface charge neutralization. In the first, coagulant compounds that carry a charge opposite in sign to the net surface charge of the particles are adsorbed on the particle surface. (In some cases the coagulant is a small particle that deposits on the particle surface.) The coagulants used to accomplish this usually have a strong tendency to adsorb on (attach to) surfaces. Examples include the synthetic and natural organic polyelectrolytes and some of the hydrolysis products formed from hydrolyzing metal salt coagulants. The tendency for these compounds to adsorb is usually attributable to both poor coagulant-solvent interaction and a chemical affinity of the coagulant or chemical groups on the coagulant for the particle surface. Most of the coagulants that are used

for charge neutralization can adsorb on the surface to the point that the net surface charge is reversed and, in some cases, increased to the point that the suspension is restabilized.

Adjustment of the chemistry of the solution can be used to destabilize some common types of suspensions by reducing the net surface charge of the particle surfaces. For example, when most of the surface charge is caused by the ionization of surface sites, pH adjustment with acid or base may lead to destabilization. For some surfaces, such as positively charged oxides and hydroxides, the adsorption of simple multivalent anions (such as sulfate and phosphate) or complex polyvalent organic compounds such as humic materials will reduce the positive charge and destabilize the suspension.

Heterocoagulation is a destabilization mechanism that is similar to the process of surface charge neutralization by the adsorption of oppositely charged soluble species. However, in this case, the process involves one particle depositing on another of opposite charge. For example, large particles with a high negative surface charge may contact smaller particles with a relatively low positive charge. Because the particles have opposite surface charge, electrostatic attraction enhances particle-particle interaction. As the stabilizing negative charge of the larger particles is reduced by the deposited positive particles, the suspension of larger particles is destabilized.

Adsorption and Interparticle Bridging

Destabilization by bridging occurs when segments of a high-molecular-weight polymer adsorb on more than one particle, thereby linking the particles together. When a polymer molecule comes into contact with a colloidal particle, some of the reactive groups on the polymer adsorb on the particle surface and other portions extend into the solution. If a second particle with open surface is able to adsorb the extended molecule, then the polymer will have formed an interparticle bridge. The polymer molecule must be long enough to extend beyond the electrical double layer (to minimize double-layer repulsion when the particles approach) and the attaching particle must have available surface. The adsorption of excess polymer may lead to restabilization of the suspension. Ions such as calcium are known to affect the bridging process, apparently by linking sites on interacting polymer chains (Black et al., 1965; Lyklema, 1978; Dentel, 1991).

Application of External Fields

The utilization of external fields in aggregation processes, for example, magnetic fields, introduces an additional force among magnetic (paramagnetic, ferrimagnetic, or ferromagnetic) particles. When the magnetic field is applied, the particles experience an attractive force along the direction of the external field and a repulsive force normal to the external field; consequently, linear aggregates of magnetic particles are formed (Chin et al., 2000). The application of magnetic fields has been proposed to enhance aggregation processes or other separation processes like magnetic seeded filtration (Yavuz et al., 2006; Ying et al., 2000).

COAGULANTS

Hydrolyzing Metal Salt Coagulants

The most widely used coagulants in water treatment are sulfate or chloride salts that contain the metal ions Al^{3+} or Fe^{3+} . In aqueous solutions these small, highly positive ions form such strong bonds with the oxygen atoms of six surrounding water molecules that

FIGURE 8-6 Deprotonation of the aquo aluminum ion, initial step in aluminum hydrolysis. (Source: Letterman, 1991.)

the oxygen-hydrogen atom association in the water molecules is weakened and hydrogen atoms tend to be released to the solution (see Fig. 8-6). This process is known as *hydrolysis* and the resulting aluminum and ferric hydroxide species are called *hydrolysis products*. The water molecules are frequently omitted when writing the chemical formula for these species, but their role is important in determining species behavior. These Fe and Al coagulants are hydrolyzing metal salt (HMS) coagulants.

The chemistry of aluminum and iron hydrolysis reactions and products is complex (see Fig. 8-7). As the pH increases and hydrolysis proceeds and if there is a high total metal ion concentration in the solution, simple mononuclear products can form complex

FIGURE 8-7 Schematic diagram of the essential steps in aluminum hydrolysis.

polynuclear species. Eventually microcrystals and the amorphous metal hydroxide precipitate are formed. Under certain conditions (e.g., low total metal ion concentration) the precipitate can form directly from mononuclear species. Dissolution of the metal hydroxide precipitate forms mononuclear species but not polynuclear forms.

The pure amorphous precipitate is a low density, gelatinous material, consisting of agglomerated microcrystals and water. It changes physically with aging, and it can be dehydrated by freezing and thawing. The various hydrolysis products can adsorb (and continue to hydrolyze) on many types of particulate surfaces, and they may form a precipitate with the higher-molecular-weight fraction of NOM. This NOM fraction strongly adsorbs on the metal hydroxide precipitate. The precipitate can be an effective adsorbent for a number of inorganic anions such as fluoride and arsenate. Models for predicting the dosage of coagulants needed for the effective removal of particles and NOM are discussed later in this chapter.

The solubility of the metal hydroxide precipitate is one factor that must be considered in maximizing coagulant performance and in minimizing the amounts of residual Al and Fe in treated water. At low pH the dissolution of the metal-hydroxide precipitate produces positively charged, soluble hydrolysis products and the aquo-metal ion (Al^{3+} and Fe^{3+}).

At high pH, the negatively charged, soluble hydrolysis products $\text{Al}(\text{OH})_4^-$ and $\text{Fe}(\text{OH})_4^-$ are formed. The minimum-solubility pH of aluminum hydroxide precipitate at 25°C is approximately 6.3 (Fig. 8-8); for ferric hydroxide it is about 8 (Fig. 8-9). The theoretical solubility of ferric hydroxide is significantly lower than that of aluminum hydroxide. For example at 25°C with $I = 0.001$, the minimum concentrations of soluble Al and Fe are about 17 $\mu\text{g}/\text{L}$ and 0.01 $\mu\text{g}/\text{L}$, respectively. Metal hydroxide solubility should be considered when selecting the type and dosage of a coagulant, especially Al salt products. How to do this and the effect of water temperature on metal hydroxide precipitate solubility are discussed in a later section of the chapter.

FIGURE 8-8 Solubility diagram for amorphous, freshly precipitated aluminum hydroxide. Water molecules are omitted in species notation, temperature = 25°C.

The solubility diagrams of Figs. 8-8 and 8-9 were plotted using the formation constants ($\beta_{x,y}$) and solubility constants (K_{sp}) listed in Table 8-2. The ionic strength was assumed to be 0.001 M. The formation constants in Table 8-2 are for reactions and mass action expressions of the form

FIGURE 8.9 Solubility diagram for amorphous, freshly precipitated ferric hydroxide. Water molecules are omitted in species notation, temperature = 25°C.

and

$$\beta_{x,y} = \frac{[M_x(OH)_y^{(3x-y)+}][H^+]^y}{[M^{3+}]^x} \quad (8-2)$$

The solubility constants are for reactions and solubility product relationships of the form

and

$$K_{sp} = \frac{[M^{3+}]}{[H^+]^3} \quad (8-4)$$

TABLE 8-2 Aluminum and Iron Hydrolysis and Solubility Constants Used to Plot Solubility Diagrams for Amorphous Aluminum Hydroxide and Amorphous Ferric Hydroxide Precipitates, $T = 25^\circ\text{C}$ and $I = 0.001$

Amorphous aluminum hydroxide		
Hydrolysis product	Log $\beta_{x,y}$ and Log K_{sp}	Reference
$Al(OH)^{2+}$	-5.07	Ball et al. (1980)
$Al(OH)_4^-$	-23.12	Ball et al. (1980)
$Al(OH)_3(s)$	10.64	Ball et al. (1980)
Amorphous ferric hydroxide		
$Fe(OH)^{2+}$	-2.2	Stumm and Morgan (1996)
$Fe(OH)_2^+$	-5.7	Stumm and Morgan (1996)
$Fe(OH)_4^-$	-21.6	Stumm and Morgan (1996)
$Fe(OH)_3(s)$	3.6	Stumm and Morgan (1996)

[For aluminum this is a simplified set of hydrolysis products that have been found to effectively predict filtrate Al concentrations under laboratory and field conditions (Letterman and Driscoll, 1993; Van Benschoten and Edzwald, 1990). A more complete list of hydrolysis products and constants can be found in Sposito (1996).]

When the dissolution reaction is written as

the corresponding solubility product relationship is

$$K_{so} = [\text{M}^{3+}][\text{OH}^-]^3 \quad (8-6)$$

The equilibrium constants K_{sp} (Eq. 8-4) and K_{so} are related by

$$K_{so} = K_{sp}(K_w)^3 \quad (8-7)$$

where K_w is the ion product of water ($K_w = 1 \times 10^{-14}$ at 25°C and infinite dilution).

A number of researchers have assumed that the important mononuclear Al hydrolysis products include Al(OH)^{2+} , Al(OH)_2^+ , Al(OH)_3 , and Al(OH)_4^- (Bertsch and Parker, 1996). Others, including Letterman and Driscoll (1993), Hayden and Rubin (1974), and van Benschoten and Edzwald (1990a), have reported that the effect of pH on the solubility of freshly precipitated aluminum hydroxide can be effectively predicted using just the aquo Al species (Al^{3+}) and two mononuclear hydrolysis products (Al(OH)^{2+} and Al(OH)_4^-). This assumption was used to plot Fig. 8-8. The term *solubility* in the articles cited means the concentration of aluminum that is not removed by membrane filtration and not the true thermodynamic equilibrium solubility of the precipitate.

The dotted lines plotted in Fig. 8-8 give the concentrations of each Al species when it is in equilibrium with the Al(OH)_3 precipitate. The equation of each line was derived by combining Eqs. 8-1 and 8-3 and using the appropriate equilibrium constants corrected for ionic strength. For example, the equation for $\log [\text{Al(OH)}^{2+}]$ when the ionic strength $I = 0.001 \text{ M}$ is

$$\log [\text{Al(OH)}^{2+}] = \log \beta_{11} + \log K_{sp} + 2 \log \text{H}^+ = 5.57 - 2 \text{pH} \quad (8-8)$$

Polynuclear hydrolysis products are known to form under certain conditions, typically where hydrolysis is induced by the slow and spatially uniform addition of base to a high-concentration aluminum salt solution. The different types of polynuclear species proposed in the literature range from small units with two aluminum atoms ($\text{Al}_2(\text{OH})_2^{4+}$) to $\text{Al}_{54}(\text{OH})_{144}^{18+}$ with 54. A species with 13 aluminum atoms, $\text{Al}_{13}\text{O}_4(\text{OH})_{24}^{7+}$, has been identified with NMR spectroscopy (Bertsch et al., 1986), and a significant number of investigators including Bertsch and Parker (1996) believe this is the predominant species in commercial polyaluminum chloride coagulant solutions. Zhao et al. (2009) used a total Al concentration of $1.5 \times 10^{-4} \text{ M}$ and increasing pH to show that a continuum of Al hydrolysis products is formed: monomeric species at pH = 4, small polymeric species ($\text{Al}_3 - \text{Al}_5$) at pH = 4.8, and aggregation and self-assembly of the small polymeric units to form medium polymeric species ($\text{Al}_6 - \text{Al}_{10}$) at pH = 5. Above pH 5, the small and medium polymers aggregated into large ($\text{Al}_{11} - \text{Al}_{21}$) polymeric species. Bertsch and Parker (1996) suggest that polynuclear species are metastable intermediates in solutions that reach or exceed a critical degree of supersaturation with respect to a solid phase such as gibbsite (Al_2O_3) or perhaps amorphous aluminum hydroxide (Al(OH)_3).

Bertsch and Parker (1996) have argued that complex formation reactions (such as Eq. 8-1) use electrolyte theory and conventions that do not apply to large, polyvalent, polynuclear species, and consequently, it is not thermodynamically correct to include polynuclear species concentrations in plots such as Figs. 8-8 and 8-9. Also polynuclear species are not formed in the equilibration process when aluminum dissolves from aluminum-hydroxide precipitate, a prerequisite for including them in an equilibrium solubility diagram based essentially on thermodynamic relationships. The next section describes Al and Fe coagulant products that contain polynuclear species.

Types of Hydrolyzing Metal Salt Coagulants Used in Water Treatment

Some of the hydrolyzing metal salt (HMS) coagulant product groups are described in this section. The list is not comprehensive because new types of products are constantly entering the water treatment market in this competitive business.

Simple Metal Salts. The simple HMS coagulants are aluminum sulfate ($\text{Al}_2(\text{SO}_4)_3 \cdot 14 \text{H}_2\text{O}$, alum), ferric sulfate ($\text{Fe}_2(\text{SO}_4)_3 \cdot X \text{H}_2\text{O}$), and ferric chloride ($\text{FeCl}_3 \cdot X \text{H}_2\text{O}$). These are sold as dry crystalline solids and as concentrated aqueous solutions. For example, commercial alum solution is usually about 4.3 percent Al which is equal to about 2 moles Al/L or 8.2 percent Al_2O_3 by weight. Alum is the most widely used hydrolyzing metal salt coagulant.

Prehydrolyzed Metal Salts. When hydrolyzing metal salts are added to and diluted in the water to be treated, the hydrolysis reaction produces hydrogen ions that react with alkalinity species in the solution. If some of this acid is neutralized with base when the coagulant is manufactured, the resulting product is a prehydrolyzed metal salt coagulant solution. The degree to which the hydrogen ions produced by hydrolysis are preneutralized is called the *basicity*. The basicity is given by

$$\text{Basicity (\%)} = B = \left(\frac{100}{3} \right) \times \frac{[\text{OH}]}{[\text{M}]} \quad (8-9)$$

where $[\text{OH}]/[\text{M}]$ is the weighted average of the molar ratio of the bound hydroxide to metal ion for all the metal hydrolysis products in the undiluted coagulant solution. For example, if a hypothetical product solution contained just one hydrolysis product, the polynuclear species $\text{Al}_{13}\text{O}_4(\text{OH})_{24}^{7+}$, $[\text{OH}]/[\text{Al}]$ would be effectively equal to $2.46 = [24 + (2 \times 4)]/13$ and the basicity according to Eq. 8-9 would be 82 percent = $(100/3) \times 2.46$. For commercial coagulant solutions the basicity varies from ~ 10 (a low amount of prehydrolysis) to around 83 percent. As the basicity is increased beyond about 75 percent, it becomes increasingly difficult to keep the metal hydroxide precipitate from forming in the product solution during shipping and extended storage. AWWA's Standard B408, Liquid Polyaluminum Chloride (AWWA, 2003), provides a laboratory method for measuring the basicity of prehydrolyzed product solutions.

To avoid forming a precipitate in prehydrolyzed product solutions with higher basicities, they are usually manufactured with chloride as the dominant anion. Multivalent anions such as sulfate, SO_4^{2-} , (Sricharoenchaikit and Letterman, 1987) and high-ionic-strength solutions (de Hek et al., 1978) tend to destabilize positively charged polynuclear and microcrystalline hydrolysis products. Prehydrolyzed metal salt coagulants made with aluminum chloride are called *polyaluminum chloride* or sometimes *polyaluminum hydroxychloride* or simply *PACl*. Some manufacturers refer to the highest basicity products (typically about 83 percent) as aluminum chlorohydrate. These are usually sold with a total metal concentration that is higher than that of the other prehydrolyzed but lower basicity Al products. Use of the term *polyaluminum* (or *polyiron* for Fe salt products) is based on the assumption that the product solution contains significant amounts of relatively stable polynuclear metal hydrolysis products; this tends to be true only for the higher-basicity (60+ percent) solutions. A number of investigators (Bottero et al. 1987; Xu et al., 2003; Hu et al., 2005; Huang et al., 2006; Chen et al., 2007; Wu et al., 2007, 2008; Lin et al., 2008) appear to believe that the principal hydrolysis product in PACl solutions with basicities greater than about 70 percent is Al_{13} , that is, $\text{Al}_{13}\text{O}_4(\text{OH})_{24}^{7+}$.

Prehydrolyzed iron solutions exist but are still a relatively uncommon commercial product. The significance of the basicity of iron salt coagulant solutions has been discussed by Tang and Stumm (1987). Wang et al. (2003) observed that, compared to PACl, it is difficult to form stable poly-iron species in a clear solution. In their experiments increasing the

basicity without a stabilizer compound tended to form a suspension of small $\text{Fe}(\text{OH})_3$ precipitate particles and decreased the performance of the coagulant.

Jiang and Graham (2003) describe the preparation and performance of prehydrolyzed coagulants that are combination of Al and Fe sulfate salts. Gao et al. (2003) report on the preparation and application of a poly-aluminum-silicate-chloride coagulant.

In aged solutions of polynuclear (and microcrystalline) hydrolysis products, most of the metal atoms are interconnected by double-hydroxide bonds. Double-hydroxide bonds are not easily broken. Therefore, when these complex metal hydroxide species are transferred from the solution in which they were formed (e.g., in a commercial coagulant product solution) to one in which they could not be formed and are not stable (the water to be treated), the transition to the new set of species is typically slow. For example, if a concentrated solution of polynuclear species is added to a suspension as a coagulant, it is likely that a significant amount of time (days to months) will be required for a new stable distribution of hydrolysis products to form in the system; that is, the polynuclear species will tend to persist. Consequently, particle or NOM removal diagrams prepared using preformed polynuclear species (Dempsey et al., 1984) may show effective coagulation in areas where the corresponding solubility diagram based on equilibrium conditions (e.g., Fig. 8-8 for $\text{Al}(\text{OH})_3$) does not show the formation of destabilizing hydrolysis products.

Metal Salts Plus Strong Acid. Several coagulant manufacturers prepare coagulant solutions that contain the metal salt (e.g., alum) and an amount of strong acid, typically sulfuric acid. The typical acid-supplemented alum product (also called *acidulated alum* or *acid alum*) contains 5 to 20 percent (weight basis) sulfuric acid. Iron salt solutions are available that contain supplemental sulfuric acid. In some cases, especially with iron salt products, the coagulant solution contains up to several weight percent excess acid. A product solution has excess acid when, in the manufacturing process where a metal oxide is dissolved in strong acid, the amount of strong acid added is greater than the stoichiometric amount required by the dissolution reaction. For a given amount of metal ion, Al or Fe, added to the water, products with supplemental or excess strong acid react with more alkalinity and depress the pH to a greater extent than the conventional metal salt solutions.

Metal Salts Plus Additives. Metal salt coagulant solutions are available with special additives including phosphoric acid, sodium silicate, and calcium salts. Alum with phosphoric acid has some of the characteristics of acid-supplemented alum, but AlPO_4 precipitate is formed when the solution is added to the water. Metal salt solutions are also sold premixed with polyelectrolyte coagulant compounds such as epichlorohydrin dimethylamine (epiDMA) and polydiallyl dimethylammonium chloride (poly DADMAC). Some prehydrolyzed polyaluminum chloride products are sold with several percent sulfate, and there is evidence that the sulfate can have a positive effect on product performance (Pernitsky and Edzwald, 2003, 2006).

Impurities in Hydrolyzing Metal Salt Coagulant Solutions

Most of the impurities in hydrolyzing metal salt (HMS) coagulants are derived from the raw materials used to make them. For example, alum is usually made by digesting an aluminum source in sulfuric acid. Typical aluminum sources are bauxitic or high-aluminum clays, aluminum trihydrate, and high-purity bauxite. Impurities in the aluminum source tend to appear in the alum product. The most significant contaminant in aluminum salt coagulants is iron. Standard commercial alum solution may contain 1000 mg Fe/L. Small amounts of heavy metals such as chromium and lead can be found in standard-grade alum solution (Lind, 1995).

Iron salt coagulants are manufactured by dissolving various iron sources in sulfuric or hydrochloric acid. In the past they were also made by reprocessing materials such as acidic iron salt solutions from iron mills and foundries, and ferric chloride was sometimes made from reprocessed titanium dioxide liquors. Like alum, the iron salt coagulants typically contain metal contaminants. Manganese (Mn) is often the most significant contaminant; Cu, V, Zn, Pb, and Cd may also be present. The amount varies with the source of the product.

In most cases the low amounts of heavy metal contaminants in HMS coagulants will not have a significant effect on metal concentrations in the treated water. The metals may already be in an insoluble form, or they may be likely to precipitate or adsorb on the floc when the coagulant is added to the water. The metals may, however, increase the heavy metal content of treatment residue. Eyring et al. (2002) have shown that trace contaminants such as lead, chromium, and cadmium in alum will be diluted to less than drinking water standard concentrations in finished water and will not be present in alum sludge at agriculturally significant levels even under worse-case coagulant dosage conditions.

Standards for HMS coagulants (e.g., AWWA B403, Aluminum Sulfate—Liquid, Ground, or Lump [AWWA, 2009a] and NSF/ANSI 60 Drinking Water Treatment Chemicals-Health Effects [NSF, 2009]) may include limits on levels of impurities in products and on maximum dosages. Users of standards should consult with their local regulatory agencies to determine if these limits are requirements.

The amount of residual Al in treated water can be minimized by optimizing filtration to maximize the removal of particulate matter and by maintaining the pH during coagulation and flocculation at a value near the pH of minimum solubility of aluminum hydroxide precipitate (Letterman and Driscoll, 1993). The pH of minimum solubility aluminum hydroxide is between 6 and 7 and depends on the temperature of the water. At the pH of minimum solubility the soluble Al concentration increases with increasing temperature. Frommell et al. (2004) found that the addition of orthophosphate during the rapid mix following alum addition reduced residual aluminum concentrations and decreased the tendency for aluminum to precipitate (or deposit) in the distribution system. Periodically, health concerns about Al in drinking water arise; this issue is addressed in Chap. 2.

A subsequent section of this chapter discusses how to minimize residual aluminum by selecting the appropriate target pH for the coagulation process.

Models for Predicting Hydrolyzing Metal Salt Coagulant Dosages

A number of models have been developed for predicting the Al or Fe salt coagulant dosage required for effective process performance. The models are of two general types. One type calculates the coagulant dosage needed to destabilize a suspension of solid particles, and the other the dosage needed to effectively remove natural organic matter (for background material on NOM; see Chap. 3). With typical surface-water concentrations of NOM and particles the required coagulant dosage (sometimes called the *coagulant demand*) is generally much higher when NOM is present. In waters with both NOM and particles, the NOM concentration is typically the dosage-controlling factor (Semmens and Field, 1980; Edzwald, 1993; White et al., 1997; Shin and O'Melia, 2004; Archer and Singer, 2006a, 2006b).

Particle Suspensions—Destabilization by Surface Charge Neutralization. Models used to predict the dosage needed to destabilize a suspension of solid particles (e.g., mineral particles such as silica and clay) by the process called charge neutralization usually assume that the destabilization process involves the particle surfaces adsorbing coagulant species that have a charge opposite to that of the ionizable sites on the surface of the particles. Typically the pH of the solution determines the speciation of the ionizable sites and, especially with hydrolyzing

metal salt coagulants, the charge associated with the coagulant species that adsorb form by reaction on the surface or deposit there after precipitating in the bulk solution.

The amount of surface charge associated with charged sites on particles in a suspension can be calculated with expressions like the following where the quantity 1.66×10^{-24} moles/site is the reciprocal of the Avogadro constant.

$$\begin{aligned} & \text{Surface charge concentration (moles/L)} \\ &= (\text{mass particles/volume}) \times (\text{surface area/mass particles}) \\ & \times (\text{ionizable sites/surface area}) \times (\text{charge/site}) \\ & \times (1.66 \times 10^{-24} \text{ moles/site}) \end{aligned} \quad (8-10)$$

For example, a 100-mg/L colloidal silica suspension with a specific surface area of $0.010 \text{ m}^2/\text{mg}$ and ionizable surface sites ($\equiv \text{SiOH}$) called silanol groups at a surface density of $5 \times 10^{18} \text{ sites/m}^2$, would have, if every site was ionized to $\equiv \text{SiO}^-$, a negative surface charge concentration of $100 \text{ mg/L} \times 0.010 \text{ m}^2/\text{mg} \times 5 \times 10^{18} \text{ sites/m}^2 \times 1.66 \times 10^{-24} \text{ moles/site} = 8.3 \times 10^{-6} \text{ moles of negative surface charge/L}$. If surface charge neutralization occurred by the quantitative uptake of $\text{Al}(\text{OH})^{2+}$, a monomeric Al hydrolysis product with 2 moles of positive charge per mole of aluminum, the Al hydrolysis and sorption reactions might be described by

Since each mole of Al in $\text{Al}(\text{OH})^{2+}$ has 2 moles of charge the amount of aluminum required for charge neutralization is 0.5 moles of Al/mole charge $\times 8.3 \times 10^{-6} \text{ moles/L} = 4.2 \times 10^{-6} \text{ moles Al/L}$, or 0.12 mg Al/L. For comparison, if the Al that interacts with the particle surface is part of the polynuclear species $\text{Al}_{13}\text{O}_4(\text{OH})_{24}^{7+}$, which many believe to be the predominant form in prehydrolyzed Al products, the moles of Al per mole of positive charge are $13/7 = 1.86$ and the amount of aluminum required for charge neutralization is 1.86 moles of Al/mole of charge $\times 8.3 \times 10^{-6} \text{ moles of negative surface charge/L} = 1.54 \times 10^{-5} \text{ moles Al/L}$, or 0.42 mg Al/L. This hypothetical example illustrates how the amount of hydrolyzing metal salt needed for surface charge neutralization increases as the degree of hydrolysis of the metal ion increases. It also shows that the amount of coagulant needed for charge neutralization is relatively low compared to the dosages used in practice. In practice it is common to use a dosage that is high enough to form a significant amount of precipitate and increase the rate of particle aggregation by increasing the volume concentration of the suspensions. The significance of this factor in the flocculation process is discussed in later sections of this chapter.

While the example assumes a simple one-dimensional binding of Al species to ionizable surface sites, the details of this interaction are poorly understood. Letterman and Iyer (1985) used the chemical equilibrium software MINEQL+ (the most recent version is described by Schecher and McAvoy [2003]) to simultaneously predict the surface site and aluminum hydrolysis product (AHP) speciation and assumed that the AHPs were quantitatively sorbed on the particle surfaces. Different assumptions were tested when calculating the net surface charge to determine the electrical potentials associated with the double-layer and suspension stability. It was found that the model predicted results gave better agreement with the experimental particle flocculation-separation data when it was assumed that the AHPs produced a three-dimensional layer on the surfaces and that the positive countercharge from the AHPs was arranged in patches and was not uniformly distributed over the particle surfaces. More recently, Donose et al. (2007) using atomic force microscopy found that positively charged hydrolyzed aluminum sorbed on negatively charged borosilicate glass was distributed nonuniformly and patchlike. They proposed that this might explain the strong attraction they observed between partially coated silica surfaces. Ye et al. (2007) use a surface patch argument to explain the better coagulation performance they observed for prehydrolyzed Al salts compared to conventional alum.

In some treatment plants, typically direct filtration and microfiltration membrane systems, where large, settleable flocs are not required or even desirable, the target for coagulant addition is frequently the low dosage that yields charge neutralization. As described previously the amount of positive charge required for charge neutralization is proportional to the site density on the particle surface and the total surface area concentration of the suspension. The pH of the solution and the presence of site-binding cations and anions that compete with the hydrolysis products for surface sites and affect the amount of positive charge on the hydrolysis products will also be factors. When destabilization by charge neutralization is used with a dilute suspension, the rate of flocculation is usually much lower than the rate obtained when the voluminous metal hydroxide precipitate is formed.

At coagulant dosages that exceed the charge neutralization requirement, the formation of an unstable (flocculent) precipitate can lead to the relatively rapid formation of visible floc. This process is usually called *sweep flocculation* or *enmeshment*. In most cases the rate of flocculation increases in proportion to the volume concentration of precipitate in the suspension. Floc formation by enmeshment involves both the interaction of particles of metal hydroxide precipitate and contact with contaminant particles. The effect of the amount of metal hydroxide precipitate on the rate of flocculation is discussed in another section of this chapter.

Removal of Natural Organic Matter by HMS Coagulants. Edzwald (1993) listed the possible reactions involved in the coagulation of NOM by Al salt coagulants. It is reasonable to assume that these apply for both Al and Fe salt coagulants.

1. Formation of soluble complexes by the reaction of the coagulant's metal cations with the higher molecular weight fraction of the NOM. Hydrolysis of the metal cations may be a competing reaction.
2. Formation of colloidal metal ion-NOM molecule precipitate particles.
3. Adsorption of NOM species and/or soluble metal-ion-NOM complexes on the amorphous metal hydroxide precipitate.

Others (Dempsey, 1989; Bottero and Bersillon, 1989) have argued that for the common range of pH in water treatment (6 and greater) soluble hydrolysis products binding with soluble NOM is not a significant step in the removal of NOM by HMS coagulants and that the adsorption of the NOM on metal hydroxide precipitate particles is the controlling process in NOM removal.

It is also possible that the initial coagulant-NOM interaction at low dosages is by negatively charged NOM molecules coating and stabilizing (peptizing) small positive metal hydroxide microcrystals (Kodama and Schnitzer, 1980; Bertsch and Parker, 1996). As the dosage of the HMS is increased, the surface area concentration of the microcrystals increases and the amount of NOM adsorbed per unit area of particle surface decreases. Eventually, at a higher HMS dosage, there is not enough negatively charged NOM on the surfaces to stabilize the positively charged particles and the precipitate suspension becomes unstable, forming flocs that consist of the metal hydroxide precipitate and sorbed NOM.

The dosage of HMS required for destabilization and floc formation and, consequently, effective NOM removal has been shown by a number of investigators to be proportional to the initial concentration of NOM in the water (Narkis and Rebhun, 1977; Dempsey, 1987; Edzwald, 1993; Edzwald and Kaminski, 2009; Archer and Singer, 2006a, 2006b). There is evidence that the dosage is also inversely proportional to the initial positive charge on the metal hydroxide precipitate. Differences in initial hydroxide surface charge (in addition to differences in the atomic weights of Al and Fe) may explain why, at a given pH, ferric iron salts generally require a slightly higher amount of coagulant for effective NOM removal than aluminum salts.

Two types of models have been developed for predicting the amount of HMS coagulant needed for effective NOM removal. The first applies the direct proportionality (stoichiometry)

that has been observed between the initial amount of NOM and the required coagulant dosage. The second assumes that the NOM adsorbs on the metal hydroxide precipitate and that the amount of NOM removed from solution can be determined using adsorption isotherm relationships. The models are described in the next sections.

A Model That Assumes the Required Dosage Is Proportional to the Initial NOM Concentration. In this model the required dosage m in mg Al/L or mg Fe/L is given by

$$m = R \cdot \text{TOC}_0 \quad (8-12)$$

where TOC_0 is the raw-water total organic carbon concentration in mg C/L. The magnitude of the coefficient R varies with the type of metal salt, Al or Fe, and with the pH of the solution. It is also possible that water temperature and solution chemistry factors such as the presence of significant amounts of multivalent anions such as sulfate have an effect the magnitude of R but these dependencies, if they are significant, have not yet been quantified. Van Benschoten and Edzwald (1990b), Edzwald (1993), Pernitsky and Edzwald (2006), and Archer and Singer (2006a) have shown that Eq. 8-12 can be used as the basis for a method to estimate coagulant dosage.

Figure 8-10 shows the effect of pH on the magnitude of R for aluminum and iron salt coagulants. The data used to plot Fig. 8-10, were obtained from a number of papers, most involving jar test experiments (see Table 8-3). The determination of R for a given experiment typically involves plotting the amount of residual TOC or UV absorbance (UV_{254}) versus the coagulant dosage expressed as milligrams of metal per liter. The magnitude of R is equal to the *effective dosage* of the coagulant divided by the initial TOC concentration of the water used in the experiment. The corresponding pH (used in plotting the points in Fig. 8-10) is the value measured at the effective dosage. The effective dosage has been determined in a number of ways including (1) estimating the dosage that gives the maximum removal of TOC or UV_{254} , (2) as the dosage that gives a certain percentage removal of TOC or UV_{254} , and (3) as the dosage that corresponds to the *point of diminishing returns* (PODR) as defined by the USEPA in their disinfection by-product precursor removal guidance manual (USEPA, 1999). Van Benschoten and Edzwald (1990b) determined the relationship between

FIGURE 8-10 Effect of pH on the coefficient R of Eq. 8-12 for Fe and Al salt coagulants.

TABLE 8-3 References for the Data Points Plotted in Fig. 8-10 (In some cases the values of mg Al/mg C given are averages of a set of measurements at pH values close to the average value listed in the table.)

pH	mg Fe/mg C	Criterion used to determine effective coagulant dosage	Reference
3.8	0.86	90% UV ₂₅₄ decrease	Dennett et al. (1996)
4.5	1.24	90% UV ₂₅₄ decrease	Dennett et al. (1996)
4.5	1.28	90% UV ₂₅₄ decrease	Dennett et al. (1996)

5.5	0.5	UV ₂₅₄ decrease (1)	Edzwald and Van Benschoten (1990), Edzwald (1993)
6.6	0.6	TOC removal-PODR (2)	Archer and Singer (2006b)
7.0	1.0	UV ₂₅₄ decrease	Edzwald and Van Benschoten (1990), Edzwald (1993)
7.5	1.8	Maximum removal UV abs	Chappell (1996)

Notes: (1) mg Al/mg C held constant and pH varied. (2) Point of diminishing returns as prescribed in the USEPA Guidance Manual (USEPA, 1999).

R and pH using jar test experiments and a unique procedure in which the ratio of the Al coagulant dosage to initial NOM concentration was set at given values of about 0.5 or 1 mg Al/mg C and the pH was varied between roughly 3 and 9. The fraction of UV₂₅₄ removed was measured at each pH. The procedure was repeated with three initial NOM concentrations.

A coagulant dosage and pH corresponding to maximum removal of TOC or UV₂₅₄ are only observed when jar test experiments are conducted without pH control; that is, the pH of the coagulant-treated solution decreases as the coagulant dosage increases. In general, when the pH is controlled at a constant value, the TOC concentration and the UV₂₅₄ of filtered- or settled-water supernatant samples decrease continuously as the dosage increases. In constant-pH experiments the effective dosage is usually established by a given percentage removal, for example, 50 percent of TOC or, say, 60 percent UV₂₅₄.

The estimated range of magnitude of the parameter R is shown in Fig. 8-10 with pairs of dotted lines that bracket the two sets of data points. These give a rough indication of the range of values that might be expected given the different methods typically used to locate the effective coagulant dosage. For example, the dosage that corresponds to 50 percent removal of UV₂₅₄ is typically less than the dosage at 50 percent removal of TOC, and both are less than the dosages that correspond to the maximum removal of TOC and UV₂₅₄. Locating the effective dosage that maximizes TOC- and UV-adsorbing organics removal can be difficult because maximum and near-maximum removal typically occur within a wide range of coagulant dosages.

According to Fig. 8-10 at pH 6, the magnitude of R in Eq. 8-12 is approximately 0.5 mg Al/mg C for aluminum salts and about 2.5 mg Fe/mg C for ferric iron salts. For both Fe and Al the magnitude of R does not depend to a significant extent on the type of hydrolyzing metal salt coagulant. For example, prehydrolyzed products give essentially the same relationship between R and pH as the conventional salt solutions such as commercial alum, and the acidified products. The utility of these various products derives mostly from how they facilitate achieving a given target pH for a given required coagulant dosage. The acid-base chemistry of hydrolyzing metal salt coagulants and how to use the different types to simultaneously add a required dosage and meet a desired target pH is discussed in a subsequent part of this chapter.

The differences between the magnitude of R at a given pH for Al and Fe salt coagulants is explained only partially by the factor of approximately 2 difference between the equivalent weights of Fe (18.6 mg/meq) and Al (9 mg/meq). For example at pH 6 the magnitude of R expressed as meq/mg C is approximately $2.5/18.6 = 0.13$ for Fe and $0.5/9 = 0.056$ for Al. This result suggests that the effective charge per mole of hydrolyzed metal is somewhat higher for Al than for Fe at this pH.

Estimating TOC and UV_{254} Removal Using SUVA. The extent of removal of TOC and UV_{254} can be estimated using the SUVA parameter described in Chap. 3. Figure 8-11a and

FIGURE 8-11 (a) Relationship between TOC removal and source water SUVA; (b) Relationship between the percentage removal of UV_{254} and SUVA.

TABLE 8-4 References and Relevant Conditions for the Data Points and Curves Plotted in Fig. 8-11a and b

Reference	Coagulant(s) used	Separation method(s)	Effective dosage criterion
Tambo et al. (1989)	Alum	0.45- μm -pore-size membrane filter (jar test experiments)	Maximum removal of dissolved organic carbon
Archer and Singer (2006)	Alum	Sedimentation (jar test experiments)	Point of diminishing returns (TOC removal)
Pernitsky and Edzwald (2006)	Alum, PACl (several basicities and with and without sulfate)	Sedimentation or dissolved air flotation (jar test)	Maximum removal of TOC and UV ₂₅₄
Edzwald and Kaminski (2009)	Alum and cationic polyelectrolyte	Dual-media filters (full-scale plants—0.8 to 50 MGD)	Filtered water-UV ₂₅₄ goal

b shows percent TOC and UV₂₅₄ removal for jar test measurements (Tambo, et al., 1989; Archer and Singer, 2006a; Pernitsky and Edzwald, 2006) and average removals for full-scale plant operation (Edzwald and Kaminski, 2009) in all cases with Al salt coagulants. Table 8-4 summarizes the experimental conditions and methods used in these studies. At least some of the scatter in the data in these figures is attributable to the different criteria used to define an effective dosage of coagulant. The criteria are listed in the table. Edzwald and Kaminski (2009) calculated the average removals obtained in a number of full-scale treatment plants over a period of several years. Each plant's coagulant dosage was determined using a treated-water UV₂₅₄ goal.

The curve in Fig. 8-11a was plotted using an equation that relates the percent organic carbon removal to the SUVA (L/mg-m) of the untreated water.

$$\text{Percent TOC Removal} = 10.8(\text{SUVA})^{1.32} \quad (8-13)$$

Equation 8-13 is based on an empirical relationship developed by Tambo et al. (1989) using data from jar test experiments and regression analysis. Tambo et al. used a quantity they called the *DOC/E ratio* which is equal to 100/SUVA. The substitution $\text{DOC}/E = 100/\text{SUVA}$ was made to convert the Tambo et al. empirical expression to equation to Eq. 8-13. In the experiments of Tambo et al. each jar test sample was filtered with a 0.45- μm membrane filter before the organic carbon concentration was measured and percent organic carbon removal is the maximum value observed for each source water (i.e., for each DOC/E, or SUVA, value). According to Eq. 8-13 the predicted organic carbon removal is 27 percent when $\text{SUVA} = 2 \text{ L/mg-m}$ and 68 percent when $\text{SUVA} = 4 \text{ L/mg-m}$.

According to the data and curve plotted in Fig. 8-11a and b, the percent removals of TOC and UV₂₅₄ increase with increasing SUVA and for a given value of SUVA the removal of the UV-absorbing fraction is generally higher than the removal of total organic carbon. On a carbon weight basis UV₂₅₄ is influenced more by the high-molecular-weight fraction of the organic carbon than by the low-molecular-weight fraction. Since the high-molecular-weight fraction is preferentially removed by hydrolyzing metal salt coagulants, its percentage removal tends to be higher.

Models Based on the Adsorption of NOM by the Metal Hydroxide Precipitate. A number of sorption-based models have been developed for predicting NOM removal by metal salt coagulants. Dentel (1988), applying the general approach of the particle coagulation model of Letterman and Iyer (1985), used a surface charge neutralization mechanism. Dentel assumed that fulvic acid can be modeled as a suspension of spherical colloids with high specific surface area and charge. The model uses a patch-site distribution assumption to

predict the coagulant metal concentration–pH region of charge neutralization. The effective diffuse-layer charge for a coagulant-treated suspension is the area-weighted average of the diffuse-layer charges of the component patches of uncoated NOM and sorbed aluminum hydroxide.

The agreement between Dentel's predicted region of charge neutralization and NOM removal data from Dempsey et al. (1984) was good at relatively high pH values where the removal of FA, as suggested by Dentel, may occur by adsorption of FA on $\text{Al}(\text{OH})_3(\text{s})$. Less satisfactory agreement at lower pH values was probably caused, he explained, by the complexation of Al^{3+} ions by FA. Dentel's study did not provide direct evidence that aluminum hydrolysis products adsorb on FA colloids. Later investigations have used the alternative assumption that NOM removal occurs primarily by adsorption on the metal hydroxide precipitate.

Edwards (1997) and Tseng and Edwards (1999) calculated the fraction of the raw-water dissolved organic carbon (DOC)₀ that cannot be adsorbed on metal hydroxide precipitate using the specific UV absorbance (SUVA) and the equation

$$\text{Fraction nonsorbable DOC} = K_1(\text{SUVA})_{\text{raw_water}} + K_2 \quad (8-14)$$

where the parameters K_1 and K_2 are empirical coefficients that must be determined for each source water by fitting a linear equation to fraction nonsorbable DOC data plotted versus the SUVA.

The amount of adsorbable DOC removed was determined using the Langmuir equation,

$$\frac{x}{M} = \frac{ab[C]_{eq}}{1 + b[C]_{eq}} \quad (8-15)$$

where x is the amount of DOC removed (mg DOC/L), b is the sorption constant for sorbable DOC on the metal hydroxide surface (L/mg DOC), and $[C]_{eq}$ is the sorbable DOC (mg/L) remaining in solution at equilibrium. The following equation relates x to the nonsorbable fraction and the raw-water DOC concentration:

$$x = \{1 - \text{SUVA } K_1 - K_2\}(\text{DOC})_0 - [C]_{eq} \quad (8-16)$$

The magnitude of a in Eq. 8-15, the maximum DOC that can be adsorbed per amount of precipitate (mg DOC/(mM Fe^{3+} or Al^{3+})), is assumed to vary with the final pH of the solution according to the following polynomial equation:

$$a = x_3\text{pH}^3 + x_2\text{pH}^2 + x_1\text{pH} \quad (8-17)$$

Tseng and Edwards (1999) outline how the final pH of Eq. 8-17 can be estimated using the initial alkalinity of the water and assumptions about the acidity of the coagulant solution, the amount of metal ion that precipitates and whether there is exchange of carbon dioxide with the atmosphere.

In Eq. 8-15 the quantity M is the amount of metal hydroxide precipitate in mM/L present at the final pH. Edwards (1997) and Tseng and Edwards (1999) assumed that essentially all the metal ion added forms hydroxide precipitate at pH values between 3 and 8 for ferric salt coagulants and between 5.5 and 8 for aluminum salt coagulants, and consequently in these pH intervals, M is equal to the amount of Fe^{3+} or Al^{3+} coagulant added.

The magnitudes of the six parameters in Eqs. 8-14 to 8-17 (K_1 , K_2 , x_1 , x_2 , x_3 , and b) were determined (Tseng and Edwards, 1999) for each water treatment site using a search algorithm and an objective function that minimized the quantity $(\sum(\text{DOC}_{\text{measured}} - \text{DOC}_{\text{modeled}})^2)$. $\text{DOC}_{\text{modeled}}$ is the nonsorbable DOC plus $[C]_{eq}$, the calculated equilibrium concentration, that is, unadsorbed portion, of the adsorbable DOC. The model's input variables are the raw-water SUVA, the raw-water DOC and TOC, the final pH (measured or calculated), and the coagulant type and dosage. The difference between the total organic carbon (TOC) and

the raw-water DOC concentrations was assumed to be a particulate organic carbon fraction that is 100 percent removed by coagulation.

Edwards (1997) and Tseng and Edwards (1999) used USEPA and other data sets for model calibration. Since in most cases the data were from operating water treatment plants, the coagulant dosage was a value that tended to maximize DOC removal. Both papers state that the number of adjustable parameters and the limited range of DOC removals in the calibration data sets limit using their results to test the validity of the assumptions they made about removal mechanisms. In any case, the model-calculated treated-water DOC concentrations were in very good agreement with measured values.

Kastl et al. (2004) developed a modified Langmuir equation-type model in which the number of adjustable parameters is reduced from six (Tseng and Edward, 1999) to five. In contrast to Edwards and Tseng, Kastl et al. assumed that (1) the sorbable DOC fraction consists of humic acid and nonpolar fractions, (2) only the associated form of the humic acid is absorbed during coagulation and the removal of this fraction depends on pH, (3) all compounds (humic and fulvic acids) in the humic acid fraction can be represented by a single humic acid, (4) the nonpolar fraction is adsorbed regardless of pH, and (5) the maximum sorption capacity does not vary with pH. Kastl et al., as Tseng and Edwards (1999), used measured residual DOC concentrations (from the USEPA database and their own jar test results) to calibrate their model for each site. A multiple-parameter optimization method similar to that of Tseng and Edwards (1999) was employed.

Wang and Tang (2006) describe a quantitative model based primarily on Dentel's work (Dentel, 1988) but modified to accommodate the special characteristics of prehydrolyzed metal salt coagulants, particularly PACl. Wang and Tang contend that the aluminum fractions in the prehydrolyzed product solution must be considered in the model calculations. For example, the addition of a given dosage of Al at a given pH using a PACl solution affects the stability of a particle suspension much differently than if the same dosage of Al was added using an alum solution.

The models of Dentel (1988), Edwards (1997), Tseng and Edwards (1999), and Kastl et al. (2004) do not include the effects of variables such as the initial pH and alkalinity, ionic strength, and concentration of inorganic anions (SO_4^{2-} , PO_4^{3-} , etc.) that tend to affect the surface charge of metal hydroxide precipitates and their solubility. The initial alkalinity and pH and the effective acid content of the coagulant solution determine the coagulant dosage-pH relationship. Ionic strength also affects suspension stability by modifying the thickness of the diffuse electrical layer of the particles. Snodgrass et al. (1984) found that high ionic strength increases the particle flocculation rate in systems containing sulfate ions and/or fulvic acid. However, Gu et al. (1994) observed that changes in ionic strength did not significantly affect the adsorption of NOM on oxide surfaces, while sorbed oxyanions (sulfate and phosphate species) decreased DOC uptake significantly.

The effect of inorganic anions such as sulfate on the removal of NOM might be exerted in several ways. Anions might complex with aluminum species in the solution or on the surface of the aluminum hydroxide precipitate, enhancing the NOM removal by accelerating the formation of metal hydroxides. It is also possible that high anion concentrations might hinder NOM removal by competing with NOM for the available metal hydroxide sites. Cheng et al. (2004) studied the effect of phosphate on the removal of Aldrich humic acid (AHA) by alum. They found that at pH 4 the removal of AHA increased with the phosphate concentration, while at high pH (7 to 8) an increasing phosphate concentration decreased the removal of AHA.

NOM Removal—Example Jar Test Results

The jar-test results plotted in Figs. 8-12 to 8-14 are from a study of a small community water supply system in upstate New York. The raw-water sample had a pH of 7.6, an alkalinity of

FIGURE 8-12 Jar test results of effect of alum dosage on the UV_{254} of filtrate samples (filtrate samples obtained using 0.45- μ m-pore-size membrane filters).

FIGURE 8-13 Jar test results of effect of the alum dosage on filtrate total aluminum concentration and turbidity (dotted line in the upper graph is the amount of Al added; filtrate samples obtained using 0.45- μ m-pore-size membrane filters).

1 meq/L (50 mg/L as $CaCO_3$), a total dissolved-solids concentration of 190 mg/L, a turbidity of 0.9 ntu, and a color of 50 CU. The TOC concentration was approximately 6 mg C/L. The alum dose plotted in the figures is reagent-grade aluminum sulfate in milligrams of $Al_2(SO_4)_3 \cdot 18H_2O$ per liter. A dosage of 100 mg/L of reagent-grade alum is 8 mg Al/L. The

FIGURE 8-14 Jar test results of effect of the alum dosage on the filtrate pH (filtrate samples obtained using 0.45- μm -pore-size membrane filters).

effect of the coagulant concentration on the removal of NOM was determined by filtering an aliquot of supernatant using a 0.45- μm -pore-size membrane filter. Sedimentation was not effective because of the low raw-water turbidity (0.9 ntu) and, therefore, low floc density.

As discussed in Chap. 3, the ratio of the UV absorbance at 254 nm and the dissolved organic carbon concentration (the SUVA) is a useful measure of the fraction of the NOM that can be removed by HMS coagulants. In Fig. 8-12 the UV_{254} of filtrate samples is plotted versus the alum dose. Effective removal of the UV light-absorbing NOM fraction required an alum dose of at least 30 mg $\text{Al}_2(\text{SO}_4)_3 \cdot 18 \text{H}_2\text{O}/\text{L}$ (2.4 mg Al/L or 0.4 mg Al/mg C). Maximum removal was obtained at approximately 100 mg $\text{Al}_2(\text{SO}_4)_3 \cdot 18 \text{H}_2\text{O}/\text{L}$ (8 mg Al/L or 1.3 mg Al/mg C). About 12 percent of the UV-light-absorbing compounds could not be removed by coagulation and filtration at any alum dosage. This high removable fraction (88 percent) is consistent with the high raw-water SUVA of about 5 L/mg-m (See SUVA guidelines in Chap. 3 and Fig. 8-11b).

The filtrate UV_{254} curve in Fig. 8-12 shows a relatively sharp decrease in the NOM concentration as the alum dosage is increased. This is characteristic of NOM that is relatively high in molecular weight and homogeneous in composition. If this system had contained a lower-molecular-weight NOM with a broader molecular-weight distribution (typical of low, <5 mg C/L, NOM concentration waters), the decrease in the residual NOM with increasing coagulant dosage would have been more gradual and the maximum removal of NOM at high coagulant dosages would not have been as great.

Figure 8-13 shows the effect of the alum dose on the filtrate turbidity and aluminum concentration. For alum dosages in the interval 2 to 25 mg/L of $\text{Al}_2(\text{SO}_4)_3 \cdot 18 \text{H}_2\text{O}/\text{L}$ (0.2 to 2 mg Al/L), most of the aluminum added passed through the membrane filter and was measured in the filtrate. The increasing filtrate turbidity shown in the lower plot (and the high filtrate UV_{254} in Fig. 8-12) suggests that the aluminum was present in a colloidal, light-scattering form. At an alum dose of approximately 30 mg/L (2.4 mg Al/L), the filtrate turbidity and aluminum concentration decreased abruptly, indicating that at this point the suspension of Al-humate precipitate (or possibly aluminum hydroxide microcrystals stabilized by adsorbed negatively charged NOM) had become unstable and filterable flocs had begun to form.

The water pH decreased with increasing alum dose, from about 7 at 10 mg $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}/\text{L}$ (0.8 mg Al/L) to 4.3 at 200 mg $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}/\text{L}$ (16.2 mg Al/L) (Fig. 8-14). As aluminum hydrolysis released hydrogen ions, they depleted the limited alkalinity of the system, and the pH was depressed.

According to the filtrate aluminum plot of Fig. 8-13, as the alum dosage was increased beyond about 100 mg $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}/\text{L}$ (8.1 mg Al/L), the filtrate aluminum concentration increased. This behavior can be attributed, at least in part, to the solubility of aluminum hydroxide at the low pH values indicated at high alum doses in Fig. 8-14. Also, at low pH, colloidal aluminum hydrolysis products may acquire a high positive charge and pass through the membrane filter.

Acid-Base Chemistry of Hydrolyzing Metal Salt Coagulants

When a HMS coagulant solution such as alum or PACl is added in treatment, the hydrolysis reaction produces hydrogen ions (H^+) that decrease the alkalinity and pH of the solution.

The amount of hydrogen ions formed by hydrolysis or added to the water with the product solution depends on the dosage of the coagulant metal, the basicity of prehydrolyzed products, and the free acid content of products with excess or supplemental acid. When the pH of the coagulant-treated water is near neutral (pH \approx 5.5 to 8.5), the effect of these products on the pH and alkalinity of the treated water can be determined using a quantity proposed by Letterman et al., (1996) called the *effective acid content (EAC)*.

The effective acid content of Al and Fe coagulant products including those manufactured with excess acid or supplemented with acid after manufacture can be calculated using the information provided on product data sheets and the following equation:

$$\text{Effective acid content (meq/mg metal)} = \frac{300}{100(AW)} + \frac{A}{EW/M} \quad (8-19)$$

where A = weight percent of pure acid (H_2SO_4 or HCl) in products with excess acid or products supplemented with acid, EW = equivalent weight of the acid, $\text{H}_2\text{SO}_4 = 49 \text{ g/eq}$, $\text{HCl} = 36.5 \text{ g/eq}$, AW = atomic weight of the metal ($\text{Al} = 27 \text{ g}$ and $\text{Fe} = 55.9 \text{ g}$), and M = metal concentration in the product solution (weight percent).

Products have excess acid when, in the manufacturing process where a metal oxide is dissolved in strong acid, the amount of strong acid used is greater than the stoichiometric amount required by the dissolution reaction. Supplemental acid (typically expressed in product data sheets as the weight percent pure acid) is the strong acid added to a product solution, for example, the standard alum solution, to increase its effective acid content.

The effective acid content of prehydrolyzed Al and Fe products can be calculated using the basicity B of the product and the following equation:

$$\text{Effective acid content (meq/mg metal)} = \frac{300 - 3B}{300(AW)} \quad (8-20)$$

Equations 8-19 and 8-20 are based on the assumption that the predominant hydrolysis product present after coagulant addition is the metal hydroxide precipitate, $\text{Al}(\text{OH})_3$ or $\text{Fe}(\text{OH})_3$, with a molar ratio of hydroxide to metal of 3. A manufacturer would not add supplemental acid or have excess acid in a prehydrolyzed product solution, so it can be assumed that when $B > 0$, $A = 0$, and conversely when $A > 0$, $B = 0$. Examples of calculated coagulant solution effective acid content values are listed in Table 8-5 for four commercial HMS products.

TABLE 8-5 Calculated Effective Acid Content (EAC) of Selected Commercial Coagulant Products (The solution attributes used in the calculations are approximate values from the manufacturer's product data sheets.)

Type of coagulant solution	Basicity (<i>B</i> , %)	Excess or supplemental acid (<i>A</i> , weight % pure acid)	Al or Fe Conc. in product solution (<i>M</i> , weight % metal)	Specific gravity of coagulant solution (ρ_w)	Calculated effective acid content, EAC, (meq/mg metal)
Aluminum sulfate (alum)	0	0	4.3 (Al)	1.335	0.111
Polyaluminum chloride (PACl)	80	0	12.3 (Al)	1.35	0.022
Acid-supplemented alum (acidized alum)	0	10 (H ₂ SO ₄)	2.8 (Al)	1.27	0.184
Ferric sulfate (with 2% excess acid)	0	2 (H ₂ SO ₄)	10 (Fe)	1.45	0.058

The effective acid content of a commercial coagulant solution can be measured in the laboratory by titrating a volume V of the solution with strong base (e.g., NaOH) to a pH of 7. If T is the milliequivalents of strong base used to reach this end point, then the measured effective acid content of the coagulant solution is given by

$$\text{Measured EAC (meq/mg } M) = \frac{T}{M \times V \times SG \times \rho_w} \quad (8-21)$$

where M is the weight percent metal (Al or Fe) in the coagulant solution, V and SG are the volume in mL and specific gravity of the coagulant solution titrated, respectively, and ρ_w is the mass density of water in g/mL.

The effective acid content of a coagulant product can be used to determine the relationship between the coagulant dosage and the pH after flocculation and floc separation. In one approach to establishing this relationship, the water to be treated is slowly titrated with a coagulant solution of known acidity while the pH is measured. The titration results are plotted as pH versus the coagulant dosage in meq/L. The coagulant dosage in meq/L is equal to the dosage in mg metal/L times the effective acid content of that product in meq/mg metal. If the coagulant dosage is initially recorded as volume of commercial coagulant solution per volume of water, then the conversion to mass concentration units is given by

$$\begin{aligned} \text{Coagulant dosage (mg metal/L)} &= \text{volumetric dosage } (\mu\text{L/L}) \\ &\times SG \times \rho_w \times M / 100 \end{aligned} \quad (8-22)$$

where SG is the specific gravity of the coagulant solution, ρ_w is the density of water (1 mg/ μ L), and M is the metal concentration (as weight percent) in the coagulant solution. The specific gravity and metal concentration can be found on coagulant product data sheets. Examples are listed in Table 8-5.

The relationship between the amount of coagulant added and the pH of the solution can vary with time due to relatively slow steps in the hydrolysis and metal hydroxide precipitation reactions. It is also affected by the transport of carbon dioxide between the solution and the atmosphere. Consequently, the relationship obtained from laboratory measurements may not always agree exactly with what is measured in the treatment plant.

FIGURE 8-15 Titration curves for a diverse assortment of hydrolyzing metal salt coagulant products (coagulant dosages were converted to the equivalent concentration of strong acid using the effective acid content values listed in Table 8-6).

The transport of carbon dioxide across the air-water interface is relatively slow in treatment plants because full-scale tanks have relatively low interfacial surface area per volume of water (Shankar and Letterman, 1996). Consequently, a closed-to-the-atmosphere (no CO₂ transport) assumption is appropriate, especially when mixing is not intense. In small laboratory batch reactors (e.g., 1 or 2 L) with relatively high interfacial surface area per volume of water, CO₂ transport is significantly faster, the loss of inorganic carbon from the solution is higher, and, therefore, measured pH values tend to be higher than the in-plant measured values (and closer to chemical equilibrium model predictions for open systems for CO₂ in the atmosphere and water).

Figures 8-15 and 8-16 illustrate the use of the effective acid content to predict the final pH of water treated with hydrolyzing metal salt coagulants. Aluminium and iron salt commercial products, some prehydrolyzed and some with supplemental acid, were used to titrate 1-L samples of water from the Glenmore Reservoir in upstate New York. These

FIGURE 8-16 Titration curves for a diverse assortment of hydrolyzing metal salt coagulant products (coagulant dosages are plotted as milligrams metal (Al or Fe) per liter of jar test solution).

TABLE 8-6 Coagulant Solutions Used to Obtain the Titration Results Plotted in Figs. 8-15 and 8-16 (In the EAC of the third column, $M = \text{Fe}$ for iron salt products and Al for aluminum salt products.)

Coagulant product solution	Label in figures	Effective acid content (EAC, meq/mg M)
Acid supplemented alum with $A = 10\%$	Alum ($A = 10\%$)	0.168
Acid supplemented alum with $A = 5\%$	Alum ($A = 5\%$)	0.135
Conventional alum ($A = 0\%$ and $B = 0\%$)	Alum	0.111
Polyaluminum chloride with $B = 10\%$	PACl ($B = 10\%$)	0.100
Polyaluminum chloride with $B = 50\%$	PACl ($B = 50\%$)	0.056
Ferric chloride	Ferric chloride	0.054
Ferric sulfate	Ferric sulfate	0.054
Polyaluminum chloride with $B = 75\%$	PACl ($B = 75\%$)	0.028

water samples had an initial alkalinity and pH of 38.5 mg/L as CaCO_3 (0.77 meq/L) and 7.3; the temperature was approximately 20°C. The products used and their EAC values (which range from 0.028 to 0.168 meq/mg metal) are listed in Table 8-6.

Figure 8-15 is a plot of the final pH versus the equivalent strong acid concentration (the product's EAC times its dosage in mg metal/L) for all the products listed in Table 8-6. When the pH is plotted versus the equivalent strong acid concentration of the coagulant (instead of versus the coagulant dosage in mg metal/L as shown in Fig. 8-16), the results tend to follow the same trend line; this illustrates the value of using the EAC to compute the final pH of coagulant treated solutions for all types of coagulant products (and supporting the assumptions used to compute the EAC values in Table 8-6).

The solid curve plotted in Fig. 8-15 is the theoretical pH for the titration of Glenmore Reservoir water with a strong acid for a closed system, that is, constant inorganic carbon concentration, no CO_2 exchange between the water and air. The experimental pH values are slightly above this curve; this suggests that in the small batch reactor used in the titrations some inorganic carbon (carbon dioxide) may have left the solution after the acid from the product solutions and hydrolysis converted bicarbonate ion to carbon dioxide.

Residual Aluminum and Iron in Coagulant Treated Water

When a hydrolyzing metal salt coagulant is added to water buffered by the inorganic carbon system, some of the hydrogen ions produced by hydrolysis of the metal ion (and sometimes added to the coagulant product as supplemental or excess strong acid) react with the carbonate species [in many waters ($\text{pH} < 9$) this is just the bicarbonate, HCO_3^- , ion] and some remain in solution as H^+ and decrease the pH. The difference between the initial alkalinity of the solution and the alkalinity remaining at the target pH determines the amount of coagulant solution needed to reach the target pH. As the initial alkalinity increases, the capacity to react with hydrogen ions increases and, consequently, the coagulant dosage required to reach a given pH value increases. The next sections illustrate how the amount of metal hydroxide precipitate and soluble metal ion vary as a solution's inorganic carbon species are titrated by H^+ from the addition of a hydrolyzing metal salt coagulant.

Aluminum Hydroxide Precipitate Solubility. Figures 8-17 and 8-18 were plotted using titration data calculated using the chemical equilibrium program MINEQL+ (Schecher and McAvoy, 2003) and the constants listed in Table 8-7. The figures show the theoretical

FIGURE 8-17 Titration of a solution with an initial alkalinity of 0.2 meq/L (10 mg/L as CaCO_3) with alum (EAC = 0.111 meq/mg Al) using the chemical equilibrium software MINEQL⁺. Figure (a) is the soluble Al concentration, (b) is the aluminum hydroxide precipitate concentration and (c) is the solution pH as a function of the concentration of Al added in mg Al/L.

FIGURE 8-18 Titration of a solution with an initial alkalinity of 2 meq/L (100 mg/L as CaCO_3) with alum (EAC = 0.111 meq/mg Al) using the chemical equilibrium software MINEQL⁺. Figure (a) is the soluble Al concentration, the middle is the aluminum hydroxide precipitate concentration, and (b) is the solution pH as a function of the concentration of Al added in mg Al/L.

TABLE 8-7 Formation Constants, Solubility Constant, and Enthalpy Change Values Used in MINEQL+ (Schecher and McAvoy, 2003) to Plot Figs. 8-17 and 8-18

Hydrolysis product	Type of constant	Magnitude of constant at 25°C	Enthalpy change, ΔH (kcal/mol)*
Al(OH) ²⁺	Formation	4.99	11.90
Al(OH) ₄ ⁻	Formation	23.00	44.06
Al(OH) ₃ (s)	Solubility	-10.60	27.05

*The equilibrium constants are corrected for temperature using the Van't Hoff equation

$$\log K_T = \log K_{25} - \frac{1000 \cdot \Delta H}{2.303 \cdot R} \left[\frac{1}{273 + T} - \frac{1}{298} \right]$$

where R is the gas law constant (1.987 cal/deg-mol), T is in degrees Celsius, and K_{25} is the magnitude of the equilibrium constant at 25°C. See Chap. 3 for additional details.

relationship between the Al concentration added (as aluminum sulfate, alum, expressed as mg Al/L) and the pH of the solution and the concentrations of precipitate and soluble aluminum. A constant ionic strength of 0.001 M and a solution temperature of 25°C were used in these calculations. Figure 8-17 is for a low initial alkalinity of 0.2 meq/L (10 mg/L as CaCO₃), and Fig. 8-18 is for a relatively high initial alkalinity of 2 meq/L (100 mg/L as CaCO₃). The initial pH value and total dissolved inorganic carbon concentration used in the calculations were 7.5 and 2.14×10^{-4} moles C/L for Fig. 8-17 and 8.47 and 2.0×10^{-3} moles C/L for Fig. 8-18.

According to Fig. 8-17 for an initial alkalinity of 0.2 meq/L a minimum soluble Al concentration (and the maximum aluminum hydroxide precipitate concentration) is reached at an aluminum dosage of 1.1 mg Al/L. The pH at this point is approximately 6.1 and the soluble Al concentration is about 17 μg/L. For the titration results plotted in Fig. 8-18 (an initial alkalinity of 2 meq/L, or 100 mg/L as CaCO₃), the Al dosage at the minimum soluble Al concentration is approximately 11 mg Al/L, essentially 10 times greater than for an initial alkalinity of 0.2 meq/L. The minimum soluble Al concentration and corresponding pH are the same as in Fig. 8-17, 17 μg/L and 6.1, respectively.

The results plotted in Figs. 8-17 and 8-18 show that as alum is added and the pH decreases the concentration of soluble Al initially increases to a relatively high value before the solubility product of aluminum hydroxide is exceeded and the aluminum hydroxide precipitate forms, eventually becoming the predominant form of aluminum. For an initial alkalinity of 0.2 meq/L (Fig. 8-17) up to an aluminum dosage of about 0.1 mg/L (corresponding to a pH of about 7.1), essentially all the Al added becomes soluble Al. For an initial alkalinity of 2 meq/L (Fig. 8-18), the peak soluble Al concentration before the precipitate begins to form is approximately 0.55 mg/L (at a pH of about 7.8). In both examples the pH of minimum Al solubility (pH = 6.1) must be reached to achieve a minimum soluble Al concentration.

The pH of minimum solubility and the minimum soluble Al concentration for aluminum hydroxide precipitate vary with solution temperature (Van Benschoten et al., 1994). Figure 8-19a and b shows these dependancies for a solution with low ionic strength ($I = 0.001$ M). The plotted points were calculated using MINEQL+ (Schecher and McAvoy, 2003) and the constants listed in Table 8-7. At 25°C the pH of minimum solubility is approximately 6.1 and the total soluble aluminium concentration is 6.7×10^{-7} moles/L, or 17 μg Al/L. At 2°C the pH of minimum solubility is about 6.8 and the soluble Al concentration is approximately 7 μg Al/L.

Pernitsky and Edzwald (2003) measured filtrate aluminum concentrations to compare the solubility of aluminum hydroxide formed from alum with that formed from polyaluminum chloride (PACl) products. High concentrations of different types of products were added to deionized water, the pH was varied, and the concentration of aluminum was measured in samples filtered through a 0.22- μm -pore-size membrane filter. The concentration of filtrate aluminum varied with pH, temperature, and the type of coagulant. The results for alum were similar to the predicted values plotted in Figs. 8-17 and 8-18, but the results for the prehydrolyzed PACl products were not. At a given temperature the pH of minimum solubility and the minimum concentration of filtrate Al increased as the basicity B of the products increased. For example, at 20°C the pH of minimum solubility and filtrate Al concentration were 6.0 and 16 $\mu\text{g/L}$ for alum and 6.7 and 101 $\mu\text{g/L}$ for an aluminum chlorohydrate product with $B = 83$ percent. The presence of small amounts of sulfate in various products (<2.5 percent) did not affect the filtrate Al concentration. Alum contains 23.5 percent sulfate.

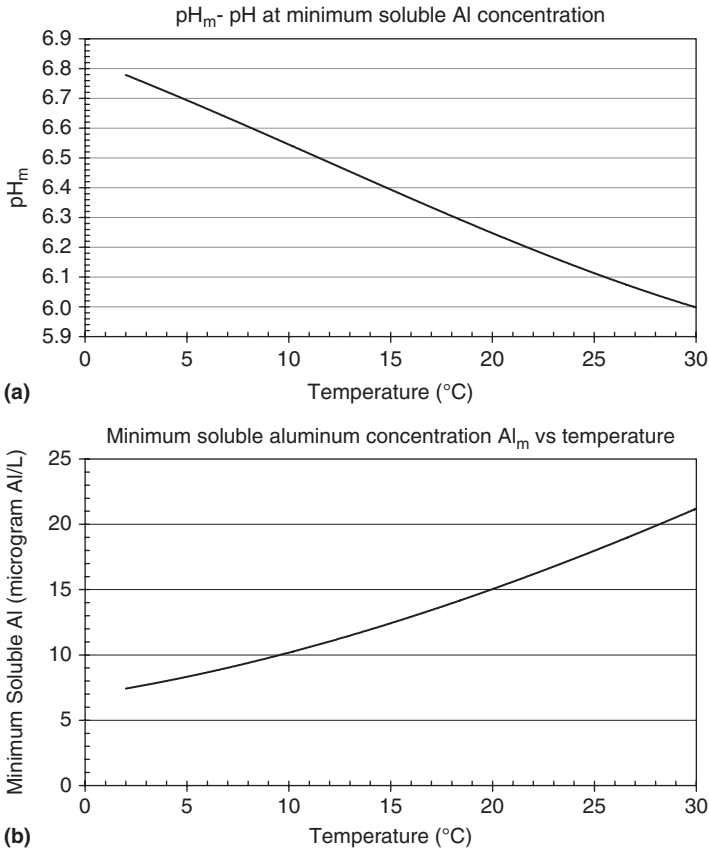

FIGURE 8-19 Effect of solution temperature on the pH of minimum aluminum hydroxide solubility (a) and minimum soluble aluminum concentration (b).

The trends observed by Pernitsky and Edzwald (2003) are informative but should be interpreted carefully. A 0.22- μm -pore-size membrane filter may not separate the hydrolyzed aluminum into precipitate and truly soluble forms; dispersed microcrystalline aluminum hydroxide may not be removed by membrane filtration under certain conditions, especially in deionized water at low pH with low concentrations of sulfate ion. Solution chemistry (especially multivalent anions such as sulfate and phosphate) can have a significant effect on the speciation of soluble aluminum, and it can affect the stability and physical form (e.g., particle size) of precipitate suspensions (Letterman and Vanderbrook, 1983).

Ferric Hydroxide Precipitate Solubility. As discussed in a previous section the solubility of amorphous ferric hydroxide precipitate is significantly less than that of amorphous aluminum hydroxide. While ferric hydroxide, like aluminum hydroxide, is amphoteric and tends to dissolve at both high and low pH, its overall low solubility leads to theoretically low concentrations of soluble iron ($<5 \mu\text{g/L}$) across the entire range of pH values (5 to 9) that is of practical importance in the coagulation process. Given ferric hydroxide's overall low solubility, the effect of temperature on it is not a significant concern.

Selecting the Type of Coagulant and Estimating the Required Dosage

The following example illustrates how the calculated or measured effective acid content (EAC) of commercial coagulant product solutions can be used with a dosage-estimating model to evaluate alternative strategies for simultaneously adding the required dosage and achieving a target value of the treated water pH. Selecting and using an appropriate target pH in coagulation is important for minimizing the concentration of residual coagulant metal in the treated water and for maximizing the efficiency of the coagulant in removing particles and natural organic material.

In the approach to coagulant selection and pH control illustrated by this example the type of coagulant, the coagulant solution's EAC and the types and amounts of any separate acids or bases used are chosen to simultaneously accomplish two objectives: (1) add the required Al dosage and (2) achieve a certain final target pH in the coagulation process. This example assumes that the objective is NOM removal with an aluminum salt coagulant.

Similar calculations are used to determine the dosage of an iron salt coagulant. However, because of the low overall solubility of ferric hydroxide, a criterion other than the pH of minimum solubility of the metal hydroxide is used to select the target pH.

Required Al Dosage. As discussed in a previous section, when the principal purpose of coagulation is effective NOM removal, the required aluminum dosage can be assumed to be proportional to the initial TOC concentration in the water, as in Eq. 8-12, where m , the coagulant dosage, is equal to R times TOC_0 . The magnitude of R is a function of pH and can be estimated for all types of aluminum salt coagulants using the curve for $M = \text{Al}$ in Fig. 8-10.

Target pH. This example applies the strategy described by Edzwald and Kaminski (2009) for choosing alum dosages that they found agreed with full-scale plant data. Their method uses a coagulation process target pH equal to the pH of minimum solubility of the

aluminum hydroxide precipitate. As discussed in a preceding section, this pH varies with the water temperature.

Determining the Required Effective Acid Content of the Coagulant Solution. An important determinant in selecting the type of coagulant is the required effective acid content of the coagulant solution, EAC in meq/mg Al, given by

$$\text{EAC} = \frac{S \pm X}{m} \quad (8-23)$$

where m is in mg Al/L and X is the change in the alkalinity (in meq/L) associated with the addition of base or strong acid before or as the coagulant solution is added. When supplemental alkalinity (base) is added along with the coagulant solution, X is positive, and when strong acid is added, X is negative. $S = \text{alk}_0 - \text{alk}$ is the difference between the raw-water alkalinity (alk_0) and the alkalinity at the target pH (alk) after coagulant addition.

The alkalinity of the coagulant-treated solution at the target pH (alk) can be determined using chemical equilibrium calculations (see Chap. 3). Programs such as MINEQL+ (Schecher and McAvoy, 2003) and water chemistry spreadsheets, for example, RTW Model 4.0 (Rothberg and Scuras, 1994), are available for doing this. If it is assumed there is no carbon dioxide transport to or from the solution, S in Eq. 8-23 can be determined easily using a graph called a Deffeyes diagram (Snoeyink and Jenkins, 1980). Najm (2001) has published sets of nomographs that can be used for this purpose.

To calculate the alkalinity of the coagulant-treated solution using equilibrium relationships, first the inorganic carbon concentration (C_T) in the raw water is calculated using alk_0 and the raw(untreated) water pH (see Chap. 3). If no inorganic carbon is added with any supplemental acids or bases and if there is negligible carbon dioxide transport between the solution and the atmosphere, then it can be assumed that C_T is essentially constant during coagulant and any acid or base addition. However, if a supplemental base contains inorganic carbon, for example, sodium bicarbonate (NaHCO_3) or sodium carbonate (Na_2CO_3), then this must be included in C_T . Table 8-8 summarizes the alkalinity and inorganic carbon contributions of selected acids, bases, and carbon dioxide. The addition of 1 mg/l carbon

TABLE 8-8 Effect of Selected Acids, Bases, and Carbon Dioxide on the Alkalinity and Inorganic Carbon Concentration

Additive	Additive dosage	Change in alkalinity (meq/L)	Change in inorganic carbon concentration, C_T (moles C/L)
Sodium bicarbonate (NaHCO_3)	1 mg/L	1.19×10^{-2}	1.19×10^{-5}
Sodium carbonate (Na_2CO_3)	1 mg/L	1.89×10^{-2}	9.43×10^{-6}
Hydrated lime (CaOH_2)	1 mg/L	2.7×10^{-2}	0
Sodium hydroxide (NaOH)	1 mg/L	2.5×10^{-2}	0
Sulfuric acid (H_2SO_4)	1 mg/L	-2.04×10^{-2}	0
Hydrochloric acid (HCl)	1 mg/L	-2.82×10^{-2}	0
Carbon dioxide (CO_2)	1 mg/L	0	2.0×10^{-5}

dioxide to reduce the pH does not change the alkalinity but increases the inorganic carbon concentration by 2.0×10^{-5} moles/L.

The calculations that follow use raw-water chemistry for two sites, Vadnais Lake in Minnesota and Hinckley Reservoir in New York. These are 2 of the 27 raw-water samples that Archer and Singer (2006a, 2006b) employed in their study of the effect of the initial TOC concentration and alkalinity on the reduction of organic halide disinfection by-product concentrations by enhanced coagulation. Their sample collection sites were selected to correspond to each of the nine cells of the TOC concentration–alkalinity matrix in the USEPA’s enhanced coagulation guidance manual (USEPA, 1999). Vadnais Lake is a raw water in the highest TOC, highest alkalinity category of the USEPA’s matrix, and Hinckley Reservoir is in the lowest TOC–lowest alkalinity category. The essential characteristics of these sites are listed in Table 8-9.

Table 8-9 also lists the calculated total inorganic carbon concentration (C_T) for each raw water. Since Archer and Singer conducted their experiments with the water at approximately 15°C, this temperature was used for the equilibrium chemistry calculations. In addition, at 15°C according to Fig. 8-19a, the pH of minimum solubility of aluminum hydroxide is approximately 6.4; therefore, this pH was used as the target pH and, with the listed C_T concentrations, to determine the alkalinity (alk) of each coagulant-treated solution.

Example 8-2 Estimating the Type and Dosage of Aluminum Coagulant and Associated Acids and Bases, if Any, for Effective NOM Removal and Minimization of Residual Soluble Aluminium

Problem Statement Given the source-water chemistries for Vadnais Lake and Hinckley Reservoir listed in Archer and Singer (2006b), determine the type and dosage of aluminium salt coagulant for each of these water sources that will maximize the removal of NOM and minimize the concentration of residual soluble aluminum, and compare these estimates with the dosages and TOC and UV_{254} removals determined by Archer and Singer using jar testing and the USEPA’s point of diminishing returns criterion.

TABLE 8-9 Raw-Water Characteristics of Two of the Source Waters Studied by Archer and Singer (2006b) (Both of these supplies are candidates for enhanced coagulation to reduce the concentration of disinfection by-product precursors.)

Raw-water characteristics	Vadnais Lake, St. Paul, MN	Hinckley Reservoir, Utica, NY
Total organic carbon (TOC, mg C/L)	8.1	3.9
SUVA (L/mg–m)	2.4	4.3
Alkalinity (alk _o , meq/L and mg/L as CaCO ₃)	2.66 (133)	0.2 (10)
pH	8.2	7.6
Calculated inorganic carbon concentration (C_T , moles C/L)	2.69×10^{-3}	2.14×10^{-4}
Calculated alkalinity (meq/L) at the target pH of 6.4 and $T = 15^\circ\text{C}$	1.35	0.10

Solution

Vadnais Lake The calculated alkalinity of the coagulant-treated water for Vadnais Lake is 1.35 meq/L, and since $\text{alk}_0 = 2.66$ meq/L for this water, $S = 2.66 - 1.35 = 1.31$ meq/L. Using $\text{TOC}_0 = 8.1$ mg C/L, Eq. 8-12, and $R = 0.65$ mg Al/mg C at pH 6.4 from Fig. 8-10, the required Al dosage is $m = 0.65 \times 8.1 = 5.3$ mg Al/L. According to Eq. 8-23 and assuming that no supplemental acids or bases will be added with the coagulant solution (i.e., $X = 0$), the required EAC for the coagulant product according to Eq. 8-23 is $\text{EAC} = 1.31 \text{ meq/L} / 5.3 \text{ mg Al/L} = 0.247$ meq/mg Al. Using Vadnais Lake's SUVA of 2.4 L/mg-m and Fig. 8-11a and b, the expected removals of TOC and UV_{254} should be about 25 and 37 percent, respectively.

An EAC of 0.247 meq/mg Al is greater than the EAC of conventional alum solution (0.111 meq/mg Al, Table 8-5) so an alum product with supplemental acid is an option. According to Eq. 8-19, with $\text{AW} = 27$ and $\text{EW} = 49$, an alum product with supplemental H_2SO_4 should have an acid to Al ratio (i.e., an A/M value) of 6.67. A product with $A = 15$ percent H_2SO_4 and $M = 2.3\%$ Al ($A/M = 15/2.3 = 6.5 \approx 6.67$) would be appropriate.

Another option is to use conventional alum solution with an aluminum content of 4.3 percent Al and EAC of 0.111 meq/mg Al and independently add a strong acid. For this option Eq. 8-23 is solved for X using $S = 1.31$ meq/L, $m = 5.3$ mg Al/L, and $\text{EAC} = 0.111$ meq/mg Al. The result is $X = -0.722$ meq/L. According to the acid equivalents listed for H_2SO_4 in Table 8-8, the required dosage is -0.722 meq/L / -2.04×10^{-2} meq/mg = 35 mg H_2SO_4 /L.

Archer and Singer (2006b) using a jar test procedure with conventional alum and the USEPA's PODR criterion measured an effective Al dosage of 4.5 mg Al/L. Their measured TOC and UV_{254} of 27.8 and 43.3 percent are similar to the values of 25 and 37 percent estimated with Fig. 8-11a and b at an SUVA of 2.4 L/mg-m. The pH at the PODR dosage is not listed in the Archer and Singer paper, but it can be estimated using equilibrium chemistry and was probably about 6.4, which is close to the target pH of 6.4 used in this example calculation.

Hinckley Reservoir (Mohawk Valley Water Authority Supply). The Hinckley Reservoir supply is a low-alkalinity water with a medium concentration of TOC. The calculated alkalinity for the coagulant-treated water based on $C_T = 2.14 \times 10^{-4}$ moles C/L and a target pH = 6.4 is 0.10 meq/L. The change in alkalinity with coagulant addition is therefore $S = 0.2 - 0.1 = 0.1$ meq/L.

With a raw-water TOC of 3.9 mg C/L and $R = 0.65$ mg Al/mg C at pH 6.4 from Fig. 8-10, Eq. 8-12 gives a required Al dosage of $m = 0.65 \times 3.9 = 2.53$ mg Al/L. Using Eq. 8-23 and assuming that no supplemental acid or base will be added with the coagulant solution (i.e., $X = 0$), the required EAC for the coagulant product is $\text{EAC} = 0.1 \text{ meq/L} / 2.53 \text{ mg Al/L} = 0.04$ meq/mg Al. According to Fig. 8-11a and b and the Hinckley Reservoir's SUVA of 4.3 L/mg-m the expected removals of TOC and UV_{254} are 52 and 75 percent, respectively.

Since the calculated EAC of 0.04 meq/mg Al is significantly less than that of conventional alum solution (0.111 meq/mg Al), this points to a prehydrolyzed aluminum product as an option. According to Eq. 8-19 with $\text{AW} = 27$, the prehydrolyzed product should have a basicity of 88 percent. The highest basicity of prehydrolyzed aluminum products is typically about $B = 80$ to 83 percent. If a prehydrolyzed product with $B = 83$ percent is used, since the basicity is slightly less than what is required ($83 < 88$ percent), the final pH may be slightly lower than the target value of 6.4. The transport of some CO_2 from the solution during coagulant addition may reduce this discrepancy.

An alternative to using a prehydrolyzed product is to add conventional alum solution with an aluminum content of 4.3 percent Al and EAC of 0.111 meq/mg Al and

independently add a strong base, for example, NaOH. For this approach Eq. 8-23 is solved for X using $S = 0.1$ meq/L, $m = 2.53$ mg Al/L, and $EAC = 0.111$ meq/mg Al. The result is $X = 0.181$ meq/L. According to Table 8-8, the required dosage of NaOH is 0.181 meq/L/ 2.5×10^{-2} meq/mg = 7.2 mg NaOH/L.

Archer and Singer (2006b) measured an effective Al dosage of 0.9 mg Al/L for Hinckley Reservoir, which is significantly less than the 2.53 mg Al/L calculated above. Their measured TOC and UV_{254} removals of 47.0 and 57.3 percent are less than the values of 52 and 75 percent estimated with Fig. 8-11a and b and this site's SUVA of 4.4 L/(mg-m). The pH at the PODR dosage of Archer and Singer is not listed in their paper, but it can be estimated using equilibrium chemistry and was approximately 7.1 . This is higher than the pH of minimum aluminum hydroxide solubility (6.4) and near the high end of the pH interval (6 to 7) of highest Al coagulant effectiveness. This suggests that the effective coagulant dosage determined by Archer and Singer using the USEPA's PODR criterion was significantly less than what is needed for maximum TOC and UV_{254} removal. Also, it is likely their dosage and the associated final pH would not minimize the concentration of residual aluminum in the treated water.

The 120 megaliter/d (32 MGD) Mohawk Valley Water Authority treatment plant at Hinckley Reservoir consists of rapid-mix units, contact basins, adsorption clarifiers, and dual-media granular bed filters. Between 1999 and 2010 the average raw-water TOC and UV_{254} were 4.85 mg C/L and 0.179 cm^{-1} and the average raw-water SUVA was 3.7 L/(mg-m). The alum dosage was usually between 1.6 and 1.8 mg Al/L. In the 1999 to 2010 period the average removal of TOC was 62 percent and the average removal of UV_{254} was 79 percent. Both TOC and UV_{254} removal percentages are somewhat higher than the values predicted using their average SUVA with Fig. 8-11a and b and significantly higher than the values obtained by Archer and Singer (2006b) using jar tests and the USEPA's PODR, although as given here, Archer and Singer used a much lower alum dose of 0.9 mg Al/L. ▲

Organic Polyelectrolyte Coagulants

The polyelectrolyte coagulants used in water treatment are high-molecular-weight, synthetic organic compounds called polymers that have a strong tendency to adsorb on the surfaces of most particles in an aqueous suspension. Polyelectrolyte polymers consist of subunits called *monomers*. A polymer's total number and types of monomer units can be varied in manufacture; consequently, a wide variety of polymers can be and has been produced. The fact that polymer chains may be linear, branched, or cross-linked increases their complexity. A review by Bolto and Gregory (2007) covers the types of polyelectrolytes used in water treatment and the mechanisms of their action in removing different types of contaminants.

Types of Polyelectrolytes. The monomer units in a polymer may have positively or negatively charged sites. In some cases, charged sites are formed by ionization reactions, with the overall charge on the molecule a function of the solution's pH and ionic strength. Polymers with a preponderance of negative sites are called anionic; those with predominately positive sites are called cationic. Polymers with no charged sites or a low tendency to develop them in aqueous solution are known as nonionic polymers. (Although not polyelectrolytes by the strictest chemical definition, the term is still used in describing nonionic polymers.) Ampholyte polymers have both positive and negative sites.

Usage. Past estimates have indicated (AWWA, 1982) that over half the water treatment plants in the United States use one or more polyelectrolytes to improve treatment efficiency.

Today this percentage is probably conservative. Cleasby et al. (1989) found that of 23 treatment plants with high-quality filtered water, 20 were using one or more polymeric flocculants and/or filter aids. The Cleasby report states that these additives are essentially required at high-rate (rapid sand) filtration plants.

Types of Polyelectrolytes Used in Water Treatment. Polyelectrolytes used to treat drinking water are often categorized as either primary coagulant polymers or flocculant (coagulant aid) polymers. Primary coagulant polymers are generally cationic and, with few exceptions, have relatively low molecular weight ($< 500,000$). Primary coagulant polymers seem to enhance the coagulation and deposition (filtration) of negatively charged particles by adsorption and particle surface-charge neutralization. If one adds too much polymer to a suspension, each particle's overall surface charge may become positive. This occurrence, known as restabilization, can adversely affect coagulation and filtration.

Primary coagulant polymers may not be as effective as aluminum and iron salts to treat dilute inorganic suspensions and water with significant amounts of NOM when aggregate removal is by, for example, sedimentation. Enmeshment by the voluminous metal hydroxide precipitates can be used to increase the volume concentration of the suspension and increase the rate of particle aggregation to efficient levels. Enmeshment is not usually a significant factor with polyelectrolytes, and while a dilute suspension can be effectively destabilized by a primary coagulant, the rate of particle aggregation may be too low to produce large, settleable aggregates in a reasonable period of time.

On the other hand, when the pretreatment objective is to produce small, high-density aggregates for direct filtration (i.e., with no intervening aggregate removal step like sedimentation), a primary coagulant used alone is often an effective alternative. One must be careful, however, never to exceed the product dosage limit recognized by the review authority for health protection.

The use of dual coagulants (a hydrolyzing metal salt and a low concentration of cationic polyelectrolyte) is a common procedure. The typical purpose is to reduce the dosage of hydrolyzing metal salt and therefore the amount of treatment residue and the amount of alkalinity consumed in the process. The polyelectrolyte may also increase the strength of the floc, reducing the tendency for flocs to break under adverse flow conditions.

Cationic Polyelectrolytes. The two most widely used cationic polyelectrolytes in water treatment are polydiallyldimethyl ammonium chloride (polyDADMAC) and epichlorohydrin dimethylamine (epiDMA). Both compounds are sold as aqueous solutions, and both are in a class called *quaternary amines*. Each monomer in a quaternary amine contains a nitrogen atom bound to four carbon atoms and carries a positive charge. This positive charge, unlike the charge of an ionizable group, is not affected to a significant extent by a dilute solution's chemistry (especially the pH). According to Bratby (2006) the molecular weight of polyDADMAC is around 2 to 3×10^6 Daltons and for epiDMA it is approximately 8×10^5 Daltons, but manufacturers can prepare specific products with different molecular weights.

Figure 8-20 shows the results of a jar test experiment in which a silica suspension was treated with a cationic polyelectrolyte (polyDADMAC). Turbidity was maximally removed at a polyelectrolyte product solution concentration of 10^{-4} g/L (0.1 mg/L). The product solution in this case contained about 20 percent by mass polyelectrolyte. The range for all the types of products sold as solutions is roughly 10 to 60 percent.

The dosage at maximum turbidity removal in this example is relatively low because, while the silica suspension concentration was relatively high (500 mg/L), the silica particles were rather large in size making the surface area concentration and the concentration of surface charge relatively low. In real source waters with smaller particles and higher

FIGURE 8-20 Effect of polyelectrolyte concentration (PolyDADMAC) on particle electrophoretic mobility and residual turbidity after flocculation and sedimentation.

particle surface area concentrations, polyelectrolyte dosages when used as the primary coagulant are typically in the 1 to 10 mg/L range.

The electrophoretic mobility (EM) at the dosage of maximum effectiveness (minimum residual turbidity) in Fig. 8-20 is approximately zero. Maximum particle removal at the point of zero EM is consistent with a charge neutralization mechanism. Above a product dosage of about 1 mg/L (for this silica particle size and concentration), the adsorption of polyelectrolyte causes the EM to become positive. The high positive charge on the particles causes restabilization of the suspension, with turbidity removal negligible.

Anionic and Nonionic Polyelectrolytes. Flocculant polymers are generally anionic or nonionic and have relatively high molecular weight, perhaps 10 times or more that of the typical primary coagulant polymer but usually less than about 10^7 daltons. They are often added after the flocculation process to increase the size and strength of particle aggregates. Because of their high molecular weight and, therefore, appreciable length, the polymers are able to bridge or interconnect particles in the agglomerates.

Low dosages of high-molecular-weight nonionic polymers (0.005 to 0.05 mg/L) are often applied just before granular bed filtration. This procedure may improve overall effluent quality and reduce the tendency for perturbations, such as an abrupt change in the filtration rate, to have an adverse effect on performance. The ripening period of granular bed filters has been decreased by adding low dosages of nonionic polymers to all or part of the backwash water (Harris, 1972; Yapijakis, 1982).

Most anionic and nonionic polymers are made with the monomer acrylamide and are known as polyacrylamide polymers. Surveys of the water-supply industry (AWWA, 1982; Dentel et al., 1989) indicate that many treatment plants use this type of polymer and, as noted previously, Cleasby et al. (1989) suggest that their use is almost essential to high performance in high-rate filtration. Dentel et al. (1989) have prepared a manual that guides the testing needed to determine a feasible type and cost effective dosage of flocculant polymers used in water treatment.

Polymeric Coagulants from Natural Organic Compounds. Polymeric coagulants made from natural organic compounds are sometimes used for water treatment. This practice is most common in developing countries where these compounds may be cheaper than hydrolyzing metal salt coagulants. An example is the water extract of the macerated seeds of the tropical shade plant *Moringa oleifera* (Jahn, 1988; Sutherland et al., 1989). The extract contains a dimeric cationic protein with a molecular weight of approximately 13 kilodaltons. The treatment performance of *moringa* seed extract has been discussed by Folkard (2002).

Another example of a cationic polymer is chitosan, a partially deacetylated chitin derived from crustacean shells. Commercial chitosan has a molecular weight of about 10^6 daltons (Bratby, 2006) and has a relatively low positive charge at neutral pH. Its charge density is pH dependent (Rinaudo, 2006). Its use in a variety of applications is described by Pariser and Lombardi (1989). Bolto and Gregory (2007) describe a cationic derivative of starch and flocculating agents that is lignin based and an anionic natural polymer lignin sulphonate made from kraft pine lignin, a by-product of papermaking.

Impurities in Polyelectrolyte Products. Polyelectrolyte formulations contain contaminants from the raw materials and the manufacturing process, such as residual monomers and other reactants and reaction by-products that have potential human health significance (Letterman and Pero, 1990). Concern about certain contaminants has limited the use of polyelectrolytes in certain countries and caused some to establish quantitative limits on applications rates. Some states in the United States require plants that use polyacrylamide and epichlorohydrin/dimethylamine (epi/DMA) compounds to notify them of monomer content.

For many years the U.S. Public Health Service and the USEPA evaluated the health significance of polyelectrolyte products and maintained a list of accepted products that many states used in their regulatory/review activities. The list included a maximum dosage for each accepted product. In the 1980s the USEPA sponsored the development and initiation of a new system based on a voluntary, third-party standard prepared through the auspices of NSF International (NSF, 2009). NSF International and other accredited organizations test and certify compliance with NSF/ANSI Standard 60, a service that is paid for by each product's manufacturer. Most of the states and many provinces in Canada require polyelectrolyte products used in their jurisdictions to be certified as in compliance with NSF/ANSI Standard 60.

A large number of polymer products are listed as certified to be in compliance with NSF/ANSI Standard 60, but this does not mean that hundreds of different compounds are being used in potable water treatment. A number of years ago Letterman and Pero (1990) found that fewer than 12 compounds made up the products on the USEPA's list of acceptable products in use at that time. It is reasonable to assume that only polyDADMAC and epi/DMA are widely used.

Supplemental (Coagulant Aid) Materials

Activated Silica. The first application of activated silica was described by Baylis (1937). The material was prepared on-site by acidifying a sodium silicate solution. Acidification formed negatively charged polysilicate compounds which were added in combination with a hydrolyzing metal salt coagulant to enhance flocculation and sedimentation. Activated silica was often used in treating low-temperature, low-turbidity water. O'Melia (1985) has described the mode of action of activated silica and the factors that affect its performance. Its use today is limited.

Clay and Fine Sand. In the process called *ballasted flocculation* a ballasting agent, typically clay or fine silica particles, microsand, in the 50- to 400- μm range (Ghanem et al., 2007), is added before or with the coagulant(s) in the rapid-mix unit. Polyelectrolytes are typically used to bind the mineral particles to the floc. Incorporation of these relatively dense particles in the floc tends to enhance flocculation and floc separation processes by displacing water and increasing floc density and settling properties. Ghanem et al. found that the bulk density of the flocs is directly proportional to the ballasting agent dosage.

Combinations of Coagulants. In a 1982 national survey of treatment plants (AWWA, 1982), a majority of respondents stated that they use cationic polymers in combination with hydrolyzable metal coagulants such as alum. Some benefits of dual coagulant use were discussed earlier.

Results obtained in jar test studies with silica suspensions (Letterman and Sricharoenchaikit, 1982) suggest that under a condition where the positively charged, aluminum hydrolysis products cause destabilization by charge neutralization, a simple trade-off relationship exists between the amounts of Al and cationic polyelectrolyte required to achieve maximum turbidity removal. In experiments where aluminum hydroxide precipitate was formed and enmeshment of the silica particles occurred, the adsorbed polyelectrolyte became covered by the precipitate and the stability of the suspension was controlled by the precipitate coating. A number of companies are marketing coagulant solutions that are a mixture of two active ingredients, for example, alum or prehydrolyzed aluminum salt with a cationic polyelectrolyte.

Hubel and Edzwald (1987) studied the use of combinations of cationic polyelectrolyte and alum for the removal of NOM from low-turbidity, low-alkalinity water. Low-molecular-weight cationic polyelectrolytes used alone were less effective than alum used alone. Without alum the dosage of cationic polyelectrolyte required to achieve charge neutralization and effective removal was proportional to the initial NOM concentration. This dosage was high for all but the lowest initial NOM concentrations and tended to exceed the health-based product dosage limit.

The use of high-molecular-weight polyelectrolytes as flocculants in water that had already been treated with alum improved turbidity removal and reduced the sludge volume but did not improve NOM removal over what was obtained with alum alone (Hubel and Edzwald, 1987). The use of high-charge-density cationic polyelectrolytes as primary coagulants with alum as a supplemental coagulant achieved high NOM removal and reduced the amount of solids produced by the process.

Ozone and Coagulation. In addition to being an effective disinfectant and oxidant, ozone can cause particle destabilization and flocculation. In the Los Angeles Aqueduct treatment plant, preozonation has been shown to improve filtration efficiency and to reduce the need for conventional coagulants and long flocculation periods (Prendiville, 1986; Monk et al., 1985; Becker and O'Melia, 2001). Ozone under certain conditions can reduce the coagulant dosage required for effective NOM removal; see Chap. 7 and the book by MWH (2005). This source recommends that, in general, NOM removal by coagulation be carried out before ozonation.

The mechanism(s) by which ozone causes particle destabilization is not well understood. It is possible that the ozone oxidizes metal ions such as Fe(II) that then form insoluble precipitates. Humic materials, both free and sorbed, may be oxidized and made more polar. It has also been suggested that ozone treatment causes the desorption of stabilizing NOM from the surfaces of mineral colloids (Edwards and Benjamin, 1992; Chandrakanth and Amy, 1996; Paralkar and Edzwald, 1996).

THE RAPID MIXING AND FLOCCULATION PROCESSES

Purpose of Rapid Mixing

Rapid, or flash, mixing is a high-intensity mixing step used before the flocculation process to disperse the coagulant(s) and to initiate the particle aggregation process (Amirtharajah and Mills, 1982). In the case of hydrolyzing metal salts, the primary purpose of the rapid mix is to quickly disperse the salt so that contact between the simpler hydrolysis products and the particles occurs before the metal hydroxide precipitate has formed. Rapid dispersal before precipitation helps ensure that the coagulant is distributed uniformly among the particles. This process is poorly understood, but probably depends on factors such as the concentration of salt in the coagulant feed solution, the coagulant dosage, the concentration and size distribution of the particulate matter, the temperature and ionic constituents of the solution, and the turbulent flow conditions (overall energy input and the flow and kinetic energy spectrum of the turbulent motion) in the rapid-mixing device. Amirtharajah and O'Melia (1990) have reviewed how some of these factors might affect rapid-mix unit performance and a report from the Awwa Research Foundation (now the Water Research Foundation) on mixing in coagulation and flocculation (AwwaRF, 1991) is also useful.

The significance of the rapid-mix step when polyelectrolyte coagulants are used is probably similar to that for hydrolyzing metals except that the reactions involving the coagulant and the water are not as important. Polyelectrolytes rapidly and irreversibly adsorb on the particulate surfaces. Therefore, in the absence of intense mixing at the point of coagulant addition, it is logical to assume that some particles might adsorb more polymer than others. If the overdosed particles became surrounded by other particles that have little or no adsorbed polymer, it is possible that the aggregation process would slow or stop before sufficiently large flocs were formed. Bratby (2006) presents useful practical information about the application of polyelectrolytes in flocculation tanks and before filtration to enhance the performance of these processes.

Rapid mixing is also the start of the flocculation process. When coagulant is added, the particles become destabilized and the high-intensity mixing leads to rapid aggregation. Particle disaggregation may become important as the aggregates grow. Evidence suggests that a steady state size distribution of relatively small aggregates may characterize the suspension leaving the rapid-mix process (AwwaRF, 1991). Furthermore, there is limited evidence that mixing at high intensity for too long can be detrimental to subsequent process performance, possibly because aggregates that are eroded or broken have a reduced tendency to reform with time because of changes in surfaces' chemical or physical properties.

Purpose of Flocculation

The purpose of the flocculation process is to promote the interaction of particles and form aggregates that can be efficiently removed in subsequent separation processes such as sedimentation, flotation, and granular media bed filtration. For efficient flocculation to occur the suspension must be destabilized. This is usually accomplished by the addition of a coagulant.

Transport Mechanisms

A number of mechanisms can cause relative motion and collisions between particles in a destabilized suspension, including Brownian motion, velocity gradients in laminar flow, magnetic attraction, unequal settling velocities, and turbulent transport. All but laminar

flow velocity gradients and magnetic attraction are important in typical water treatment systems. Flocculation rate equations have been derived for each of these mechanisms by assuming that the aggregation process is a second-order rate process in which the rate of collision N_{ij} between i - and j -size particles is proportional to the product of the concentrations of the two colliding units n_i and n_j . The general form of these relationships is

$$N_{ij} = \alpha_{ij} k_{ij} n_i n_j \quad (8-24)$$

where k_{ij} is a second-order rate constant that depends on the transport mechanism and a number of factors including particle size, and α_{ij} is a flocculation rate correction factor that is usually called a *collision efficiency factor* in the water treatment literature. It is equal to the inverse of the stability ratio W of the colloid chemistry literature, and its magnitude ranges from 0 (when the suspension is completely stable) to slightly greater than 1 (when an attractive forces affects the motion of interacting particles).

The α_{ij} term in Eq. 8-24 corrects for the simplifying assumption that transport is not influenced by the short-range forces that affect particle motion when two particles move close together. The important short-range forces are double-layer repulsion, van der Waals attraction, and hydrodynamic retardation. The first two were discussed earlier in the chapter; hydrodynamic retardation is caused by the viscous flow of fluid from between the particles as they start to collide. Hydrodynamic retardation and double-layer repulsion tend to slow particle motion and inhibit collisions, and van der Waals attraction tends to promote them. Equations for predicting the magnitude of α_{ij} are usually from studies in which numerical solutions of the complete equations of motion for interacting particles are compared with solutions obtained with the simplified transport equations that do not consider the short-range forces. Han and Lawler (1992) in modeling the flocculation process summarize the various studies regarding particle transport and the significance and incorporation of short-range forces into the models.

Brownian Diffusion. Small particles suspended in a fluid move about in a random way due to continuous collisions with the surrounding water molecules. The intensity of this motion is a function of the thermal energy of the fluid k_B times T , where k_B is Boltzmann's constant and T is the absolute temperature. The process is called *Brownian diffusion* and the particle interaction it causes is Brownian or perikinetic flocculation. The flocculation rate constant (k_{ij} of Eq. 8-24) for perikinetic flocculation in an infinite stagnant fluid, k_p , is given by

$$k_p = \left(\frac{2}{3}\right) \frac{k_B T (d_1 + d_2)^2}{\mu (d_1 d_2)} \quad (8-25)$$

According to Eq. 8-25, the rate of perikinetic flocculation is proportional to the absolute temperature, and, for particles of equal diameter ($d_1 = d_2$), is independent of the particle size. The quantity μ is the dynamic viscosity.

For transport by Brownian diffusion, the flocculation rate correction factor α_{ij} of Eq. 8-24 is α_p . It accounts for the retarding effect of hydrodynamic forces, double-layer repulsion, and other collision inhibiting factors such as steric repulsion and hydration forces on particle-particle interaction. The magnitude of α_p can be estimated with laboratory experiments or by using expressions derived by Kim and Rajagopalan (1982). These expressions include the effects of double-layer repulsion and hydrodynamic forces and use the following parameters: the height of the potential barrier in the net energy of interaction curve (ψ_{\max} in Fig. 8-3c, $A/(6k_B T)$), d_1 , and d_2 . The quantity A is the Hamaker constant.

In systems with significant mixing and convection, Brownian diffusion becomes relatively unimportant in the bulk fluid. However, where small particles contact large floc

particles, Brownian diffusion can still control transport of the small particles over a final short distance at the floc surface. The rate of transport to the floc surface is a function of the floc size and the intensity of the turbulent fluid motion as well as the Brownian diffusivity D , where $D = k_B T / (3\pi\mu d)$; d is the diameter of the diffusing particle.

Transport in Laminar Shear. When particles are suspended in a laminar flow field, a particle located at a point with high fluid velocity tends to move faster than one at a point with low velocity. If the particles are close enough together, their different velocities will eventually cause them to come into contact. This process is called orthokinetic flocculation and its flocculation rate constant $k_{ij} = k_o$ is given by,

$$k_o = \left[\frac{(d_1 + d_2)^3}{6} \right] \left(\frac{du}{dz} \right) \quad (8-26)$$

where du/dz is the magnitude of the velocity gradient.

The flocculation rate correction factor in Eq. 8-21 for orthokinetic flocculation ($\alpha_{ij} = \alpha_o$) has been evaluated by van de Ven and Mason (1977). They presented an approximate expression for the factor when double-layer repulsion is negligible ($\psi_{\max} \rightarrow 0$) and van der Waals attraction and hydrodynamic retardation are the controlling short-range forces. The two interacting particles are assumed to have the same diameter d . The expression is

$$\alpha_o = 0.8 \left[\frac{A}{4.5 \pi \mu d^3 (du/dz)} \right]^{0.18} \quad (8-27)$$

According to Eq. 8-27, hydrodynamic retardation reduces the collision rate in orthokinetic encounters even when double-layer repulsion is negligible. The effect is greater for larger particles and higher shear rates. For example, assuming a water temperature of 20°C and using A (Hamaker constant) = 8×10^{-20} J, $\mu = 1 \times 10^{-3}$ kg/(m-s), $d = 2 \times 10^{-6}$ m, $du/dz = 10$ s⁻¹, and $\alpha_o = 0.62$. If du/dz is increased to 100 s⁻¹, α_o decreases to 0.41. The significance of hydrodynamic retardation is reduced if the particles are porous and intervening fluid can move through the particle structure, rather than just flowing from between the colliding surfaces.

Differential Settling. Flocculation by differential settling occurs when particles have unequal settling velocities and their alignment in the vertical direction makes them tend to collide when one overtakes the other. The driving force for this mechanism is gravity, and the flocculation rate constant $k_{ij} = k_d$ is given by

$$k_d = \frac{\pi g (s-1)}{72\nu} (d_1 + d_2)^3 (d_1 - d_2) \quad (8-28)$$

where s is the specific gravity of the particles and ν is the kinematic viscosity. This expression is based on several assumptions; the particles are spherical and have the same density and their settling velocities are predicted by Stokes' law. According to Eq. 8-28 the rate of flocculation by differential settling is maximized when both particles are large and dense and the difference in their sizes is great. The effect of the short-range attractive forces and hydrodynamic retardation on the rate of flocculation by differential settling has been evaluated by Han and Lawler (1991).

Turbulent Transport. In turbulent flow the fluctuating motion of the fluid forms eddies that vary in size. The largest eddies are of comparable size to the vessel or impeller. The kinetic energy in large-scale eddies is transferred to smaller and smaller eddies. Eventually,

below a certain length scale, the energy is dissipated as heat. An eddy size, known as the *Kolmogoroff microscale*, separates the inertial size range, where energy is transferred with very little dissipation, from the viscous subrange, where the energy is dissipated as heat. Within the eddies of turbulent flow are time-varying velocity gradients. These velocity gradients cause relative motion of entrained particles, and this relative motion, as in laminar flow, causes flocculation.

The flocculation rate constant $k_{ij} = k_t$ for collisions between two neutrally buoyant particles (i.e., particles with insignificant settling velocities) in homogeneous and isotropic turbulent fluid motion is given by

$$k_t = \left[\frac{(d_1 + d_2)^3}{6.18} \right] \left(\frac{\epsilon}{\nu} \right)^{1/2} \quad (8-29)$$

where ϵ is the local rate of turbulent energy dissipation per unit mass of fluid and ν is the kinematic viscosity. Equation 8-29 was derived by Saffman and Turner (1956) using the assumption that the diameter of the particles is less than the Kolmogoroff microscale of the turbulent motion, $\eta = (\nu^3/\epsilon)^{1/4}$. According to Eq. 8-29, the rate at which particles collide by turbulent diffusion increases with particle size and with the rate of energy dissipation in the fluid.

Spielman (1978) stated that the magnitude of the flocculation rate correction factor $\alpha_{ij} = \alpha_t$ for the interaction of equal-size particles in turbulent flow can be approximated using Eq. 8-27, the expression derived by van de Ven and Mason (1977) for particle interactions in laminar shear. Spielman substituted the quantity $(\epsilon/\nu)^{1/2}$ for the laminar velocity gradient du/dz and obtained

$$\alpha_t = 0.8 \left[\frac{A}{4.5 \mu d^3 (\epsilon/\nu)^{1/2}} \right]^{0.18} \quad (8-30)$$

This expression suggests that α_t decreases with increasing particle diameter and increasing mixing intensity.

Delichatsios and Probstein (1975) derived a kinetic model for flocculation in isotropic turbulent flow for two conditions. In the first the radius $(d_1 + d_2)/2$ of the collision sphere is smaller than the Kolmogoroff microscale, and in the second it is greater. For the first condition, the equation for the flocculation rate constant is similar in form to Eq. 8-29 with a constant 1/19.6 instead of 1/6.18. For the second condition, $(d_1 + d_2)/2$ larger than the microscale, the expression is

$$k_{t,d-p} = (0.427)(d_1 + d_2)^{7/3} \epsilon^{1/3} \quad (8-31)$$

This equation suggests that for larger floc particles the rate of particle interaction is proportional to ϵ to the 1/3 power instead of the 1/2 power of Eq. 8-29. Also, in contrast to Eq. 8-29, the rate of interaction is independent of the viscosity of the fluid.

G Value Concept. In the 1940's Camp and Stein (1943) used Smoluchowski's (1917) equation for flocculation in uniform laminar shear to derive a widely used flocculation rate equation for turbulent flow. They calculated that for turbulent fluid motion a rms (root-mean-square) velocity gradient can be used in place of the laminar velocity gradient in the laminar shear flocculation rate equation (Eq. 8-26). Their rms velocity gradient, or *G* value, is given by

$$G = \left(\frac{P}{V\mu} \right)^{1/2} \quad (8-32)$$

where P is the power input to the fluid (through, for example, the blades of a rotating impeller) and V is the volume of water in the vessel. The flocculation rate constant in Camp and Stein's modified Smoluchowski equation for orthokinetic flocculation is

$$k_{o,c-s} = \frac{(d_1 + d_2)^3}{6} G \quad (8-33)$$

Equation 8-33 becomes similar to the more rigorous expression (Eq. 8-29) derived by Saffman and Turner (1956) if it is assumed that the G value is equal to $(\epsilon/\nu)^{1/2}$ where ϵ , as noted previously, is the local rate of energy dissipation per unit mass of fluid.

The limitations of the G -value concept have been discussed by a number of authors including Cleasby (1984), McConnachie (1991), Hanson and Cleasby (1990), and Han and Lawler (1992). Clark (1985) has argued that inappropriate assumptions were made in the derivation of the Camp and Stein G value, and therefore, it is not a valid representation of the average velocity gradient in a turbulent fluid. The theoretical validity of the G value of Eq. 8-32 as a design parameter and reactor scale-up tool is questionable because the rate of flocculation is affected not only by the intensity of the fluid motion but also by how the kinetic energy of the fluid is distributed over the size of the eddies in the turbulent flow field. For a given mixing intensity (either overall power input to the fluid or local rate of energy dissipation), the distribution of energy is determined by the size and geometry of the impeller and vessel system.

Use of the G -value concept in flocculation is affected by three other considerations. First, the local rate of energy dissipation in a mechanically mixed vessel varies widely with location in the vessel, from several hundred times the overall energy input rate per unit mass of fluid $P/(V\rho_w)$ near the rotating impeller to a fraction of this overall value away from the impeller (Schwartzberg and Treybal, 1968; McConnachie, 1991). Consequently, the local rate of particle aggregation (and possibly the local rate of floc breakup) will tend to vary widely with location in the vessel, increasing the tendency for floc structure and density to change through breakup and reformation as the flocs are moved around the vessel by the fluid (Clark and Flora, 1991).

Second, some of the energy supplied to the rotating impeller shaft is dissipated directly as heat at the surfaces of the impeller and vessel walls and does not produce turbulent fluid motion. The weighted average (by fluid mass) of ϵ for all elements of fluid in the vessel will tend to be less than $P/(V\rho_w)$, the overall energy input per unit mass of fluid in the vessel; the efficiency with which the motion of the impeller increases the kinetic energy of the turbulent flow will vary with the geometry of the mixing system.

Third, according to theoretical calculations by Han and Lawler (1992), fluid shear, and therefore the G value, is a controlling factor in flocculation kinetics only when the interacting particles are larger than $1\ \mu\text{m}$ and about the same size. When one particle is large and the other is small ($< 1\ \mu\text{m}$), Brownian diffusion tends to control the relative motion between the particles, and while mixing intensity is still important, the form of the relationship between flocculation rate and the overall energy dissipation rate in the fluid is likely to be different than that predicted by Eq. 8-29.

Our understanding of turbulent flow in mechanically agitated vessels is incomplete but growing rapidly. For example, Liu et al. (2004) have shown how point-to-point calculations using computational fluid dynamics can predict flocculation performance in open-channel flow flocculators more effectively than the mean velocity gradient approach. Unfortunately, sensitive methods for measuring flocculator performance, especially the performance of full-scale units, are not available. Until this capability improves, it seems reasonable to use the Camp and Stein G value for flocculator design and scale-up, along with other empirically derived design best practices related to mixer and reactor configuration.

Flocculation Kinetics in Batch and Plug Flow Reactors

Flocculation in a well-mixed batch reactor is described by Eq. 8-34 for the rate of change in the concentration of k -size particles. The equation assumes that k -size particles are formed by the collision of i - and j -size particles; that is, $k = i + j$. The term dn_k/dt on the left is the rate of change in the concentration of k -size particles in the reactor. The first term on the right is for the rate of formation of k -size particles by the collision of i - and j -size particles and the second term on the right accounts for the loss of k -size particles by their collision with any other particle. This expression only applies to irreversible aggregation; it does not account for the breakup or erosion of aggregates. For continuous particle-size distributions an integral form of this expression can be written (Elimelech et al., 1995).

$$\frac{dn_k}{dt} = \frac{1}{2} \sum_{\substack{i+j=k \\ i=1}}^{i=k-1} \alpha_{ij} k_{ij} n_i n_j - n_k \sum_{k=1}^{\infty} \alpha_{ik} k_{ik} n_i \quad (8-34)$$

The effective use of Eq. 8-34 is difficult. One of the most significant problems is assigning values to the rate constants k_{ij} and k_{ik} and the flocculation rate correction factors α_{ij} and α_{ik} . These depend on the nature of the particles and on the transport processes that cause the particle interaction (Elimelech et al., 1995). Relationships must be established for how aggregate shape and density vary with size. The simplest assumption is that the particles coalesce like oil droplets, but this is obviously very approximate for the interaction of solid particles.

Most flocculators are mechanically mixed, continuous-flow reactors and the fluid motion is turbulent; particle interaction through laminar velocity gradients and unequal settling velocities tend to be insignificant. The next section describes and applies relationships that predict the performance of completely mixed, continuous-flow flocculation reactors in which turbulent fluid motion is the predominant particle transport mechanism and that make simplifying assumptions about the size distributions of the particles. These relationships are presented as a framework for understanding the flocculation process and not a design methodology.

Ideal Continuous-Flow Flocculation Reactors

Argaman and Kaufman (1970) have shown that the performance of a continuous-flow flocculation reactor can be predicted using relationships based on the completely mixed, tanks-in-series model (see Chap. 4). It was assumed that each completely mixed (CFSTR) compartment in the reactor contains a bimodal particle-size distribution where the smaller particles in the distribution are from the influent and are called *primary particles*, and the larger particles are the aggregates or flocs. The flocs grow by the attachment of primary particles. Since each compartment is assumed to be completely mixed, at steady state the effluent characteristics (a mixture of flocs and primary particles) are the same as the vessel contents.

The following equations are based on a simplified version of Argaman and Kaufman's (1970) model in which floc disruption is ignored. The rate at which primary particles contact the larger floc particles in one of the completely mixed compartments is calculated using Eqs. 8-24 and 8-29. It is assumed that the flocs have a spherical shape and are much larger than the primary particles; that is, $d_2 \gg d_1$. By substituting $\Phi = n_2 \pi d_2^3 / 6$, where n_2 and d_2 are the floc number concentration and diameter and Φ is the floc volume fraction (volume of floc per volume of suspension), Eqs. 8-24 and 8-29 yield

$$N_{12} = \alpha_{12} \frac{0.97}{\pi} \Phi \left(\frac{\epsilon}{\nu} \right)^{1/2} n_1 \quad (8-35)$$

Equation 8-35 is a first-order expression in terms of n_1 . A mass balance on primary particles in the completely mixed reactor compartment can be combined with this expression and the assumption that $\alpha_{12} = 1$ to result in

$$\frac{n_1}{n_{10}} = \frac{1}{1 + k\bar{t}} \quad (8-36)$$

where the flocculation rate constant k is

$$k = \frac{0.97}{\pi} \phi G \quad (8-37)$$

\bar{t} is the mean residence time of the fluid in the reactor compartment, and n_1 and n_{10} are the effluent and influent primary particle number concentrations, respectively. It is assumed that ε is equal to $P/(V\rho_w)$, the overall energy input rate per unit mass of fluid where V is the volume of water in the reactor and ρ_w is the density of water.

For destabilization by charge neutralization, the floc volume concentration in the reactor is determined by the volume of primary particles that has been incorporated in the flocs and by the density of the flocs; that is,

$$\phi = V_1 n_{10} \left(1 - \frac{n_1}{n_{10}} \right) \left(\frac{\rho_f - \rho_w}{\rho_f - \rho_w} \right) \quad (8-38)$$

where V_1 is the volume of a primary particle and ρ_f and ρ_p are the floc and primary particle densities, respectively. The quantity $V_1 n_{10}$ is equal to C_o/ρ_p , where C_o is the mass concentration of primary particles in the influent to the first compartment. According to Eqs. 8-36 through 8-38, flocculator performance n_1/n_{10} is a function of n_{10} , ρ_f , ρ_p , the dimensionless product $G \times \bar{t}$, and the amount of primary particles that attach to the flocs in the reactor. These equations are approximate due to the simplifying assumptions that have been made; however, they illustrate the importance of mixing intensity, residence time, and influent particle concentration in affecting the performance of continuous-flow flocculation reactors.

It is frequently noted that raw-water supplies with a relatively high concentration of particulate matter is easier to treat than water with a low concentration. There are also proprietary treatment systems that use a buoyant coarse media in the flocculator (Schulz et al., 1994) or the addition of supplemental suspensions such as silica particles to enhance the rate of flocculation for what would otherwise be dilute and slowly flocculating suspensions. One of the reasons for this observation and the efficacy of the proprietary systems is that, for a given value of $G \times \bar{t}$, as the influent particle concentration increases, the floc volume concentration increases and, consequently, the aggregation rate and the fractional conversion of primary particles to flocs become greater.

The typical continuous-flow flocculator has multiple compartments, and the mean fluid detention time and G value may be different for each compartment. As primary particles contact the flocs in each compartment, the floc volume concentration and the flocculation rate constant increase. The equations listed in Table 8-10 are based on Eqs. 8-36 through 8-38 and were used to calculate values of the quantity n_{1m}/n_{10} as a function of the dimensionless product $G \times \bar{t}$ for three values of the influent particle mass concentration. (n_{10} is the number concentration of primary particles in the influent to the first compartment, n_{1m} is the number concentration in the effluent of the m th compartment, and $\bar{t} = \sum \bar{t}_i$). For this example it was assumed that the flocculator has three equal volume compartments ($m = 3$) each with the same value of \bar{t}_i , and the same mixing intensity ($G_i = G$); the primary particle and floc densities are 2.5 and 1.02 g/cm³, respectively. The results are plotted in Fig. 8-21.

TABLE 8-10 Equations Used to Calculate the Performance of a Compartmentalized, Completely Mixed, Continuous-Flow Flocculation Reactor*

$$\frac{n_{1m}}{n_{10}} = \prod_{i=1}^m \frac{1}{1 + k_i \bar{t}_i} \tag{8-39}$$

$$k_i = \left(\frac{0.97}{\pi} \right) \phi_i G_i \tag{8-40}$$

$$G_i = \left(\frac{\varepsilon}{\nu} \right)_i^{1/2} \tag{8-41}$$

$$\phi_i = \frac{C_o}{\rho_p} \left(1 - \frac{n_i}{n_{10}} \right) \left(\frac{\rho_p - \rho_w}{\rho_f - \rho_w} \right) \tag{8-42}$$

*In these equations the subscript *i* refers to the *i*th compartment in a series of *m* compartments. *n*₁₀ is the number concentration of particles in the influent to the first compartment, and *n*_{1*m*} is the concentration in the effluent of the *m*th compartment. *C*₀ is the mass concentration of primary particles in the influent to the first compartment. The overall mean fluid residence time for the reactor is $\bar{T} = T = \sum \bar{t}_i$. It is assumed that α for primary-particle-floc interaction is equal to 1.

According to Fig. 8-21, flocculator performance increases with increasing $G \times \bar{t}$ and increasing influent particle concentration. For *C*₀ = 5 mg/L, as $G \times \bar{t}$ increases, the effect of flocculation on the primary particle concentration in the flocculator effluent is insignificant until $G \times \bar{t}$ is approximately 50,000. From $G \times \bar{t}$ = 50,000 to 200,000, the quantity *n*_{1*m*}/*n*₁₀ decreases from slightly less than 1 to approximately 0.02. For *C*₀ = 5 mg/L, *n*_{1*m*}/*n*₁₀ = 0.5

FIGURE 8.21 Effect of the dimensionless parameter $G \times T$ ($T = \bar{t}$) on the performance of a flocculation reactor with three equal compartments for several influent primary particle concentrations. The primary particle and floc density are 2.5 and 1.02 g/cm³ and the *G* value in each compartment is 25 s⁻¹.

corresponds to $G \times \bar{t} = 72,000$. For $C_o = 100$ mg/L, significant primary particle removal begins at $G \times \bar{t} = 2800$ and $n_{1m}/n_{10} = 0.5$ corresponds to $G \times \bar{t} = 3600$. When C_o is equal to 50 mg/L, $n_{1m}/n_{10} = 0.5$ corresponds to $G \times \bar{t} = 7200$. This general relationship between the influent primary-particle concentration and the primary-particle removal efficiency exists because the flocculation rate constant k_i for a given flocculator compartment depends on the magnitude of the floc volume concentration Φ_i in that compartment, and Φ_i depends on the primary-particle concentration in the flocculator influent (see Eqs. 8-40 and 8-42 in Table 8-10). This dependency has been observed in practice (Hudson, 1981).

The equations in Table 8-10 can be used to show that the relationship between flocculator performance n_{1m}/n_{10} and $G \times \bar{t}$ depends on the number m of equal volume compartments in the flocculation reactor. For example, for $C_o = 100$ mg/L and $m = 3$, $n_{1m}/n_{10} = 0.5$ is obtained at $G \times \bar{t} = 3600$. For a single compartment ($m = 1$), this value of $G \times \bar{t}$ decreases to 2200, and for $m = 5$ it increases to 5300. Similar trends are calculated at other values of C_o . In general, a flocculation reactor with a single CFSTR compartment requires the lowest value of $G \times \bar{t}$ to reach a given level of performance. This is because the performance of each compartment depends on the product $[(G \times \bar{t})/m]\Phi_i$ (see Eqs. 8-39, 8-40, and 8-42 in Table 8-10). In the initial compartments of a multiple-compartment flocculator the magnitude of Φ_i is lower than in a single-compartment reactor, and therefore, a larger value of $(G \times \bar{t})/m$ is required to achieve a given level of overall performance.

The curves in Fig. 8-22 were plotted using the equations in Table 8-10 to illustrate the effect of flocculator compartmentalization and the influent primary-particle concentration on flocculator performance for a given value of $G \times \bar{t}$. The primary-particle and floc density were 2.5 and 1.02 g/cm³ and the G value in each compartment was 25 s⁻¹. The product $G \times \bar{t}$ was constant and equal to 90,000. For the lowest influent primary-particle concentration, $C_o = 10$ mg/L, $m = 5$ yields maximum performance. The fraction of primary particles

FIGURE 8-22 Effect of influent primary particle concentration and the number of completely mixed compartments on flocculator performance, $G \times T = 90,000$, where T is the overall mean fluid detention time. The primary particle and floc density are 2.5 and 1.02 g/cm³ and the G value in each compartment is 25 s⁻¹.

remaining is approximately 0.12 when $m = 1$ and 0.017 when $m = 5$. For $C_o = 20$ and 100 mg/L and $m < 10$, flocculator performance increases with increasing compartmentalization. For a given number of compartments, the fraction of primary particles remaining in the flocculator effluent decreases with increasing influent primary-particle concentration.

Floc Disaggregation. Floc disaggregation can apparently influence flocculator performance, especially when the mixing intensity is high ($G > 100 \text{ s}^{-1}$) and the flocs have grown to a significant size. Investigators have observed with batch reactors, using a high intensity and relatively long duration of mixing, that the flocs tend to approach a constant size distribution. One explanation for this behavior is that with time the surfaces of the flocs and primary particles change (chemically and physically), and the floc suspension becomes restabilized. In another explanation it is assumed that a dynamic equilibrium is eventually reached between the rates of particle aggregation and disaggregation. A review of floc strength and breakage by Jarvis et al. (2005) concludes that smaller flocs tend to have greater strength than larger ones and that the use of polymeric flocculation aids tends, in general, to strengthen chemical flocs. Useful models of floc breakage await a better understanding of the internal composition and bonding of the floc structure.

According to a number of investigations conducted in the 1970s (Spielman, 1978; Argaman and Kaufman, 1970; Parker et al., 1972), the principal mechanisms of disaggregation or floc breakup are (1) surface erosion of primary particles from the floc and (2) fracture of the floc to form smaller daughter aggregates.

Argaman and Kaufman (1970) considered both particle aggregation and floc erosion in deriving an equation similar to Eq. 8-29 for predicting the performance of a single-compartment, completely mixed, continuous-flow flocculator. The following first-order rate expression was used to describe the disappearance and formation of primary particles by aggregation and erosion mechanisms:

$$r = -k_a G C + k_b G^2 \quad (8-43)$$

where C is the mass concentration of primary particles, k_a is the agglomeration rate constant, and k_b is the floc breakup (disaggregation) coefficient. For a single-compartment, completely mixed flocculator reactor, Eq. 8-43 yields the following flocculator performance equation:

$$\frac{n_{11}}{n_{10}} = \frac{1 + k_b G^2 \bar{t}}{1 + k_a G \bar{t}} \quad (8-44)$$

The effect of including the erosion term in the rate expression is illustrated by Fig. 8-23, where flocculator performance curves are shown for $k_a = 5 \times 10^{-5}$ and $k_b = 1.0 \times 10^{-7} \text{ s}$, and $k_b = 0 \text{ s}$. With $k_b = 0 \text{ s}$, the plotted curve is essentially the same as that obtained using Eqs. 8-31, 8-37, and 8-38.

According to Fig. 8-23, including floc disaggregation in the continuous-flow flocculator performance equation yields an optimum mixing intensity, a result that differs from that obtained using Eq. 8-36. Also, when floc erosion is included, constant $G \times \bar{t}$ does not yield constant performance.

Equation 8-44 is appropriate only for completely mixed reactors, where each compartment is populated by a floc suspension of constant size distribution. It is not appropriate to use it (or Eq. 8-36) to derive an expression for flocculation in a plug flow reactor where the floc size distribution is not constant with time.

Floc Size and Density. Experiments have shown that the floc size distribution is a function of the intensity of the turbulence and the structural characteristics of the flocs. A number of investigators (Parker et al., 1972; Mühle and Domasch, 1991; Tambo and François, 1991)

FIGURE 8-23 Flocculator performance curves illustrating the significance of the floc disaggregation term in Eq. 8.43 (G versus T for $n_{11}/n_{10} = 0.3$, $k_b = 1.0 \times 10^{-7}$ s and $k_b = 0$ s).

have suggested the following simple relationship between a characteristic floc size, d_f (e.g., the “maximum” diameter), and G for a steady state condition in which the rate of disaggregation equals the aggregation rate, where the exponent b is a positive integer. According to Eq. 8-45, the steady state floc size decreases as the mixing intensity increases.

$$d_f = \frac{P}{G^b} \quad (8-45)$$

The coefficient P in Eq. 8-45 has been related to the strength of the floc (Parker et al., 1972; Tambo and François, 1991). According to Parker et al., the magnitude of the exponent b depends on the size of the flocs relative to the characteristic size of the turbulent eddies that cause the erosion of primary particles or floc breakage. For flocs that are large relative to the Kolmogoroff microscale of the turbulence, $b = 2$, and for flocs smaller than this scale, $b = 1$. For the floc breakage mechanism, in both turbulence scale regimes, $b = 0.5$. Some experimental investigations (Argaman and Kaufman, 1970; Lagvankar and Gemmill, 1968) have reported the value of the exponent b to be 1.0; that is, the characteristic size of the flocs is inversely proportional to G . Equations similar in form to Eq. 8-45 have been derived using theoretical approaches for floc disruption in turbulent flow (Tambo and François, 1991; Mühle, 1993). The removal of flocs in most separation processes, such as sedimentation, is determined by floc density, and floc density is related to floc size and composition.

It is important to note that the separation process used for floc removal determines what constitutes the best type of floc. For example, with sedimentation the flocs should be relatively large and of high density to maximize their settling velocity. With flotation the flocs should be about 25–50 μm (see Chap. 9) and of low density. The effectiveness of a granular bed filter in a direct filtration system would be increased by relatively small but filterable flocs that can penetrate the filter bed, distributing the deposit over the depth of the bed and minimizing the headloss increase per unit of deposited particles.

Using a computer simulation of the aggregation process, Vold (1963) determined the following inverse relationship between floc buoyant density ($\rho_f - \rho_w$) and diameter, d_f (of a circle with equal projected area):

$$\rho_f - \rho_w = B d_f^{-0.7} \quad (8-46)$$

This relationship, which shows that the floc density tends to decrease as the floc size increases, is in general agreement with experimental results (Lagvankar and Gemmill, 1968). Equations 8-45 and 8-46 considered together suggest that as the mixing intensity used in the flocculator is increased, the steady state, characteristic floc size will decrease (Eq. 8-45) and the floc buoyant density (Eq. 8-46) will increase.

According to Eqs. 8-36 to 8-38, increasing the floc buoyant density tends to have an adverse affect on flocculator performance. For example, for a primary particle density of 1.5 g/cm^3 and with the floc buoyant density increasing from 2×10^{-3} to $1 \times 10^{-2} \text{ g/cm}^3$, the fraction of primary particles remaining in the continuous-flow flocculator effluent increases from 1.6×10^{-5} to 2×10^{-3} . This result is obtained because as the floc buoyant density increases Φ in Eq. 8-38 and the flocculation rate constant k in Eqs. 8-36 and 8-37 decrease. It suggests that the beneficial effect of increasing the mixing intensity on flocculator performance may be offset to some extent by the tendency for higher mixing intensities to produce smaller (see Eq. 8-45), less voluminous, that is, higher-density, flocs (see Eq. 8-46).

Mathematical models of the flocculation process, especially those which use the population balance equation, require assumptions about the physical characteristics of the aggregates formed. These assumptions are important because they shape the calculations used to determine how the aggregate will interact with other particles (Lee et al., 2002) and stationary surfaces such as filter grains, how it will be affected by disruptive forces (Jarvis et al., 2005), and how it will behave in floc separation processes such as sedimentation and flotation (Lee et al., 2000) and be detected in floc measurement instrumentation (Gregory, 2008).

If N spherical primary particles of diameter d_o , density ρ_o , and mass m_o form an aggregate, its mass will be $N \times m_o$, but the determination of its "size" requires assumptions about its geometry, that is, how the primary particles are spatially arranged in the structure of the floc. If the spherical primary particles in the floc are arranged in a linear string the "size", that is, length of the floc, will be $N \times d_o$. However, if the primary particles aggregate by coalescence (like oil droplets) and the aggregate of N primary particles is spherical in shape, then its diameter is given by

$$d = \left[\frac{6Nv_o}{\pi} \right]^{1/3} \quad (8-47)$$

where $v_o = m_o/\rho_o$, the volume of each primary particle. This equation also applies if the primary particles are arranged in a compact spherical shape with constant porosity ϵ ; the quantity in the brackets must be replaced by $6Nv_o/\pi\epsilon$. This example is an application of Euclidean geometry.

Fractal geometry provides an alternative approach to floc characterization in the flocculation process (Lee et al., 2000; Somasundaran and Runkana, 2003). However, true fractal structure requires a hierarchy of space sizes within the aggregate and uniform fractal dimensionality throughout the floc. Aggregates have a random structure and, logically, varying fractal dimensionality. It might be better to use the term *power law relation* instead of *fractal geometry* for floc particle characterization, but *fractal geometry* is widely used in the literature.

Flocs formed by aggregation processes tend to have porous and irregular structures which change as the aggregates increase in size (Chakraborti et al., 2003). As these irregular objects grow it becomes increasingly difficult to quantify their "size." Fractal geometry has been used to characterize the structural characteristics of particle aggregates (Meakin, 1988; Lee et al., 2000; Somasundaran and Runkana, 2003). As a fractal object, the "size" d of the aggregate is related to its mass ($N \times m_o$) by

$$d \propto (Nm_o)^{1/F} \quad (8-48)$$

where F in the exponent is called the *fractal dimension* (or *mass fractal dimension*). As a limit, if a floc particle is formed by coalescence (the spherical oil droplet described above) or if the primary particles form compact flocs of nearly spherical shape and uniform porosity, then F is equal to 3, the expected magnitude for a Euclidean object. In general, when aggregates of irregular shape are formed from solid primary particles, the magnitude of F can be considerably smaller than 3. Its magnitude decreases as the aggregate structure becomes more open and irregular. Jiang and Logan (1991) observed that aggregates formed by shear (velocity gradient) flocculation had fractal dimensions greater than 2.4 whereas aggregates formed from differential sedimentation (a less energetic mode of interaction) had values in the 1.6 to 2.3 range. According to Elimelech et al. (1995), fractal dimensions in the range 1.6 to 2 are typical for computer model simulation results and model systems.

The exponent S in the relationship between buoyant density and aggregate size is related to the fractal dimension by the equation $F = 3 + S$. According to Eq. 8-48, for the flocs formed by Vold (1966) using computer simulation, $S = -0.7$, and therefore, in this case F is $3 - 0.7 = 2.3$.

$$\rho_f - \rho_w = Bd_f^S \quad (8-49)$$

Floc Density—Significance of Enmeshment by Hydroxide Precipitates. When aluminum and ferric coagulants are used at concentrations in the enmeshment range, the metal hydroxide precipitate can significantly influence the floc volume concentration and buoyant density as well as flocculator performance. This effect is especially significant at low influent primary-particle concentrations. Letterman and Iyer (1985) determined that, for alum and an enmeshment condition, Φ is given by

$$\Phi = \frac{S}{\rho_p} + 120 [Al_p] \quad (8-50)$$

where S is the mass concentration of primary particles of density ρ_p that are enmeshed in the precipitate and $[Al_p]$ is the molar concentration of Al in the precipitate. The coefficient, 120 L/mole Al, was determined by measuring the buoyant density of flocs as a function of the ratio of Al precipitate to primary-particle mass.

For aluminum salt coagulants, the buoyant density of the flocs is determined by the ratio of the primary-particle mass concentration and the alum dosage. An empirical relationship, derived by Letterman and Iyer (1985) using floc-density measurements by Lagvankar and Gemell (1968), is

$$\rho_f - \rho_w = 4.5 \times 10^{-3} \left[1 + \frac{S}{Q} \right]^{0.8} \quad (8-51)$$

where Q is the alum ($Al_2(SO_4)_3 \cdot 18 H_2O$) dosage. Both S and Q are in mg/L and $\rho_f - \rho_w$ is in g/cm^3 . When $S/Q \ll 1$, $\rho_f - \rho_w$ is a minimum and approximately equal to $4.5 \times 10^{-3} g/cm^3$, the buoyant density, in these experiments, of the aluminum hydroxide precipitate. For $S/Q \gg 1$, the flocs' buoyant density is roughly proportional to S/Q , the ratio of floc incorporated primary particles and amount of metal hydroxide precipitate. Since the primary particles in Lagvankar and Gemell's experiments were kaolin clay platelets, Eq. 8-51 pertains only when the primary particles are of this type. There is evidence that the chemical makeup of the solution affects the structure and density of the metal hydroxide precipitate, and this factor must also be considered.

According to Eq. 8-51, the amount of higher-density particulate material that is enmeshed in the lower-density precipitate matrix has a significant effect on the density

of the flocs. Decreasing the amount of coagulant relative to the concentration of particulate matter, (increasing S/Q) increases the density of the flocs. Ballasted flocculation uses fine sand added during the rapid mix to increase the density of the flocs (Ghanem et al., 2007). However, as indicated by Eq. 8-50, reducing the amount of coagulant also reduces the floc volume concentration, and according to Eqs. 8-36 to 8-38, this general reduction can decrease the performance of the flocculator. Of course, as the coagulant concentration becomes less than the amount needed for suspension destabilization and NOM removal, the tendency for particles to aggregate and form flocs will become negligible.

The effect of metal hydroxide precipitate on the performance of a flocculation reactor is especially significant when the influent particle concentration is low. This important relationship is illustrated by the following example.

Example 8-3 Flocculator Performance—Significance of the Metal Hydroxide Precipitate and Enmeshment

Problem Statement Example calculations with the flocculator performance equations described previously show that with low influent particle concentrations addition of a hydrolyzing metal salt coagulant and enmeshment in a metal hydroxide precipitate can significantly enhance aggregation efficiency.

Solution This example assumes that the flocculator is a single compartment. Equations 8-36 to 8-38, 8-50, and 8-51 were used with $C_o = S = 5 \text{ mg/L}$, $G \times t = 1 \times 10^5$, $\rho_p = 2.5 \text{ g/cm}^3$, and $Q = 20 \text{ mg/L}$. For aggregation in the absence of precipitate ($Q = 0$), it was assumed that the flocs have a density of 1.01 g/cm^3 , a reasonable density for particles destabilized with a polyelectrolyte, and Eq. 8-38 was used in place of Eq. 8-50 to calculate Φ .

For a low influent particle concentration ($C_o = S = 5 \text{ mg/L}$), the calculated Φ (Eq. 8-50) for flocs formed in the presence of aluminum hydroxide precipitate is $7.2 \times 10^{-3} \text{ L/L}$ and significantly less, $3 \times 10^{-4} \text{ L/L}$, for flocs formed without a precipitate matrix (Eq. 8-38). Consequently, the fraction of primary particles remaining in the flocculator effluent is 0.005 with Al and significantly higher, 0.10, without Al.

When C_o is increased to 100 mg/L and all other parameters are held constant, the fraction of primary particles remaining is approximately 0.005 for both conditions. The higher influent primary-particle concentration yields a floc volume concentration ($6 \times 10^{-3} \text{ L/L}$) which does not require augmentation with precipitate to obtain a high level of primary-particle aggregation in a simple, single-compartment flocculator. ▲

Effect of Temperature on Coagulation and Flocculation

The temperature of the water can have a significant effect on coagulation and flocculation (Hanson and Cleasby, 1990; Kang and Cleasby, 1995). In general, the rate of floc formation and the efficiency of primary-particle removal decrease as the temperature decreases. The negative effect is greatest with dilute suspensions. As discussed in a previous section, the solubility of $\text{Al}(\text{OH})_3$ decreases (see Fig. 8-19a) and the pH of minimum $\text{Al}(\text{OH})_3$ solubility increases (see Fig. 8-19b) with decreasing temperature. The rate of hydrolysis and metal hydroxide precipitation, and the rate of hydrolysis product dissolution or reequilibration (as in the disappearance of a polynuclear species when the product solution is diluted in the water to be treated) decrease with decreasing temperature. At lower temperatures polynuclear species tend to persist for a longer period of time.

Temperature also alters the distribution of kinetic energy over the scale of fluid motion in a turbulent flow field. Kang and Cleasby (1995) concluded that chemical factors are more significant than fluid motion effects, but Morris and Knocke (1984) presented evidence that physical rather than chemical kinetic factors are behind the effect of temperature on coagulation and flocculation performance. In their work they observed a significant effect of temperature on the size distribution of aluminium hydroxide floc.

Evaluating Coagulant Performance Using Bench-Scale Testing

It is difficult to predict a priori how a coagulant will perform in a given application. Consequently, it is common to use bench-scale testing to evaluate the performance of chemical coagulants. The jar test procedure is the oldest and most widely used method.

The bench-scale jar test procedure typically includes the following general steps:

1. Coagulant solution addition during a short period (typically 1 min in duration) of high-intensity mixing (rapid mixing)
2. A period of low-intensity (relatively low impeller speed) mixing for floc formation
3. A floc separation step
4. Sample withdrawal and measurement of residual quantities (e.g., turbidity, UV_{254} (DOC or TOC), particle count, coagulant cation concentration, etc.) and solution acid/base chemistry (e.g., pH and alkalinity)

The USEPA includes a recommended jar test procedure in their guidance manual on enhanced coagulation and enhanced precipitative softening (USEPA, 1999), as does the AWWA in their Manual of Practice, M37, *Operational Control of Coagulation and Filtration Processes*, third edition (AWWA, 2010). AWWA also supplies a video on jar testing (AWWA, 2009b).

Jar testing is typically done using a multiple batch reactor device called a *jar test apparatus* or *gang stirrer*. A number of these are commercially available. In the typical jar test unit, the mixing impellers all turn at the same rotational speed and it is difficult to add the coagulant and rapid mix for a given period of time and then immediately begin the slow mixing step unless the coagulant solution can be added rapidly and simultaneously to all the containers. In an alternative setup an independent rapid-mix unit is used. Each filled jar test container is put in the rapid-mix unit, and the coagulant solution is added. At the end of the rapid-mix period, the container is immediately transferred to the jar test unit and the low-intensity mixing step commences without delay. In any case, a coagulant-treated jar test container should always move without delay between the rapid- and slow-mixing stages. It should never be set aside to wait for a place in the jar test apparatus. If possible, jar tests should be conducted using water that is the same temperature as the water in the full-scale facility.

A disposable-tip microdispenser capable of adding microliter volumes is a convenient and effective way to add coagulant solution in the rapid-mix step. Jar test results tend to be more consistent and reproducible when the same undiluted commercial strength coagulant solution is used in all the jar test containers. If a significant range of coagulant dosages is to be tested, two or more microdispensers of adjustable capacities (e.g., one with a 1- to 10- μL capacity and one with a 10- to 100- μL capacity) may be needed. The use of laboratory-made stock or commercial coagulant solutions of different concentrations obtained by dilution before addition should be avoided especially with PACl and other prehydrolyzed products because the rate of coagulant solution dispersal and the rate of coagulant cation hydrolysis vary with the volume of solution added and the cation concentration.

A number of floc particle separation steps are used in the jar test procedure depending on the type of system to be simulated. The most common method is sedimentation. The jar test container with flocculated suspension is removed from the slow-mixing apparatus and covered (to minimize the effect of air currents in the room), and the floc particles are allowed to settle in a time period that typically ranges from 15 to 60 min. The residual particles are measured in a quantity of supernatant that has been carefully withdrawn from a certain depth in the container. The approximate sedimentation overflow rate (in $\text{m}^3/\text{m}^2\text{-h}$) for a given settling time S and sampling depth D is equal to D/S . For example, if the sample is withdrawn from a depth of 10 cm (0.1 m) in the jar test container and the settling period is 20 min (0.33 h) the corresponding overflow rate is $(0.1 \text{ m}/0.33 \text{ h}) = 0.3 \text{ m}^3/\text{m}^2\text{-h}$ ($0.12 \text{ gpm}/\text{ft}^2$).

Floc particle separation with filter membranes is sometimes used, either alone or after sedimentation, to obtain a water sample for measuring residuals such as DOC (dissolved organic carbon), UV absorbance (UV_{254}), and coagulant cation concentration (Al(III) or Fe(III)). Membrane filtration, compared to, for example, sedimentation, tends to give results that are in better agreement with those from the full-scale facility, but results should be tested for agreement by a comparison with the full-scale system. Membrane filtration is not an appropriate floc separation technique for a plant that uses sedimentation or flotation.

Manufactured membrane filter units with a membrane enclosed within a plastic housing that attaches to a syringe are convenient. The sample is drawn quickly into the syringe and then immediately forced through the filter unit into the sample container. Care should be used in selecting the effective pore size and material of the membrane because some membranes leach significant amounts of organic carbon. Pore sizes that are too small may lead to rapid clogging that limits the amount of sample filtered.

Dissolved air flotation is also used for floc separation. A bench-scale apparatus that resembles a jar test apparatus is commercially available (ECE, 2009). Water supersaturated with air is mixed with the flocculated suspension in the desired proportions in a jar-test-type container that contains the flocculated suspension, and the clarified water is sampled from the bottom of the jar and used to measure the residuals. Jar test results from studies that used a flotation unit for floc separation have been reported in the literature (e.g., Malley and Edzwald, 1991).

Jar tests do not tell us exactly how the coagulant will perform in the full-scale system. One reason for discrepancies is that even with the same apparent chemical conditions, the pH of the treated water of the jar test is significantly higher than the pH in the full-scale plant because there is more postcoagulation dissolved carbon dioxide in the full-scale system compared to the jar test vessels. This CO_2 difference is typically caused by the higher rate of mass transfer of carbon dioxide from the solution to the atmosphere in the jar test compared to the full-scale system. The interfacial area per volume (which is proportional to the depth of the water) in a 1- or 2-L jar test container is much greater than that of the much deeper and many thousands of liters tank of the full-scale treatment system.

The mixing intensity or G value or G (in s^{-1}) used in a jar test should be as close as possible to conditions in the full-scale system. The magnitude of the G in the jar test apparatus (and in the full-scale system if mixing is provided by a single rotating impeller with a vertical shaft) can be estimated using the following relationship:

$$G = K N^{1.5} \quad (8-52)$$

where N is the rotational speed of the impeller in revolutions per second and K (in $\text{s}^{0.5}$) is given approximately by

$$K = \left(\frac{D^5 k}{Vv} \right)^{0.5} \quad (8-53)$$

where D is the diameter of the impeller, ν is the kinematic viscosity of the water, V is the volume of water in the vessel, and k is a dimensionless constant that varies between 0.1 and about 5 depending on the geometry of the impeller. This equation assumes the vessel is shaped or baffled so that fluid rotation and vortex formation is minimal and that the mixing regime is fully turbulent; that is, the impeller Reynolds number $ND^2/\nu > 1 \times 10^4$.

Example 8-4 Estimating the G Value in a Jar-Test-Type Rotating Impeller Mixing Device

Problem Statement Estimate the G value in a 1-L baffled vessel with a single paddle impeller (8 cm long) rotating at 60 rpm. The temperature of the water is 20°C.

Solution According to Eqs. 8-52 and 8-53 the G value for a 1-L baffled vessel ($V = 1000 \text{ cm}^3$) with a flat paddle impeller ($k = 2$ and $D = 8 \text{ cm}$), rotating at 60 rpm (1 rps) in water with a kinematic viscosity of $1.1 \times 10^{-6} \text{ m}^2/\text{s}$, is given by

$$K = \left[\frac{(0.08^5)(2)}{(0.001)(1.1 \times 10^{-6})} \right]^{0.5} = 77.2 \text{ s}^{0.5} \quad \text{and} \quad G = 77.2 (1)^{1.5} = 77.2 \text{ s}^{-1}$$

The Reynolds number for this case is $DN^2/\nu = 0.08 \text{ m} (1 \text{ s}^{-1})^2 / 1.1 \times 10^{-6} \text{ m}^2/\text{s} = 7.3 \times 10^4$ which is greater than 1×10^4 so the mixing is fully turbulent and Eq. 8-53 tends to apply. ▲

A more thorough discussion of mixing in the flocculation process can be found in the book by MWH (2005).

Monitoring the Particle Aggregation Process

An alternative way of evaluating the performance of coagulants is to measure the physical characteristics of the particle aggregates as they form or are disrupted in the flocculation process. Gregory (2008) prepared a comprehensive review of the instrumental methods available for monitoring the flocculation process. A focus of the review is the turbidity fluctuation technique developed by Gregory and Nelson (1986).

In the turbidity fluctuation technique (Gregory, 2008) a low flow rate of suspension is continuously drawn from the flocculation reactor through a small transparent tube where the particles are illuminated by a narrow light beam. The transmitted light beam (the classical turbidity of the suspension) is directed to a photodiode tube. The output from the photodiode fluctuates as the particles move through the light beam. The fluctuations vary with the number, concentration, and size of the aggregates. The signal is electronically modified so that it varies in a sensitive way with the state of aggregation of the suspension. As aggregation increases the signal increases allowing the flocculation rate and extent to be monitored in a semiquantitative way. The method can be used to compare the performance of coagulants, and by varying the mixing intensity in the flocculation reactor, it can be used to evaluate aggregate strength, that is, the sensitivity of the particle aggregates to disruption by the fluid motion. A typical experimental setup for the turbidity fluctuation method is shown in Fig. 8-24.

In Fig. 8-25 the turbidity fluctuation instrument's output, called the *flocculation index*, is plotted versus time as filtered tap water is dosed with a ferric salt coagulant. The flocculation reactor impeller rotational speed is set at 100 rpm. A 120- to 180-sec lag period occurs after

FIGURE 8-24 Typical experimental set-up for the turbidity fluctuation method for monitoring the floc formation and disruption processes. (Source: Gregory, 2008. Reprinted with permission from Elsevier.)

coagulant addition because the hydrolysis products are initially too small to scatter sufficient light. At about 250 s the flocculation index begins to increase, and by about 700 s it reaches a maximum indicating that the ferric hydroxide flocs have grown to a steady state size distribution. At 900 s the impeller speed is increased to 400 rpm, and the flocculation index decreases and then increases as the aggregates are broken and partially reformed.

FIGURE 8-25 Example results from the turbidity fluctuation method. (Source: Gregory, 2008. Reprinted with permission from Elsevier.)

Electrokinetic Measurements

Electrokinetic measurements are used to monitor the effect of coagulants and changes in solution chemistry on particle surface chemistry and the stability of particle and precipitate suspensions. Two types of electrokinetic measurements, electrophoretic mobility (zeta potential is then calculated and displayed by some instruments) and streaming current are used in water treatment practice to control the addition of coagulants and monitor the conditions that affect coagulant performance. Streaming current is sometimes used to simply trigger an alarm when the coagulant feed stops functioning.

Electrophoretic Mobility Measurements. The engineering literature contains numerous references to the use of electrophoretic mobility (EM) or zeta potential (ZP) measurements as a coagulation process control technique. Many of these papers describe attempts to correlate ranges of EM values or changes in the EM, such as sign reversal, with the efficiency of particle removal by flocculation followed by sedimentation and filtration.

Electrophoresis is an electrokinetic effect and is, therefore, explained by the same fundamental principles as other electrokinetic phenomena such as streaming current (or streaming potential), sedimentation potential, and electro-osmosis. In electrophoresis, particles suspended in a liquid are induced to move by the application of an electric field across the system. This technique has been used by colloid chemists for many years to determine the net electric charge or near-surface (zeta) potential of particles with respect to the bulk of the suspending phase (Hunter, 1981; Anonymous, 2000).

The use of EM measurements as a method to control the application of coagulant chemicals in solid-liquid separation systems has been known for many years. However, while there have been convincing advocates for the use of EM measurements for coagulation process control, inconsistent and difficult-to-interpret results and the time-consuming nature of the EM determination appear to have limited the widespread use of EM measurements in routine treatment plant operation.

A number of different techniques are used to determine particle EM. The most important of these in water treatment applications has been microelectrophoresis. In microelectrophoresis, the suspension is contained in a small-diameter glass or plastic tube that has, in most cases, a round or rectangular cross section. An electric field is applied across the contents of the tube in the axial direction using a stable, constant-voltage power supply and inert (e.g., platinized platinum) electrodes inserted in sealed fluid reservoirs at the end of the tube. When the voltage is applied, the particles tend to migrate in the axial direction. The EM is determined by measuring the average velocity of particle migration and dividing this by the voltage gradient across the cell. Unless special procedures are used, the measured velocity must be corrected for the particle movement caused by electroosmotic flow in the electrophoresis cell.

Streaming Current Measurements. The original *streaming current detector* (SCD) was patented by Gerdes (1966) in 1965 and variants of this device have been used in water treatment plants for coagulant dosage control for a number of years. The electronic output from an SCD has been shown by Dentel and Kingery (1988) to be proportional to the net charge on the surfaces of the particles that have been treated with the coagulant chemical.

The cross section of a widely used type of SCD is shown in Fig. 8-26. The purpose of the sample chamber is to contain the coagulant-treated suspension. Within the chamber is a reciprocating piston that moves vertically inside a cylinder. The movement of the piston causes water to flow inside the annular space between the cylinder and piston and to be pumped through the sample chamber. The streaming current is detected by electrodes attached inside the cylinder.

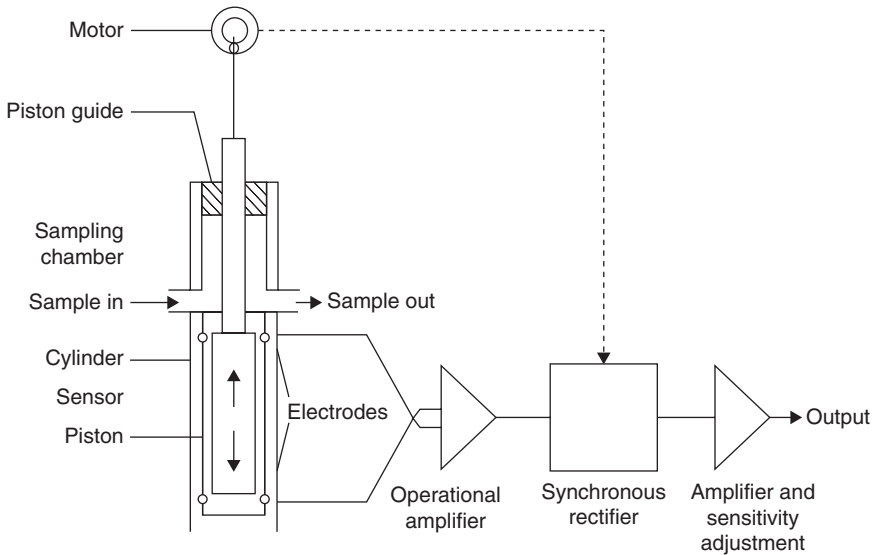

FIGURE 8-26 Cross section of a widely used type of streaming current detector.

The streaming current is determined by the charged particles that attach to the walls of the stationary cylinder and the moving piston. As water flows back and forth cyclically in the annulus, some of the ions in the electrical double layer next to the charged particles are transported with the flow. This displacement of electric charge by the movement of the fluid past the stationary particles creates the sinusoidal current that tends to flow between the electrodes that are in contact with the solution within the cylinder. The magnitude of the current depends on the amount of charge on the attached particles. If the surfaces are not covered by particles, it is also affected to some extent by the charge on the surfaces of the piston and cylinder. The current is amplified, rectified, and time smoothed by circuitry in the instrument. The processed signal is called the *streaming current (SC)*.

Interpreting EM and SC Measurements. The rate of particle interaction for orthokinetic flocculation is determined (approximately) by the product of the collision efficiency factor α and the volume concentration of the suspension Φ (see Eq. 8-27). Theoretical relationships show that α is related to the EM of the particles in the suspension (Anonymous, 2000). As the EM approaches zero, α should approach a maximum value of approximately 1. (This also applies to the SC if the instrument has been adjusted to give $SC \approx 0$ at the dosage that yields $EM = 0$.) As discussed, the magnitude of Φ depends on the volume concentration of the particles and precipitate in the suspension.

EM and SC measurements effectively predict the rate of flocculation when Φ is relatively constant, and the rate is influenced only on the magnitude of α . When the addition of a coagulant, typically a HMS coagulant, affects both α and Φ , the interpretation of EM and SC measurements can be difficult.

The data plotted in Fig. 8-27 were obtained using jar test measurements and a suspension containing 50 mg/L silica and 3×10^{-4} M sulfate. To maintain a constant

FIGURE 8-27 Jar test data showing the effect of the aluminum nitrate dosage on the electrophoretic mobility and residual turbidity after flocculation and sedimentation for 50 mg/L silica, pH = 6, and $[\text{SO}_4^{2-}] = 3 \times 10^{-4}$.

sulfate concentration, the aluminum has been added as AlCl_3 . This figure illustrates an important aspect of hydrolyzing metal coagulants that can make the application of EM measurements for dosage control difficult. Note that between aluminum concentrations of about 10^{-6} and 10^{-5} (0.027 and 0.27 mg Al/L), the residual turbidity is high suggesting that restabilization has occurred. However, as the aluminum concentration is increased beyond 2×10^{-5} M (0.54 mg Al/L), the residual turbidity decreases to values lower than the minimum observed at the point of charge neutralization ($\text{EM} = 0$). The EM measurement remains at +2 and gives no indication that flocculation efficiency should improve with increasing aluminum concentration beyond the point of charge neutralization.

The results presented in Fig. 8-27 can be explained by a consideration of the effect of the aluminum concentration on the rate Φ of flocculation and on the magnitude of the product α . Apparently under the experimental conditions used to obtain the results plotted in Fig. 8-27 and at aluminum concentrations between 10^{-6} (0.027 mg Al/L) and 10^{-5} (0.27 mg Al/L), the magnitude of α and the product $\alpha\Phi$ are not high enough to yield efficient flocculation. However, as the aluminum concentration is increased beyond 10^{-5} (0.27 mg Al/L), the magnitude of Φ increases until the modest value of α is compensated for and efficient flocculation is obtained.

The streaming current measurement has been found to be a useful technique for controlling the HMS coagulant dosage in the removal of NOM. According to Dempsey (1994) the streaming current detector response is sensitive to conditions that lead to effective NOM removal. However, Dentel (1994) has noted that while streaming current appears to have promise, problems may occur with low turbidity, high-NOM-concentration waters, especially at high pH.

ABBREVIATIONS

AHP	aluminum hydrolysis product
ANSI	American National Standards Institute
AWWA	American Water Works Association
CFSTR	continuous-flow stirred tank reactor (tanks in series)
DBP	Disinfection By-Product
DBPR	Disinfection By-Products Rule
DLVO	Derjaguin, Landau, Verwey, Overbeek
DOC	dissolved organic carbon concentration (mg C/L)
EAC	effective acid content (meq/mg M)
EM	electrophoretic mobility
epiDMA	epichlorohydrin dimethylamine
HAA5	haloacetic acid group
HMS	hydrolyzing metal salt
NOM	natural organic matter
NSF	National Sanitation Foundation
ntu	nephelometric turbidity unit
PACl	polyaluminum chloride
PICl	polyiron chloride
PODR	point of diminishing returns
polyDADMAC	polydiallyl dimethylammonium chloride
SC	streaming current
SCD	streaming current detector
SOC	synthetic organic chemical
SUVA	specific ultra-violet light absorbance
TOC	total organic carbon
TTHM	total trihalomethane
USEPA	U.S. Environmental Protection Agency
ZP	zeta potential

EQUATION NOTATION

A	Hamaker constant
B	basicity of hydrolyzing metal salt coagulant solution (%)
C_{eq}	concentration of organic carbon in the solution at equilibrium
C_T	inorganic carbon concentration (moles C/L)
D	sampling depth
d_1, d_2	particle diameters
d_f	floc diameter (circle with equal projected area)

d_o	diameter
du/dz	velocity gradient
F	fractal dimension (or mass fractal dimension)
G	G value or rms velocity gradient
$K_1, K_2, b, a, x_1, x_2, x_3$	constants in organic carbon adsorption equations
k_{ij}, k_o	flocculation rate constants
K_{so}, K_{sp}	solubility constants
K_w	ion product of water
M	aluminum or iron concentration (mg M/L)
M	mass of metal hydroxide precipitate
m_o	mass of particle
n_i, n_j	particle number concentrations
N_{ij}	rate of collision between i - and j -size particles
P	power input
Q	alum dosage
R	coefficient in Eq. 8-12 (mg M/mg C)
S	mass concentration of clay
s	separation distance between interacting particles
TOC_o	total organic carbon in the source water (mg C/L)
V	volume
$\alpha_i, \alpha_{ij}, \alpha_t$	collision efficiencies
$\beta_{x,y}$	formation constants
ε	energy dissipation rate in the fluid
η	microscale of turbulent fluid motion
μ	dynamic viscosity
ν	kinematic viscosity
ρ_f	floc density
$\rho_f - \rho_w$	floc buoyant density
ρ_o	density of particle
ρ_w	density of water
Ψ_A	magnitude of the attractive energy of interaction
Ψ_{\max}	maximum in potential energy of interaction curve
Ψ_R	magnitude of repulsive energy of interaction

General Description	9.47	REFERENCES	9.92

Sedimentation and flotation are the principal solid-water separation (clarification) processes used in water treatment mostly to reduce the particle concentration, or load, on granular filters. As a result, filters can be operated more easily and cost-effectively to produce acceptable-quality filtered water. Many sedimentation and flotation processes and variants of them and other clarification processes exist, including types of filtration (e.g., upflow filtration, moving-bed filtration, buoyant-media filtration, horizontal roughing filters, etc.; see Chap. 10 on filtration), and each has advantages and disadvantages. The theory and application of sedimentation are addressed in the next three sections followed by the theory and application of dissolved air flotation in the next three sections. The most appropriate choice of a sedimentation or flotation process for a particular application depends on the water to be treated as well as local circumstances and requirements, and this is addressed in the last section.

MODERN HISTORY OF SEDIMENTATION

Emergence of Modern Sedimentation Methods

The art of sedimentation progressed little until the industrial age and its increased need for water. Storage reservoirs developed into settling reservoirs. Perhaps the largest reservoirs constructed for this purpose were in the United States at Cincinnati, Ohio, where two excavated reservoirs held approximately 1.48×10^6 m³ (390 million gal) and were designed to be operated by a fill-and-draw method though they never were used in this way (Ellms, 1928). The development of settling basins led to the construction of rectangular masonry settling tanks that assured more even flow distribution and easier sludge removal. With the introduction of coagulation and its production of voluminous sludge, mechanical sludge removal was introduced.

Attempts to make rectangular tanks more cost effective led to the construction of multi-layer tanks. Large-diameter, 60 m (200 ft), circular tanks also were constructed at an early stage in the development of modern water treatment. Other applications and industries, such as wastewater treatment, mineral processing, sugar refining, and water softening, required forms of sedimentation with specific characteristics, and various designs of settling tanks particular to certain applications were developed. Subsequently, wider application of successful industrial designs was sought. Out of this emerged circular radial-flow tanks and a variety of proprietary designs of solids-contact units with mechanical equipment for pre-mixing and recirculation.

The inclined plate settler also has industrial origins (Barham et al., 1956), although the theory of inclined settling dates back to experiments using blood in the 1920s and 1930s (Nakamura and Kuroda, 1937; Kinoshita, 1949). Closely spaced inclined plate systems for water treatment have their origins in Sweden in the 1950s, resulting from a search for high-rate treatment processes compact enough to be economically housed against winter weather. Inclined tube systems were spawned in the United States in the 1960s. The most recent developments have involved combining inclined settling with ballasting of floc to reduce plant footprint further (de Dianous et al., 1990).

Floc Blanket Sedimentation and Other Innovations

The floc blanket process for water treatment emerged from India in about 1932 as the simple inverted-pyramidal Candy sedimentation tank. Imhoff used a tank of similar shape in 1906 for wastewater treatment (Kalbskopf, 1970). The Spaulding Precipitator (with its

FIGURE 9-1 The flat-bottom clarifier with candelabra flow distribution. (Source: PWT.)

annular trough settlement zone surrounding a central mixing and flow distribution chamber) soon followed in 1935 (Hartung, 1951). Other designs that were mainly solids-contact clarifiers (i.e., high concentration of solids in suspension but not usually forming a distinct fluidized bed—further explanation in the sections Sedimentation Theory and Operational and Design Considerations for Sedimentation) rather than true floc blanket tanks (i.e., with a fluidized bed of floc) were also introduced.

The Candy tank can be expensive to construct because of its large sloping sides, so less costly structures for accommodating floc blankets were conceived. The aim was to decrease the hopper component of tanks as much as possible yet provide good flow distribution to produce a stable floc blanket. Development from 1945 progressed from tanks with multiple hoppers or troughs to the present flat-bottom tanks. Efficient flow distribution in flat-bottom tanks is achieved with either candelabra or lateral inlet distribution systems (Figs. 9-1 and 9-2).

An innovation in the 1970s was the inclusion of widely spaced inclined plates in the floc blanket region (Fig. 9-2). Other developments that also have led to increased surface loadings include the use of polyelectrolytes, ballasting of floc with disposable or recycled solids, and improvements in blanket-level control. The principal centers for these developments have been in the United Kingdom, France, and Hungary.

SEDIMENTATION THEORY

The particle water separation processes of interest to water engineers and scientists are difficult to describe by a theoretical analysis, mainly because the particles involved are not regular in shape, density, or size. Consideration of the theory of ideal systems is, however, a useful guide to interpreting observed behavior in more complex cases.

FIGURE 9-2 The Superpulsator flat-bottom clarifier with lateral-flow distribution. (Courtesy of Infilco Degremont, Inc., Richmond, Va.)

The various regimes in settling of particles are commonly referred to as Types 1 to 4. The general term *settling* is used to describe all types of particles falling through water under the force of gravity and settling phenomena in which the particles or aggregates are suspended by hydrodynamic forces only. When particles or aggregates rest on one another, the term *subsidence* applies. The following definitions of the settling regimes are commonly used in the United States and are compatible with a comprehensive analysis of hindered settling and flux theory:

Type 1: Settling of discrete particles in low concentration (less than about 1 percent on a volume concentration basis), with flocculation and other interparticle effects being negligible.

Type 2: Settling of particles in low concentration (less than about 8 percent) but with coalescence or flocculation. As coalescence occurs, particle sizes increase and particles settle more rapidly.

Type 3: Hindered or zone settling in which particle concentration (more than about 8 percent) causes interparticle effects, which might include flocculation, to the extent that the rate of settling is a function of solids concentration. Zones of different concentrations may develop from segregation of particles with different settling velocities. Two regimes exist, (a) and (b), with the concentration being less and greater than that at maximum flux, respectively. In the latter case the concentration has reached the point that most particles make regular physical contact with adjacent particles and effectively form a loose structure. As the height of this zone develops, this structure tends to form layers of different concentration, with the lower layers establishing permanent physical contact, until a state of compression is reached in the bottom layer.

Type 4: Compression settling or subsidence develops under the layers of zone settling. The rate of compression is dependent on time and the force caused by the weight of solids above.

Settling of Discrete Particles (Type 1)

Terminal Settling Velocity. When the concentration of particles is very small, each particle settles discretely, as if it is alone, unhindered by the presence of other particles. Starting from rest, the velocity of a single particle settling under gravity in water will increase where the density of the particle is greater than the density of the water. Acceleration continues until the resistance to flow through the water, or drag, equals the effective weight of the particle. Thereafter the settling velocity remains essentially constant. This velocity is called the *terminal settling velocity*, v_t . The terminal settling velocity depends on various factors relating to the particle and the water.

For most theoretical and practical computations of settling velocities, the shape of particles is assumed to be spherical. The size of particles that are not spherical can be expressed in terms of a sphere of equivalent volume. The general equation for the terminal settling velocity of a single particle is derived by equating the forces on the particle. These forces are the drag f_d , buoyancy f_b , and gravity f_g . Hence,

$$f_d = f_g - f_b \quad (9-1)$$

The drag force on a particle traveling in a resistant fluid is (Prandtl and Tietjens, 1957)

$$f_d = \frac{C_D v^2 \rho A}{2} \quad (9-2)$$

where C_D = drag coefficient, v = settling velocity, ρ = mass density of water, and A = projected area of particle in direction of flow. Any consistent dimensionally homogeneous units may be used in Eq. 9-2 and all subsequent rational equations.

At constant, that is, terminal, settling velocity v_t ,

$$f_g - f_b = Vg(\rho_p - \rho) \quad (9-3)$$

where V is the effective volume of the particle and ρ_p is the density of the particle. When Eqs. 9-2 and 9-3 are substituted in Eq. 9-1,

$$\frac{C_D v_t^2 \rho A}{2} = Vg(\rho_p - \rho) \quad (9-4a)$$

Rearranging, we get

$$v_t = \left[\frac{2g(\rho_p - \rho)V}{C_D \rho A} \right]^{1/2} \quad (9.4b)$$

When the particle is solid and spherical (d is the diameter of the sphere),

$$v_t = \left[\frac{4g(\rho_p - \rho)d^3}{3C_D \rho} \right]^{1/2} \quad (9-5)$$

The value of v_t is the difference in velocity between the particle and the water and is essentially independent of horizontal or vertical movement of the water, although in real situations there are secondary forces caused by velocity gradients and other factors. Therefore, the relationship also applies to a dense stationary particle with water flowing upward past it or a buoyant particle with water flowing downward.

Calculation of v_t for a given system is difficult because the drag coefficient C_D depends on the nature of the flow around the particle. This relationship can be described using the

FIGURE 9-3 Variation of drag coefficient, C_D , with Reynolds Number, Re , for single-particle sedimentation.

Reynolds number Re (based on particle diameter), as illustrated schematically in Fig. 9-3, where

$$Re = \frac{\rho v d}{\mu} \tag{9-6}$$

μ is the absolute (dynamic) water viscosity, and v is the velocity of the particle relative to the water.

The value of C_D decreases as the value of Re increases, but at a rate depending on the value of Re . In Region (a) in Fig. 9-3 of small Re value, $10^{-4} < Re < 0.2$, the laminar flow region, the equation of the relationship approximates to

$$C_D = \frac{24}{Re} \tag{9-7}$$

This when substituted in Eq. 9-1 gives Stokes' settling velocity equation for laminar flow conditions

$$v_t = \frac{g(\rho_p - \rho)d^2}{18\mu} \tag{9-8}$$

For Region (b), $0.2 < Re < 500$ to 1000 , classically for water treatment, the Fair and Geyer equation is promoted (Fair et al., 1971).

$$C_D = \frac{24}{Re} + \frac{3}{\sqrt{Re}} + 0.34 \tag{9-9}$$

Region (c), $500 < 1000 < Re < 2 \times 10^5$, is one of turbulent flow. The value of C_D is almost constant at 0.44, such that substitution of this into Eq. 9-5 results in Newton's equation

$$v_t = 1.74 \left[\frac{(\rho_p - \rho)gd}{\rho} \right]^{1/2} \tag{9-10}$$

In Region (d), $Re < 2 \times 10^5$, the drag force decreases considerably with the development of turbulent flow at the surface of the particle, such that C_D becomes equal to 0.10. This region is unlikely to be encountered in sedimentation in water treatment.

However, Brown and Lawler (2003) have challenged the acceptance of dividing the relationship for spheres into four zones according to Re value and in particular the use of the Fair and Geyer equation. They noted that the Fair and Geyer equation was the least accurate of those they reviewed. They found, from pooling all published data on settlement of spheres relevant to Regions (a), (b), and (c) and accounting for wall effects, that a single equation can represent the data accurately. They recommended for $Re < 2 \times 10^5$, the use of

$$C_D = \frac{24}{Re} (1 + 0.150Re^{0.681}) + \frac{0.407}{1 + 8,710/Re} \quad (9-11)$$

Brown and Lawler (2003) also developed equations to determine the terminal settling velocities of spheres. They recommended that for $Re < 5000$ use of

$$v_{ts} = \frac{d_*^3 (22.5 + d_*^{2.046})}{0.0258d_*^{4.046} + 2.81d_*^{3.046} + 118d_*^{2.046} + 405} \quad (9-12)$$

where the subscript ‘*’ denotes dimensionlessness, such that in dimensionless terms the Stokes’ settling velocity (Eq. 9-8) is given by

$$v_{ts} = \frac{d_*^2}{18} \quad (9-13)$$

For $Re < 2 \times 10^5$, Brown and Lawler also recommended for general use:

$$v_{ts} = \left[\left(\frac{18}{d_*^2} \right)^{[(0.936d_*+1)/(d_*+1)] \cdot 0.898} + \left(\frac{0.317}{d_*} \right)^{0.449} \right]^{-1.114} \quad (9-14)$$

Effect of Particle Shape. Equation 9-4b shows how particle shape affects velocity. The effect of a non-spherical shape is to increase the value of C_D at a given value of Re. As a result, the settling velocity of a non-spherical particle is less than that of a sphere having the same volume and density. Sometimes a simple shape factor (Θ) is determined and incorporated into Eq. 9-7; this yields:

$$C_D = \frac{24\Theta}{Re} \quad (9-15)$$

Typical values found for Θ for rigid particles are sand 2.0, coal 2.25, gypsum 4.0, and graphite flakes 22 (Degremont, 1991). Details on the settling behavior of spheres and non-spherical particles can be found in standard texts (e.g., Richardson and Harker, 2002).

Flocculation. A shape factor value is difficult to determine for floc particles because their size and shape are interlinked with the mechanics of their formation and disruption in any set of flow conditions. When particles flocculate, a loose and irregular structure is formed, which is likely to have a relatively large-value shape factor. Additionally, while the effective particle size increases in flocculation, the effective particle density decreases in accordance with a fractal dimension (Lagvankar and Gemmel, 1968; Tambo and Watanabe, 1979; Bache and Gregory, 2007; also see Chap. 8 on flocculation).

Flocculation is a process of aggregation and attrition. Aggregation can occur by Brownian diffusion, differential settling, and velocity gradients caused by fluid shear. Attrition is caused mainly by excessive velocity gradients (see Chap. 8).

The theory of flocculation detailed in Chap. 8 recognizes the role of particle stability (attractive and repulsive forces between particles), velocity gradient G , and time t , as well as particle volumetric concentration Φ . For dilute suspensions optimum flocculation conditions are generally considered only in terms of G and t where

$$Gt = \text{constant} \quad (9-16)$$

Camp (1955) identified optimum Gt values between 10^4 and 10^5 for flocculation prior to conventional horizontal-flow settlers. In the case of floc blanket clarifiers (there being no prior flocculators), the value of G is usually less than in flocculators and the value of Gt is about 20,000 (Gregory, 1979). This tends to be less than that usually considered necessary for flocculation prior to inclined settling or dissolved air flotation, but appropriate for direct (contact) filtration (Bache and Gregory, 2007). Recently this has become considered adequate for high-rate DAF (see the section Operational and Design Considerations for Flotation).

In concentrated suspensions, such as with hindered settling, the greater particle concentration, for example, volumetric concentration Φ , contributes to flocculation by enhancing the probability of particle collisions and increasing the velocity gradient that can be expressed in terms of the head loss across the suspension. Consequently, optimum flocculation conditions for concentrated suspensions may be better represented by (Fair et al., 1971; Ives, 1968; Vostreil, 1971)

$$Gt\Phi = \text{constant} \quad (9-17)$$

The value of the constant at maximum flux is likely to be about 4000, when Φ is measured as the fractional volume occupied by floc, with little benefit to be gained from a larger value (Gregory, 1979; Vostreil, 1971).

Measurement of the volumetric concentration of floc particle suspensions is a problem because of variations in particle size, shape, and other factors. A simple settlement test is the easiest method of producing a measurement (for concentrations encountered in floc blanket settling) in a standard way, for example, half-hour settlement in a graduated cylinder (Gregory, 1979). A graduated cylinder (e.g., 100 mL or 1 L) is filled to the top mark with the suspension to be measured. The half-hour settled-solids volume is the volume occupied by the settled suspension measured after 30 min, and it is expressed as a fraction of the total volume of the whole sample.

The process of flocculation continues during conditions intended to allow settlement. Assuming collision between flocculant particles takes place only between particles settling at different Stokes' velocities, then the flocculation rate constant k_d between spherical particles of size d_i and d_j and same specific gravity s is given in Chap. 8 and shown next.

$$k_d = \frac{\pi g \rho (s-1)}{72 \mu} (d_i + d_j)^3 (d_i - d_j) \quad (9-18)$$

Practical application of Eq. 9-18 and the Stokes' velocity, Eq. 9-8 or similar, is complicated because as floc size increases, its density decreases (Lagvanker and Gemmel, 1968; Tambo and Watanabe, 1979; see Fig. 9-4). The density difference ($\Delta\rho = \rho_f - \rho_w$) between floc and water is the same as the density term in Stokes' equation (Eq. 9-8). The relationship between floc size and density means that although Stokes' velocity is proportional to the square of floc size, the decrease in density reduces the effect of increasing size. It is relevant to note that floc strength also decreases as size increases. These are key characteristics

of floc agglomerates, that is, multifractal structures (Bache and Gregory, 2007). A practical implication is that flocculation prior to sedimentation has diminishing return on the size and increase in rate of settlement of the floc that will be produced, notwithstanding the need to ensure the flocculation results in a narrow particle size range and hence settling velocity distribution. Table 9-1 has been prepared to illustrate the interaction between particle size and density at 4°C. It also illustrates the benefit of seeking to increase particle size without loss of particle density.

Settlement in Tanks. In an ideal upflow settling tank the particles retained are those whose terminal settling velocity exceeds the water upflow velocity.

$$v_t \geq \frac{Q}{A} \tag{9-19}$$

where Q is the inlet flow rate to the tank and A is the horizontal cross-sectional, or plan, area of the tank.

In a horizontal-flow rectangular tank, the settling of a particle has both vertical and horizontal components, as shown in Fig. 9-5.

$$L = \frac{tQ}{HW} \tag{9-20}$$

TABLE 9-1 Stokes' Settling Velocity at 4°C in Water: Values in Shaded Boxes Computed from Newton's Equation because $Re > 0.2$ for Stokes' Velocity

Particle density, kg/m ³	Terminal settling velocity, m/h				
	Particle size, mm				
	0.1	0.2	0.5	1.0	2.0

FIGURE 9-4 Example of size-density function for alumino-humic flocs strengthened by polymer addition (density in kg/m³ is obtained by multiplying g/cm³ by 1000). (Source: Bache and Gregory (2007), reprinted with permission from IWA Publishing, Copyright 2007, United Kingdom.)

FIGURE 9-5 Horizontal and vertical components of settling velocity.

where L = horizontal distance traveled, t = time of travel, H = depth of water, and W = width of tank. When h = the vertical distance traveled, the settling time for a particle that has entered the tank at a given level h is

$$t = \frac{h}{v} \tag{9-21}$$

Substitution of this in Eq. 9-20 gives the length of tank required for settlement to occur under ideal flow conditions.

$$L = \frac{hQ}{vHW} \tag{9-22a}$$

or

$$v = \frac{hQ}{HLW} \tag{9-22b}$$

If all particles with a settling velocity of v are allowed to settle, then h equals H , and consequently this special case then defines the surface loading or overflow rate v^* of the ideal tank.

$$v^* = \frac{Q}{L^*W} \tag{9-23a}$$

$$v^* = \frac{Q}{A^*} \tag{9-23b}$$

where L^* is the length of tank over which settlement ideally takes place and A^* is the plan area of tank, with horizontal flow, over which the settlement ideally takes place.

All particles with a settling velocity greater than v^* are removed. Particles with a settling velocity v' less than v^* need a tank of length L' greater than L^* for total settlement, such that

$$\frac{v'}{v^*} = \frac{L'}{L^*} \tag{9-24}$$

This ratio defines the proportion of particles with a settling velocity of v' that settle in a length L' .

Equation 9-23b shows that settling efficiency for the ideal condition is independent of depth H and dependent on only the tank plan area. This principle is sometimes referred to as *Hazen's law*. In contrast, detention time t is dependent on water depth H , as given by

$$t = \frac{AH}{Q} \quad (9-25)$$

In reality, depth is important because it can affect flow stability if it is large and scouring if it is small.

Predicting Settling Efficiency (Types 1 and 2). For discrete particle settling (Type 1), variation in particle size and density produce a distribution of settling velocities. The settling-velocity distribution may be determined from data collected from a column-settling test. These data are used to plot a settling-velocity analysis curve, and Eq. 9-26 defines the proportion of particles with settling velocity v smaller than v^* , that will be removed in a given time. If x^* is the proportion of particles having settling velocities less than or equal to v^* , the total proportion of particles which could be removed in settling is defined by (Thirumurthi, 1969)

$$F_t = (1 - x^*) + \int_0^{x^*} \frac{v}{v^*} dx \quad (9-26)$$

The settling column test is very rarely used in evaluations for water treatment although may apply to waste suspensions, or possibly preliminary settlement of highly turbid raw waters: It generally applies to concentrated suspensions of unflocculated solids, although it can also be used for flocculated suspensions (Type 2) (Zanoni and Blomquist, 1975).

Hindered Settling (Types 3a and 3b)

The following addresses Type 3 settling relevant to clarification. Types 3 and 4 settling as relevant to thickening are addressed in Chap. 22.

Particle Interaction. When particle volume concentration is greater than about 1 percent, individual particle behavior is influenced, or hindered, by the presence of other particles, and the flow characteristics of the bulk suspension can be affected. With increased particle concentration, the free area between particles is reduced; this causes greater interparticle fluid velocities and alteration of flow patterns around particles. Consequently, the average settling velocity of the particles in a concentrated suspension, especially when particle volume concentration is greater than about 8 percent, is generally less than that of a discrete particle of similar size.

When particles in a suspension are not uniform in size, shape, or density, individual particles will have different settling velocities. Particles with a settling velocity less than the suspension increase the effective viscosity. Smaller particles tend to be dragged down by the motion of larger particles. Flocculation may increase the effective particle size when particles are close together (i.e., flocculation due to differential settling, Eq. 9-18).

Solids Flux. The settling velocity v_s of a suspension depends on the suspension particle concentration. The product of velocity and mass concentration C is the solids mass flux F_M , the mass of solids passing a unit area per unit of time.

$$F_M = v_s C \quad (9-27a)$$

The equivalent relationship holds for the solids volumetric concentration Φ to define solids volume flux F_V .

$$F_V = v_s \Phi \quad (9-27b)$$

The relationship between F_M and C (or F_V and Φ) is shown in Fig. 9-6 and is complex because v_s is affected by concentration. The relationship can be divided into four regions.

FIGURE 9-6 Typical relationship between flux and concentration for batch settlement.

Region (a), Type 1 and 2 settling. Unhindered settling occurs such that the flux increases in proportion to the concentration. A suspension of particles with different settling velocities has a diffuse interface with the clear water above.

Region (b), Type 3a settling. With increase in concentration, hindered flow settling increasingly takes effect, and ultimately a maximum value of flux is reached. At about maximum flux the diffuse interface of the suspension becomes distinct with the clear water above when all particles become part of the suspension and settle with the same velocity.

Region (c), Type 3b settling. Further increase in concentration reduces flux because of the reduction in settling velocity. In this region the suspension settles homogeneously.

Region (d), Type 4 settling. Associated with the point of inflection in the flux concentration curve, the concentration reaches the point where thickening can be regarded to start leading ultimately to compression settling.

Equations for Hindered Settling. The behavior of suspensions in Regions (b) and (c) has attracted considerable theoretical and empirical analysis and is most important in understanding floc blanket clarification. The simplest and most convenient relationship is represented by the general equation (Gregory, 1979).

$$v_s = v_0 \exp(-q\Phi) \quad (9-28)$$

where q = constant representative of the suspension, v_o = settling velocity of suspension for concentration extrapolated to zero, and Φ = volume concentration of the suspension.

Other empirical relationships have been proposed. The most widely accepted and tested relationship was initially developed for particles larger than 0.1-mm diameter in rigid particle fluidized systems. This relationship has been shown to be applicable to settling and is known as the *Richardson and Zaki equation* (Richardson and Harker, 2002).

$$v_s = v_t E^n \quad (9-29)$$

where E = porosity of the suspension (i.e., volume of fluid per volume of suspension, $E = 1 - \Phi$), n = power value dependent on the Reynolds number of the particle, and v_t = terminal settling velocity of particles in unhindered flow (i.e., absence of effect by presence of other particles).

For rigid particles this equation is valid for porosity from about 0.6 (occurring at around minimum fluidization velocity) to about 0.95. The Reynolds number determines the value of n (Richardson and Harker, 2002). For a suspension with uniform-size spherical particles, n equals 4.8 when Re is less than 0.2. As the value of Re increases, n decreases until Re is greater than 500 when n equals 2.4.

When Eq. 9-29 is used for flocculent suspensions (Gregory, 1979), correction factors must be included to adjust for effective volume to account for particle distortion and compression. If particle volume concentration is measured, say, by the half-hour settlement test, then because such a test is only a relative measurement that provides a measure of the apparent concentration, correction factors are necessary.

$$v_s = v_t k_1 (1 - k_2 \Phi^*)^r \quad (9-30)$$

where k_1 , k_2 = constants representative of the system, Φ^* = apparent solids volumetric concentration, and r = power value dependent on the system.

Equation 9-29 can be substituted in Eq. 9-27b for flux with $1 - E$ substituted for Φ (Richardson and Harker, 2002).

$$F_v = v_t E^n (1 - E) \quad (9-31)$$

Differentiating this equation with respect to E gives

$$\frac{dF_v}{dE} = v_t n E^{n-1} - v_t (n+1) E^n \quad (9-32)$$

The flux F_v has a maximum value when dF_v/dE equals zero and E equals E^+ (the porosity at maximum flux). Hence, dividing Eq. 9-32 by $v_t E^{n-1}$ and equating to zero leads to

$$n = \frac{E^+}{1 - E^+} \quad (9-33a)$$

which can be restated as

$$\Phi^+ = \frac{1}{1+n} \quad (9-33b)$$

This means that the porosity E^+ or the volume concentration Φ^+ at maximum flux is an important parameter in describing the settling rates of suspensions. In the case of rigid uniform spheres if n ranges from 2.4 to 4.6, the maximum flux should occur at a volumetric concentration between 0.29 and 0.18. In practice, the range of values generally found for suspensions of aluminum and iron flocs for optimal coagulant dose and coagulation pH, when concentration is measured as the half-hour settled volume, is 0.16 to 0.20 (Gregory, 1979;

Gregory et al., 1996), in which case n ranges from 4.0 to 5.26, reflecting the existence of low Re values.

If Eq. 9-32 is differentiated also, then when $d^2F_v/dE^2 = 0$ for real values of E , a point of inflection will exist, such that

$$E^{++} = \frac{n-1}{n+1} \quad (9-34a)$$

which can be restated as

$$\Phi^{++} = \frac{2}{n+1} \quad (9-34b)$$

This means theoretically that the concentration at the inflection point is twice that at maximum flux. In practice because of the forces on floc as concentration increases, this ratio of 2 is unlikely to apply and the ratio will be less. If the point of inflection is associated with the transition from Type 3 to Type 4 settling, then Eqs. 9-33 and 9-34 provide a basis for characterizing floc with respect to thickening. Types 3 and 4 settling in the context of thickening are considered in Chap. 22.

Prediction of Settling Rate. The hindered settling rate can be predicted for suspensions of rigid and uniform spheres using Eqs. 9-5 and 9-29. For suspensions of non-uniform and flocculent particles, however, settling rate has to be measured. This is most simply done using a settling column; a 1-L measuring cylinder is usually adequate. The procedure is to fill the cylinder to the top measuring mark with the sample and record at frequent intervals the level of the interface between the suspension and the clear-water zone. The interface is only likely to be distinct enough for this purpose if the concentration of the sample is greater than that at maximum flux. The results are plotted to produce the typical settling curve (Fig. 9-7). The slope of the curve over the constant-settling-rate period is the estimate of the Type 3 settling rate for quiescent conditions. If the concentration of the sample was greater than that at the inflection point in the mass flux curve, the transition from Region (c) to (d) in Fig. 9-7, then a period of constant settling rate and the compression point (CP) will not be found as represented by line A.

The compression point signifies the point at which all the suspension has passed into the Type 4 settling or compression regime. Up to that time a zone of solids in the compression regime has been accumulating at the bottom of the suspension with its upper interface moving upward. The compression point thus is where that interface reaches the top of the settling suspension.

Fluidization

When water is moving up through a uniform stationary bed of particles at a low flow rate, the flow behavior is similar to when the flow is down through the bed. When the upward flow of water is great enough to cause a drag force on particles equal to the apparent weight (actual weight less buoyancy) of the particles, the particles rearrange to offer less resistance to flow and bed expansion occurs. This process continues as the water velocity is increased until the bed has assumed the least stable form of packing. If the upward water velocity is increased further, individual particles separate from one another and become freely supported in the water. The bed is then said to be *fluidized*.

For rigid and generally uniform particles, such as filter sand, about 10 percent bed expansion occurs before fluidization commences. The less uniform the size and density of the particles, the less distinct is the point of fluidization. A fluidized bed is characterized

- A Concentrated, flocculated or unflocculated pulp
- B Intermediate flocculated or unflocculated pulp
- C As (B) but showing no induction period
- D Dilute, flocculated pulp
- E Dilute, unflocculated pulp
- C.P. Compression point

FIGURE 9-7 Typical batch-settling curves. (Source: Pearse, 1977.)

by regular expansion of the bed as water velocity increases from the minimum fluidization velocity until particles are in unhindered suspension, that is, Type 1 settling.

Fluidization is hydrodynamically similar to hindered, or Type 3, settling. In a fluidized bed particles undergo no net movement and are maintained in suspension by the upward flow of the water. In hindered settling, particles move downward, and in the simple case of batch settling, no net flow of water occurs. The Richardson and Zaki equation (Eq. 9-29) has been found to be applicable to both fluidization and hindered settling (Richardson and Harker, 2002), as have other relationships.

In water treatment, floc blanket clarification is more a fluidized bed than a hindered settling process. Extensive floc blanket data (Gregory, 1979) with Φ^* determined as the half-hour settled-solids volume, such that Φ^+ tended to be in the range 0.16 to 0.20, allowed Eq. 9-30 to be simplified to

$$v_s = v_o(1 - 2.5\Phi^*) \tag{9-35}$$

The data that allowed this simplification were obtained with alum coagulation (optimal coagulant dose and coagulation pH) of a high-alkalinity, organic-rich river water, but the value for k_2 (in Eq. 9-30) for other types of water producing similar-quality floc should be similar. The value of k_2 can be estimated as the ratio of the concentration at the compression point to the half-hour settled concentration. Values predicted for v_o by Eq. 9-35 are less, about one-half to one-third, than those likely to be estimated by Stokes' equation for v_s , assuming spherical particles (Gregory, 1979).

The theory of hindered settling and fluidization of particles of mixed sizes and different densities is more complex and is still being developed. In some situations two or more phases can occur at a given velocity, each phase with a different concentration. This has been observed with floc blankets to the extent that an early but temporary deterioration in performance occurs with increase in upflow (Gregory and Hyde, 1975; Setterfield, 1983, Fig. 9-8). An increase in upflow leads to intermixing of the phases with further increase in

Comparison of performance of clarifiers in summer

- Square hopper (No. 8) 1 m/h = 2.40 tcmd = 0.58 mgd
- Circular hopper (No. 2) 1 m/h = 1.88 tcmd = 0.41 mgd
- - - Square flat (No. 4) 1 m/h = 2.40 tcmd = 0.528 mgd

Comparison of clarifiers in winter

FIGURE 9-8 Floc-blanket performance curves showing “temporary” deterioration in settled water quality. (Source: Setterfield, 1983.)

upflow limited by the characteristics of the combined phase. The theory has been used to explain and predict the occurrence of intermixing and segregation in multimedia filter beds during and after backwash (Patwardan and Chi, 1985; Epstein and LeClair, 1985).

Example 9-1 Floc Blanket Sedimentation

Predict the maximum volume flux conditions for floc blanket sedimentation.

Solution For a floc blanket that can be operated over a range of upflow rates, collect samples of blanket at different upflow rates. For these samples measure the half-hour settled volume. Example results are listed here.

Upflow rate, m/h	1.6	1.95	2.5	3.05	3.65	4.2	4.7	5.15
Half-hour floc volume, %	31	29	25	22	19	16	13	10
Blanket flux = upflow rate x Half-hour floc volume, %m/h	49.6	56.6	62.5	67.1	69.4	67.2	61.1	51.5

These results predict that maximum flux occurs at an upflow rate of 3.7 m/h. If flux is plotted against upflow rate and against half-hour floc volume, then the maximum flux is located at 3.4 m/h for a half-hour floc volume of 20 percent, as shown in Fig. 9-9. The above results can be fitted to Eq. 9-35.

$$v_s = v_o(1 - 2.5\Phi^*)$$

$$3.44 = v_o(1 - 2.5 \times 0.2)$$

$$v_o = 3.44/0.5 = 6.9 \text{ m/h}$$

This means that at the maximum flux the theoretical terminal settling velocity of the blanket is 6.9 m/h. The maximum operating rate for a floc blanket in a stable tank is about 70 percent of this rate (Gregory, 1979), or 4.8 m/h. ▲

Clarifiers as Collectors. Bache and Gregory (2007) regard flocculators, floc blanket clarifiers, DAF, and filters as having much in common, in that in each case the incoming stream of flocs encounters an array of *collectors*. In clarifiers, like flocculators, the collectors are a quasi-stationary distribution of flocs, the collection process coming under the heading of contact flocculation as described in Tambo and Hozumi (1979). The rate of loss of particles from the incoming stream depends on the flux of particles past a collector, the single collector collision efficiency (η_{pc}) and the attachment efficiency (α_{pc}). Schematically, the loss of concentration of incoming particles in passing through an absorbing layer of collectors can be represented by

$$\frac{dn_p}{dt} = -\alpha_{pc} \eta_{pc} k n_p n_c \quad (9-36)$$

where n_p is the number of incoming particles/flocs per unit volume, n_c the number of collectors per unit volume, and k a transport coefficient with units (m^3s^{-1}). The mass transfer rate constant depends on the prevailing transport mechanism, for example, diffusion, turbulent transfer, sedimentation, or local stream flow. When particles, or floc, are larger than about $1 \mu\text{m}$, k increases with size, in a manner depending on the transfer mechanism. The collision efficiency depends on both relative sizes of particles involved, but tends to follow the trend to be shown for a single collector in the section Fundamentals

FIGURE 9-9 Relationship between blanket flux, blanket concentration, and upflow rate for Example 9-1.

of Dissolved Air Flotation (see the contact zone efficiency versus particle size figure). Bache and Gregory (2007) identify that removal efficiency increases with particle size, concentration of collectors, and the attachment efficiency. Therefore, clarification (sedimentation and flotation) should be enhanced by practices that lead to an increase of these, including optimization of coagulant dose, coagulation pH, polyelectrolyte dose, choice of chemicals, their preparation, manner of dosing and order of dosing, and flocculation and floc stressing (breakup conditions) before and after entry to the process.

Amirtharajah and O'Melia (1990) considered that when a blanket behaves as a turbulent reactor, the effluent concentration of microflocs can be estimated by (Bache and Gregory, 2007)

$$\frac{n}{n_0} = \exp \left[-\frac{\alpha G \Phi_F t_L}{\pi} \right] \tag{9-37}$$

where n_0 is the number concentration of microflocs entering the base of the blanket, α the trapping efficiency, and t_L the water retention time. The equation shows that effluent concentration is reduced by increasing the value of $\alpha G \Phi_F t_L$. It can be shown (Bache and Gregory, 2007) that particle attenuation is steered by the dependence

$$G \Phi_F t_L \propto \Phi_F^{3/2} (1 - \Phi_F)^{1/2} (1 - k \Phi_F)^{r/2} \tag{9-38}$$

where r is defined by Eq. 9-30. This relationship (which is nominally valid for $0.1 < \Phi_F < 0.25$) highlights the dependence of floc blanket performance on blanket floc concentration (floc volume fraction) Φ_F .

Example 9-2 Floc Volume Fraction

With reference to Eq. 9-38, at what value of Φ_F is $G \Phi_F t_L$ a maximum (and n/n_0 is minimum), when $v_0 = 3.5$ m/h, $k = 2.9$, and $r = 1.16$, for which maximum flux occurs when $\Phi_F = 0.16$ (see Bache and Gregory, 2007)?

Solution Calculate the value of each term for $0.9 \geq \Phi_F \geq 0.27$ and determine their products $F(\Phi_F)$.

Φ_F	0.9	0.11	0.13	0.15	0.17	0.19	0.21	0.23	0.25	0.27
$F(\Phi_F)$	0.022	0.029	0.035	0.040	0.046	0.050	0.053	0.055	0.055	0.054

This shows that $F(\Phi_F)$ (i.e., $G \Phi_F t_L$) has a maximum value, not when maximum flux occurs, but when Φ_F is about 0.24. This is probably associated with the transition from Type 3b to Type 4 settling. ▲

The implication from Example 9-2 is that best settled water quality might be produced when upflow rate is greater than at maximum flux, as observed by Su et al., (2004) in laboratory investigations. However, in most cases it would not be cost effective to design for or to operate at such a low flow rate. However, $t_L \propto h/v$, where h is depth of blanket, and $v \propto 1/\mu$. Therefore $\Phi_F \propto 1 - (v\mu)^{1/r}$. Also, the velocity gradient in a blanket is proportional to the head loss through the blanket which relates to the mass of floc in suspension such that

$$G \propto \sqrt{\frac{[1 - (v\mu)^{1/r}] \cdot v\rho}{\mu}} \tag{9-39}$$

Consequently, we obtain

$$G \Phi_F t_L \propto \frac{h}{(v\mu)^{1/2}} [1 - (v\mu)^{1/r}]^{3/2} \rho^{1/2} \tag{9-40a}$$

When r is approximately 1 (as per Eq. 9-35).

$$G \Phi_F t_L \propto h \left\{ \frac{[1 - (v\mu)]^{3/2}}{(v\mu)^{1/2}} \right\} \rho^{1/2} \tag{9-40b}$$

This highlights the dependence of floc blanket performance on blanket depth, upflow velocity, and water viscosity, and hence water temperature and floc density.

Inclined (Tube and Plate) Settling

The efficiency of discrete particle settling in horizontal water flow depends on the area available for settling. Hence, efficiency can be improved by increasing the area. Some tanks have multiple floors to achieve this. A successful alternative is the use of lightweight structures with closely spaced inclined surfaces.

Inclined settling systems (Fig. 9-10) are constructed for use in one of three ways with respect to the direction of water flow relative to the direction of particle settlement: countercurrent, cocurrent, and crossflow. Comprehensive theoretical analyses of the various flow geometries have been made by Yao (1970). Yao's analysis is based on flow conditions in the channels between the inclined surfaces being laminar. In practice the Reynolds number must be less than 800 when calculated using the mean velocity v_θ between and parallel to the inclined surfaces and hydraulic diameter of the channel d_H .

$$d_H = \frac{4A_H}{P} \quad (9-41)$$

where A_H is the cross-sectional area of channel to water flow and P is the perimeter of A_H , so that the equation for the Reynolds number (Eq. 9-6) becomes

$$\text{Re} = \frac{\rho v_\theta d_H}{\mu} \quad (9-42)$$

Countercurrent Settling. With reference to Fig. 9-10, the time t for a particle to settle the vertical distance between two parallel inclined surfaces is

$$t = \frac{w}{v \cos \theta} \quad (9-43)$$

where w is the perpendicular distance between surfaces and θ is the angle of surface inclination from the horizontal. The length L_p of surface needed to provide this time, if the water velocity between the surfaces is v_θ , is

$$L_p = \frac{w(v_\theta - v \sin \theta)}{v \cos \theta} \quad (9-44a)$$

By rearranging this equation, all particles with a settling velocity v and greater are removed if

$$v \geq \frac{v_\theta w}{L_p \cos \theta + w \sin \theta} \quad (9-44b)$$

When many plates or tubes are used,

$$v_\theta = \frac{Q}{Nwb} \quad (9-45)$$

where N is the number of channels made by $N + 1$ plates or tubes and b is the dimension of the surface at right angles to w and Q .

FIGURE 9-10 Basic flow geometries for inclined settling systems.

Cocurrent Settling. In cocurrent settling (Fig. 9-10), the time for a particle to settle the vertical distance between two surfaces is the same as for countercurrent settling. The length of surface needed, however, has to be based on downward and not upward water flow.

$$L_p = \frac{w(v_0 + v \sin \theta)}{v \cos \theta} \tag{9-46a}$$

Consequently, the condition for removal of particles is given by

$$v \geq \frac{v_0 w}{L_p \cos \theta - w \sin \theta} \tag{9-46b}$$

Crossflow Settling. The time for a particle to settle the vertical distance between two surfaces in crossflow settling (Fig. 9-10) is again given by Eq. 9-43. The water flow is horizontal and does not interact with the vertical settling velocity of a particle. Hence

$$L_p = \frac{v_0 w}{v \cos \theta} \tag{9-47a}$$

and all particles with a settling velocity v and greater are removed if

$$v \geq \frac{v_{\theta} w}{L_p \cos \theta} \quad (9-47b)$$

Other Flow Geometries. The above three analyses apply only for parallel surface systems. In order to simplify the analysis for other geometries, Yao (1970) suggested a parameter S_c defined as

$$S_c = v \frac{(\sin \theta + L_r \cos \theta)}{v_{\theta}} \quad (9-48)$$

where $L_r = L/w$ is the relative length of the settler.

When v^* is the special case that all particles with velocity v or greater are removed, then for parallel surfaces, S_c is equal to 1.0. But the value for circular tubes is 4/3 and for square conduits is 11/8 (Yao, 1973). Identical values of S_c for different systems may not mean identical behavior.

The design overflow rate is also defined by v^* in Eq. 9-48, and Yao has shown by integration of the differential equation for a particle trajectory that the overflow rate for an inclined settler is given by

$$v^* = \frac{k_3 K v_{\theta}}{L_r} \quad (9-49)$$

where k_3 is a constant equal to $8.64 \times 10^2 \text{ m}^3/\text{day}/\text{m}^2$ and

$$K = \frac{S_c L_r}{\sin \theta + L_r \cos \theta} \quad (9-50a)$$

For given values of overflow rate and surface spacing and when $\theta = 0$, Eq. 9-50a becomes

$$\frac{S_c}{L} = \text{constant} \quad (9-50b)$$

Equation 9-50b indicates that the larger the value of S_c , the longer the surface length must be to achieve the required theoretical performance. In practice, compromises must be made between theory and the hydrodynamic problems of flow distribution and stability that each geometry poses.

Example 9-3 Inclined Plate Settling

A tank has been fitted with 2.0-m (6.6-ft)-square inclined plates spaced 50 mm (2.0 in.) apart. The angle of inclination of the plates can be altered from 5° to 85° . The inlet to and outlet from the tank can be fitted in any way so that the tank can be used for either countercurrent, cocurrent, or crossflow sedimentation. If no allowances need to be made for hydraulic problems due to flow distribution and so on, then which is the best arrangement to use?

Solution Equation 9-44b for countercurrent flow, Eq. 9-46b for cocurrent flow and Eq. 9-47b for crossflow sedimentation are compared. As an example, the calculation for countercurrent flow at 85° is

$$\frac{v}{v_{\theta}} = \frac{50}{2000 \cos 85 + 50 \sin 85} = \frac{50}{174.3 + 49.8} = 0.223$$

The smallest value of v is required. Thus for the range,

Angle (θ)	5	15	30	45	60	75	85
Countercurrent (v/v_0)	0.025	0.026	0.028	0.035	0.048	0.088	0.223
Cocurrent (v/v_0)	0.025	0.026	0.029	0.036	0.052	0.106	0.402
Crossflow (v/v_0)	0.025	0.026	0.029	0.035	0.050	0.096	0.287

From the above, little difference exists between the three settling arrangements for an angle of less than 60° . For angles greater than 60° , countercurrent flow allows settlement of particles with the smallest settling velocity. ▲

Floc Blanket Clarification

A simple floc blanket tank has a vertical parallel-walled upper section with a flat or hopper-shaped base; see Figs. 9-1 and 9-2. Water that has been dosed with an appropriate quantity of a suitable coagulant, and pH adjusted if needed, is fed downward into the base. The resultant expanding upward flow allows flocculation to occur, and large floc particles remain in suspension within the tank. Particles in suspension accumulate slowly at first, but then at an increasing rate due to enhanced flocculation and other effects, eventually reaching a maximum accumulation rate limited by the particle characteristics and the upflow velocity of the water. When this maximum rate is reached, a floc blanket can be said to exist.

As floc particles accumulate, the volume occupied by the suspension in the floc blanket, increases and its upper surface rises. The level of the floc blanket surface is controlled by removing solids from the blanket to keep a zone of clear water or supernatant water between the blanket and the decanting troughs, launders, or weirs.

A floc blanket is thus a fluidized bed of floc particles even though the process can be regarded as a form of hindered settling. However, true hindered settling exists only in the upper section of sludge hoppers used for removing accumulated floc for blanket-level control. Thickening takes place in the lower section of the sludge hoppers. Excess floc removed from the floc blanket becomes a residue stream and may be thickened to form sludge (see Chap. 22).

Mechanism of Clarification. Settling, entrainment, and particle elutriation occur above and at the surface of a blanket. The mechanism of clarification within a floc blanket is more complex, however, and involves flocculation, entrapment, and sedimentation. In practice, the mean retention time of the water within a blanket is in excess of the requirements for floc growth to control the efficiency of the process; that is, the opportunity for the small particles to become parts of larger and more easily retained floc is substantial, and therefore there are other factors that cause particles to pass through a blanket.

Physical removal by a collector process, involving interception and agglomeration, occurs throughout a floc blanket. Probably the most important process is mechanical entrapment and straining in which rising small particles cannot pass through the voids between larger particles that comprise the bulk of the blanket. (The mechanisms are not the same as in filtration through a fixed bed of sand because all the particles are in fluid suspension.) The efficiency of entrapment is affected by the spacing of the larger suspended floc particles, which in turn is related to floc quality (shape, density, etc.) and water velocity. When suspension destabilization, coagulation, is not optimal, then flocculation will be poor and result in a greater number of smaller particles that can pass through the floc blanket (see Chap. 8 for material on coagulation and particle destabilization).

Performance Prediction. Within a floc blanket, the relationship between floc concentration and upflow velocity of the water is represented by Eqs. 9-27 to 9-30 for hindered

settling and fluidization. Unsuccessful attempts have been made to establish a simple theory for predicting solids removal (Cretu, 1968; Shogo, 1971). The relationships between settled water quality and floc concentration in the blanket, upflow velocity, and flux (Fig. 9-11) are of practical importance for understanding and controlling plant performance (Gregory, 1979). Floc blanket clarification has been modeled successfully (Hart, 1996; Gregory et al., 1996; Head et al., 1997), although calibration is essential.

FIGURE 9-11 Typical relationships between settled-water quality and blanket concentration, upflow velocity and blanket flux. (Source: Gregory, 1979.)

The modeling by Head and associates has been successfully tested in dynamic simulations of pilot-scale and full-scale plants. The modeling is based on the theories and work of various researchers, including Gould (1967) and Gregory (1979). While the model accommodates the principle that removal rate of primary particles is dependent on blanket concentration, removal is simulated on the basis that the blanket region of a clarifier is a continuous stirred tank reactor (CSTR, see Chap. 4 about CSTR hydraulics and performance). To take into account the possibility of poor coagulation, the model can assume a non-removable fraction of solids.

The relationships in Fig. 9-11 show that settled water quality deteriorates rapidly (point A) as the floc concentration (point B) is decreased below the concentration at maximum flux (point C). Conversely, little improvement in settled water quality is likely to be gained by

increasing floc concentration to be greater than that at maximum flux (to the left of points A and B). This is because for concentrations greater than that at maximum flux, interparticle distances are small enough for entrapment to dominate the clarification process.

As the concentration decreases below that at maximum flux, interparticle distances increase, especially between the larger particles, and the motion of the particles becomes more intense. Some of the larger particles might not survive the higher shear rates that develop. Thus smaller particles may avoid entrapment and escape from the floc blanket. Consequently the maximum flux condition represents possible optimum operating and design conditions. Maximum flux conditions and performance depend on various factors, which account for differences between waters and particle surface and coagulation chemistry and are described later. All this serves to make the point that the blanket floc volume fraction Φ_F has a central role and impact on the behavior of floc blanket clarifiers.

Effects of Upflow Velocity. The surface loading for floc blanket clarification is expressed as the upflow velocity or overflow rate. For some floc blanket systems the performance curve is quartic (fourth order) reflecting an early or premature deterioration in water quality of limited magnitude with increase in upflow velocity (Fig. 9-8). This deterioration is associated with segregation of particles, or zoning, in the blanket at low surface loading (Gregory, 1979) because of the wide range in particle settling velocities. This has been observed not only in the treatment of waters with a high silt content but also with the use of powdered carbon (Setterfield, 1983) and in precipitation softening using iron coagulation (Gregory and Hyde, 1975). As surface loading is increased, remixing occurs at the peak of the "temporary" deterioration as the lower-lying particles are brought into greater expansion.

For floc blanket clarification, the "corner" of the performance curve (point A in Fig. 9-11) is associated with the point of maximum flux. The limit to upflow velocity for reliable operation has been expressed by some (Bond, 1965; Tambo and Abe, 1969; Gregory, 1979) in simple terms of terminal velocity. Bond (1965) noted that the blanket surface remained clearly defined up to a velocity of about half of the zero-concentration settling rate v_o , that slight boiling occurred above $0.55v_o$, and that clarification deteriorated noticeably at about $0.65v_o$. Tambo and Abe (1969) found that a floc blanket is stable for velocities less than about $0.7v_o$ and very unstable at velocities greater than $0.8v_o$. Gregory (1979) found that the velocity at maximum flux was about $0.5v_o$, as given by Eq. 9-35, when the maximum flux half-hour settled solids volume is 20 percent. Gregory also observed that for velocities less than at maximum flux the blanket interface was sharp. However, as upflow velocity increased beyond this, the blanket surface became more diffuse to the extent that a blanket was very difficult to sustain for a velocity greater than $0.75v_o$. Su et al., (2004) examined blanket behavior for a synthetic suspension at small laboratory scale and observed that best settled water quality occurred when upflow was less than for maximum flux. If such observation also applies to full scale, then with due regard to the economic utilization of sedimentation and the effectiveness and economics of subsequent filtration, optimal operation lies between the upflow rate that produces best-quality water and the rate that can be safely used without easily resulting in loss of blanket by washout. The optimal rate is most likely to be at a higher than at a lower upflow rate; refer to Example 9-1.

The half-hour settled solids volume at maximum flux has been found to be in the range of 16 to 20 percent when coagulant dose and coagulation pH are selected from jar tests to minimize metal-ion concentration and turbidity. This has been observed for both alum and iron coagulation with and without using polyelectrolyte flocculant aid (Gregory et al., 1996). The actual value depends on the quality of the water as well as the choice of coagulation chemistry, because these govern such characteristics as floc strength, size, and density. The lowest blanket solids volume concentration that a discernible blanket can be found to exist with is about 10–12 percent. If upflow rate is increased to cause further dilution, then the blanket effectively becomes washed out.

Hydraulic Characteristics of Sedimentation Tanks

Reference should be made to Chap. 4 for more detailed information on the nature of the hydraulic characteristics of processes such as sedimentation tanks.

Ideal Flow Conditions. The simplest flow condition is plug flow when all water advances with equal velocity. Conditions only approximate to this when turbulence is small and uniform throughout the water. In laminar, non-turbulent, flow conditions, a uniform velocity gradient exists, with velocity zero at the wall and maximum at the center of the channel through which the water flows, and therefore plug flow cannot exist.

Major departures from plug and laminar flow conditions in sedimentation tanks are associated with currents caused by poor flow distribution and collection, wind, rising bubbles, or density differences caused by temperature or concentration. Currents caused by these factors result in short-circuiting of flow and bulk mixing and reduce the performance of the process predicted by ideal theory. The extent of departure from ideal plug flow performance can be assessed by residence time distribution analysis with the help of tracer studies and modeling with computational fluid dynamics (CFD); see Chap. 4.

Residence Time. The theoretical mean residence time of a process is the volume of the process from the point of dosing or end of the previous process through to the point at which separation efficiency is measured or the outlet of the process, divided by the flow-through rate (see Chap. 4). For horizontal-flow sedimentation, the volume of the entire tank is important in assessing the effect on sedimentation efficiency. For inclined settlers the volume within the inclined surfaces, and for floc blankets the volume of the blanket itself, is most important. Depth can be used to reflect the volume of a floc blanket.

The mean residence time of a process is effectively the length, in the direction of flow, divided by the average flow velocity. Thus, the mean residence time reflects the average velocity or overflow rate and will relate to sedimentation efficiency accordingly.

Flow-through curves (fluid residence time distributions) determined by the use of tracer tests are a graphical depiction of the distribution of fluid element residence times (see Chap. 4). These can be analyzed to produce estimates of efficiency of flow distribution and volumetric utilization of a tank, that is, its hydraulic characteristics. Consequently the extent to which sedimentation efficiency might be improved by modifying flow conditions can be estimated. Clements and Khattab (1968) have shown with model studies that sedimentation efficiency is correlated with the proportion of plug flow. Hydraulic characteristics were determined in Japan for a range of flow rate for five types of circular and rectangular tanks and compared (Kawamura, 1991). The results showed that a rectangular tank with an inlet diffuser wall was generally the superior design for minimizing short-circuiting and maximizing plug flow.

OPERATIONAL AND DESIGN CONSIDERATIONS FOR SEDIMENTATION

Types of Sedimentation Tanks

Horizontal-Flow Tanks

Rectangular Tanks. With rectangular horizontal-flow tanks, the water to be settled flows in one end, and the treated water flows out at the other end. The inlet flow arrangement must provide a flow distribution that maximizes the opportunity for particles to settle. If flocculation has been carried out to maximize floc particle size, then the flow at the inlet

should not disrupt the flocs. This requires minimizing the head loss between the distribution channel and the main body of the tank. A certain amount of head loss is necessary, however, to achieve flow distribution. One option is to attach the final stage of flocculation to the head of the sedimentation tank to assist flow distribution.

The length and cross-sectional shape of the tank must not encourage the development of counterproductive circulatory flow patterns and scour. Outlet flow arrangements also must ensure appropriate flow patterns. The principal differences between tanks relate to inlet and outlet arrangements; length, width, and depth ratios; and the method of sludge removal. For horizontal-flow tanks with a small length/width ratio, the end effects dominate efficiency. Inlet and outlet flow distribution substantially affect overall flow patterns and residence time distribution. When the depth is greater than the width, the length/depth ratio is more important than the length/width ratio.

A length/width ratio of 20 or more ideally is needed to approach plug flow (Hamlin and Wahab, 1970; Marske and Boyle, 1973) and maximum efficiency for horizontal-flow and, presumably, inclined settlers, by determination of the reactor dispersion, (see Chap. 4). Such a high-value ratio may not be economically acceptable, and a lower ratio, possibly as low as about 5, may give acceptable efficiency if the flow distribution is good. The length/width ratio can be increased by installing longitudinal baffles or division walls.

Increasing the length/width ratio also has the effect of increasing the value of the *Froude number*.

$$Fr = \frac{2v^2}{d_H g} \quad (9-51)$$

The value of *Fr* increases with the length/width ratio because of the increase in velocity *v* and decrease in hydraulic diameter d_H . Camp (1936) has shown that the increase in value of *Fr* is associated with improved flow stability.

Poor flow distribution may produce currents or high flow velocities near the bottom of a tank. This may cause scour, or resuspension of particles from the layer of settled sludge. Scour may cause transportation of solids along the bottom of the tank to the outlet end. An adequate tank depth can help to limit scour, and consequently depths less than 2.4 m (8 ft) are rarely encountered (Gemmell, 1971). To avoid scour, the ratio of length to depth or surface area to cross-sectional area must be kept less than 18 (Kalbskopf, 1970). This has implications for limiting the length/width ratio.

Initially, sludge was removed from tanks by simple manual and hydraulic methods. To avoid interruption in operation and to reduce manpower, mechanically aided sludge removal methods were introduced. In the most common method, mechanical scrapers push the sludge to a hopper at the inlet end of the tank. Periodically, the hopper is emptied hydraulically.

If sludge is not removed regularly from horizontal-flow tanks, allowance must be made to the tank depth for sludge accumulation so that the sedimentation efficiency remains unaffected. Sludge can be allowed to accumulate until settled water quality starts to be impaired. The tank floor should slope toward the inlet, because the bulk of solids generally settle closer to the inlet end.

The frequency of sludge removal depends on the rate of sludge accumulation. This can be estimated by mass balance calculations. Sometimes the decomposition of organic matter in the sludge necessitates more frequent sludge removal. Decomposition can be controlled by prechlorination, if this practice is acceptable, otherwise decomposition may produce gas bubbles that disturb the settled sludge, create disruptive flow patterns, and impair settled water quality by releasing reduced manganese (Mn) and iron (Fe).

Frequent sludge removal is best carried out with mechanical sludge scrapers that sweep the sludge to a hopper at the inlet end of the tank. Frequent removal results in easy maintenance of tank volumetric efficiency, and better output efficiency with continuous operation.

FIGURE 9-12 Multistory horizontal tank with parallel flow on three levels. (Courtesy of OTV, Paris, France, and Kubota Construction Co., Ltd., Tokyo, Japan.)

Multistory Tanks. Multistory, or tray, tanks are a result of recognizing the importance of settling area to settling efficiency. Two basic flow arrangements are possible with multistory tanks. The trays may be coupled in parallel with flow divided between them (Fig. 9-12) or coupled in series with flow passing from one to the next. A few of the latter reverse-flow tanks exist in the United States with two levels.

Multistory tanks are attractive where land value is high. Difficulties with these tanks include a limited width of construction for unsupported floors, flow distribution, sludge removal, and maintenance of submerged machinery. Successful installations in the United States show that these difficulties can be overcome in a satisfactory manner. However, tanks with reverse flow (180° turn) tend to be the least efficient (Kawamura, 1991).

Circular Tanks. Circular tank flow is usually from a central feedwell radially outward to peripheral weirs (Fig. 9-13). The tank floor is usually slightly conical to a central sludge well. The floor is swept by a sludge scraper that directs the sludge toward the central well. Circular tanks incorporate a central feedwell which is needed to assist flow distribution but also is often designed for flocculation and so incorporate some form of agitation. If this agitation is excessive, it carries through to the outer settling zone and affects sedimentation efficiency (Parker et al., 1996).

Radial outward flow is theoretically attractive because of the progressively decreasing velocity. The circumference allows a substantial outlet weir length and hence a relatively low weir loading. Weirs must be adjustable or installed with great accuracy to avoid differential flow around a tank. Circular tanks are convenient for constructing in either steel or concrete although they might be less efficient in the use of land than rectangular tanks. Sludge removal problems tend to be minimal.

The settling efficiency might be less than expected because of the problem of achieving good flow distribution from a central point to a large area. The principal differences between circular tanks are associated with floor profile and sludge scraping equipment.

FIGURE 9-13 Circular radial-flow clarifier. (Courtesy of Baker Process Equipment Co., Salt Lake City, Utah.)

Inclined (Plate and Tube) Settlers. Individual or prefabricated modules of inclined plate or tube settlers can be constructed of appropriate materials. The advantages of prefabricated modules include efficient use of material, accuracy of separation distances, lightweight construction, and structural rigidity. Inclined surfaces may be contained within a suitably shaped tank for countercurrent, cocurrent, or crossflow sedimentation. Adequate flocculation is a prerequisite for inclined settling if coagulation is carried out. The tank containing the settler system also can incorporate the flocculation stage and preliminary

FIGURE 9-14 Inclined-plate settler with preflocculation and combined thickening. (Courtesy of US Filter-Zimpro Products, Rothschild, Wis.)

sludge thickening (Fig. 9-14). Particle removal can be enhanced by ballasting the floc. The angle of inclination of the tubes or plates depends on the application, the tendency for self-cleaning, and the flow characteristic of the sludge on the inclined surface. If the angle of inclination of the inclined surfaces is great enough, typically more than 50° to 60° (Yao, 1973), self-cleaning of surfaces occurs. Demir (1995) found for inclined plates fitted at the end of a pilot horizontal-flow settler the optimum angle is about 50° , with this becoming more pronounced as surface loading rate increases. When the angle of inclination is small, the output of the settler must be interrupted periodically for cleaning. This is because the small distance between inclined surfaces allows little space for sludge accumulation. An angle as little as 7° is used when sludge removal is achieved by periodic backflushing, possibly in conjunction with filter backwashing. The typical separation distance between inclined surfaces for unhindered settling is 50 mm (2 in.) with an inclined length of 1 to 2 m (3 to 6 ft).

The main objective in inclined settler development has been to obtain settling efficiencies close to theoretical, for example, as predicted by Eqs. 9-44, 9-46, and 9-47. Considerable attention must be given to providing equal flow distribution to each channel, producing good flow distribution within each channel, and collecting settled sludge while preventing its resuspension.

With inclined settlers, the velocity along the axis of the channels defines the flow regime. In practice, the efficiency is usually related to either the surface loading on the basis of the

plan area occupied by the settling system, to the upflow velocity, or to the loading based on the total area available for settlement. Countercurrent settlers are probably more numerous than cocurrent and crossflow settlers, although each type has advantages and disadvantages.

Countercurrent Settlers. In countercurrent inclined settlers, the suspension is fed below the settling modules and the flow is up the channels formed by the inclined surfaces (Fig. 9-10). Solids settle onto the lower surface in each channel. If the angle of inclination is great enough, the solids move down the surface counter to the flow of the water; otherwise, periodic interruption of flow, possibly with flushing, is necessary for cleaning.

Tube settlers are used mostly in the countercurrent settling mode. Tube modules have been constructed with various configurations (Fig. 9-15), including square tubes between vertical sheets, alternating inclination between adjacent vertical sandwiches, chevron-shaped tubes between vertical sheets, and hexagonal tubes.

Countercurrent modular systems are suitable for installing in existing horizontal flow tanks and some solids contact clarifiers to achieve upgrading and uprating. Closely spaced inclined surface systems are not cost-effective in floc blanket clarifiers although widely spaced (0.3 m [1 ft]) inclined plates are. Tube modules may aid up-rating by acting in part as baffles that improve flow uniformity following poor inlet flow distribution or counteracting the effect of strong wind blowing across the water surface.

FIGURE 9-15 Various formats for tube modules.

Cocurrent Settlers. In cocurrent sedimentation, the suspension is fed above the inclined surfaces and the flow is down through the channels (Fig. 9-10). Settled solids on the lower surface move down the surface in the same direction as the water above. Special attention must be given to collecting settled water from the lower end of the upper surface of each channel to prevent resuspension of settled solids.

Crossflow Settlers. In crossflow sedimentation, the suspension flows horizontally between the inclined surfaces and the settled solids move downward (Fig. 9-10). In this case, resuspension of settled solids is usually less of a problem than in countercurrent and cocurrent settling. This might not be true in some systems in which the direction of inclination alternates (Fig. 9-16) (Gomella, 1974). Alternating inclination can allow efficient use of tank volume and results in rigidity of modular construction. Development and application of crossflow systems has occurred mainly in Japan.

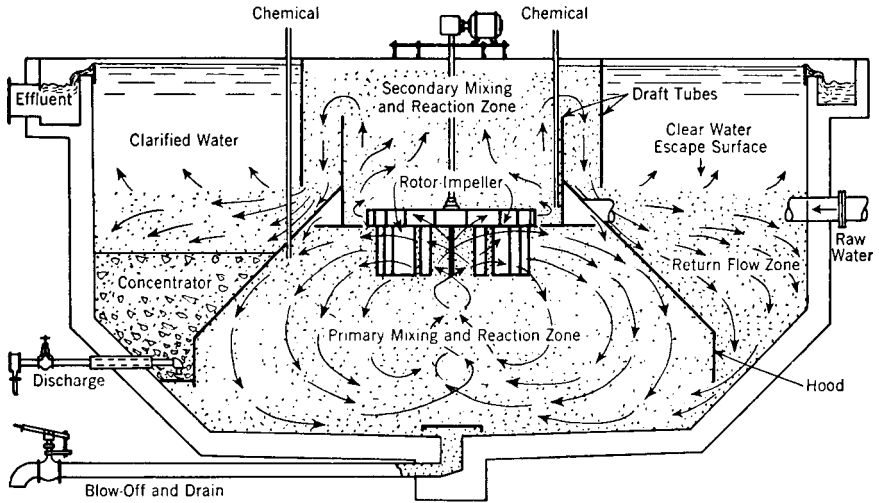

FIGURE 9-16 Alternating cross-flow lamella settler. [Source: Gomella, C. "Clarification avant filtration; ses progress recents" (Rapport General 1). Int'l Water Supply Assoc. Int'l Conf., 1974.]

Solids-Contact Clarifiers. Solids-contact clarifiers are generally circular in shape and contain equipment for mixing, flow recirculation, and sludge scraping. There is a wide variety of these tanks and most are of proprietary design. Hartung (1951) has presented a review of eight different designs. Contact clarifiers are of two types: premix, and premix-recirculation like that in Fig. 9-17.

In the simpler premix system, water is fed into a central preliminary mixing zone which is mechanically agitated. This premix zone is contained within a shroud that acts as the inner wall of the outer annular settling zone. Chemicals can be dosed into the premix zone. Water flows from the premix zone under the shroud to the base of the settling zone.

In the premix-recirculation system, water is drawn out of the top of the premix zone and fed to the middle of the settling zone. The recirculation rate can exceed the actual flow of untreated water to the tank such that the excess flow in the settling zone is drawn downward and under the shroud back into the premix zone. This movement recirculates solids that can assist flocculation in the premix zone.

Mechanical equipment associated with solids-contact clarifiers must be adjusted or tuned to the throughput. Excessive stirring motion in the premix zone can be counterproductive, whereas too little stirring can result in poor radial-flow distribution under the shroud as well as poor chemical mixing and flocculation. In solids-contact units, sludge settles to the

Slurry Pool Indicated by Shaded Areas

FIGURE 9-17 The Accelerator® solids contact clarifier. (Source: Hartung, 1951.)

tank floor and is removed with mechanical equipment. Clarifiers with recirculation to keep solids in suspension allow excess solids to accumulate in sludge pockets or concentrators as illustrated in Fig. 9-17. Appropriate operation of these pockets contributes to controlling the concentration of solids in suspension and influences the sedimentation efficiency of the clarifier.

Floc Blanket Clarifiers. Both types of solids-contact tanks, premix and premix-recirculation, can function as floc blanket clarifiers if stable and distinct floc blankets can be established and easily maintained in the settling zone. Only a few designs of solids-contact clarifiers have been developed with this objective. Usually, the volume and concentration of solids in circulation in contact units is not great enough to maintain a blanket in the outer separation zone.

Hopper-Bottomed Tanks. The first-designed floc blanket tanks had a single hopper bottom, square or circular in cross section. In these units coagulant-dosed water was fed down into the apex of the hopper. The hopper shape assists with even flow distribution from a single-point inlet to a large upflow area. The expanding upward flow allows floc growth to occur, large particles to remain in suspension, and a floc blanket to form. The pressure loss through the floc blanket, although relatively small, helps to create homogeneous upward flow.

A single hopper, conical or pyramidal, only occupies 33 percent of available volume relative to its footprint. In addition, it is expensive to construct and its size is limited by constructional constraints. Consequently, alternative forms of hopper tanks have been developed to overcome these drawbacks yet retain the hydraulic advantage of hoppers. These include tanks with multiple hoppers, a wedge or trough, a circular wedge (i.e., premix type of clarifier), and multiple troughs.

As a floc blanket increases in depth, settled water quality improves but with diminishing return (Fig. 9-18). Equation 9-40 has been fitted to the data in Fig. 9-18, assuming constant

FIGURE 9-18 Example of the effects of upflow velocity and blanket depth on removal of aluminum from water by a floc blanket. (Based on Fig. 40 in Miller et al., 1965.)

floc density and an optimum value of $r = 1.62$, on the basis that alum residual is dependent on the collector function $G\Phi t$ resulting in Fig. 9-19. There were problems of flow control with the pilot plant and positive displacement pumps were used to try and overcome these. The outliers to the general trend in Fig. 9-19 are likely to reflect this problem.

Figure 9-19 accounts for the effect of upflow velocity. The blanket depth defines the quantity of solids in suspension and collector time, that is, the value of t in the term $G\Phi t$. If effective depth is defined as the total volume of blanket divided by the area of its upper interface with supernatant, then the effective depth of a hopper is roughly 1/3 the actual depth. This applies similarly for collector time. As a result, flat-bottomed tanks have an actual depth that is much less than that of hopper tanks with the same effective depth (or collector time). Effective depths of blankets are typically in the range 2.5 to 3 m (8 to 10 ft).

The quantity of solids in suspension, established by the blanket depth and concentration, affects sedimentation efficiency because of the effect on flocculation. In addition, the head loss assists flow distribution, ensuring a more stable blanket (delaying the onset of boiling and loss of blanket) and thereby greater blanket concentration.

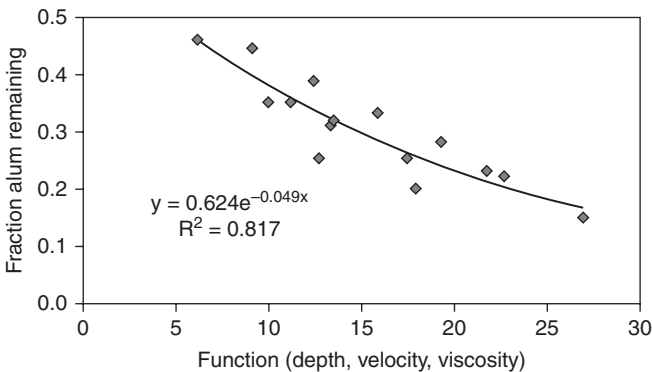

FIGURE 9-19 Figure 9-18 data normalized with collector model, Eq. 9-40.

FIGURE 9-20 Change in settled-water quality as depth of supernatant increases above a floc blanket. (Source: Miller et al., 1966.)

A very stable floc blanket (e.g., as in a pilot plant) can be operated with little depth of supernatant water, less than 0.3 m (1 ft), without significant solids carryover (Fig. 9-20) (Miller et al., 1966). In practice, the feasibility of this depends on weir spacing and likely disturbance by wind. Generally, blankets are operated in a manner likely to produce a blanket with a diffuse surface, have a tendency to exhibit some unstable boiling, and have poor level control methods. Thus, a supernatant water depth of at least 1 m (3 ft) may be necessary to minimize carryover, especially after increases in upflow velocity. Supernatant water depths of 2 m (6 ft) are commonly provided, but this may be unnecessary if there is good blanket-level control and care is taken when increasing the upflow rate (Hart, 1996).

Control of the blanket surface is easily achieved using a slurry weir or sludge hopper with sills set at an appropriately high level. Sludge hoppers can be emptied frequently by automatically timed valves. The Gravilectric[®] proprietary suspended sludge hopper system utilizes a strain gauge to initiate drainage of sludge from suspended canvas cones (Fig. 9-1). Another method is to monitor the magnitude of the turbidity in a sample drawn continuously from a suitable point.

Sludge hoppers, pockets, and cones must be sized to allow efficient removal of sludge (Pieronne, 1997). They must be large enough to allow in situ preliminary thickening, even when the sludge removal rate has to be high. High rates might occur following a substantial increase in flow-through rate during periods of high chemical doses. Dynamic simulation modeling by Hart (1996), Gregory et al., (1996), and Head et al., (1997) has shown the importance of correct sizing of sludge hoppers and their operation, especially for handling increases in flow through the clarifiers. If sizing and operation are inadequate, then loss of blanket level control and poor settled water quality will occur when the flow is increased.

Example 9-4 Floc Blanket Clarifier

What area will be needed for removing floc to control the blanket level in a floc blanket clarifier using the conditions for Example 9-1?

Solution Assume the aluminum coagulant dose to the water is 3.2 mg Al/L. The aluminum concentration in the floc blanket at maximum flux (when the floc volume concentration is 20 percent) is 110 mg Al/L. The concentration of aluminum in the blanket is proportional to the floc volume.

From Example 9-1 the conditions are

Upflow rate, m/h	1.6	1.95	2.5	3.05	3.65	4.2	4.7	5.15
Half-hour floc volume, %	31	29	25	22	19	16	13	10

The proportion of the floc blanket tank area needed for removing floc is determined by a mass balance.

$$\begin{aligned} & (\text{Aluminum dose}) \times (\text{total volumetric flow rate to tank}) \\ & = (\text{blanket aluminum concentration}) \times (\text{volumetric settlement rate into removal area}) \end{aligned}$$

But

$$(\text{Total volumetric flow rate to tank}) = (\text{upflow rate}) \times (\text{total tank upflow area})$$

and

$$\begin{aligned} & (\text{Volumetric settlement rate into removal area}) \\ & = (\text{upflow rate}) \times (\text{area for removal}) \end{aligned}$$

Thus

$$\begin{aligned} & (\text{Area for removal}) \times (\text{blanket aluminum concentration}) \\ & = (\text{total tank upflow area}) \times (\text{aluminum dose}) \end{aligned}$$

This means that the proportion of tank area needed for removing floc is the ratio of aluminum concentration in the blanket to that being dosed. For example, at the upflow rate of 1.95 m/h,

$$\text{Concentration of aluminum in the blanket} = 110 \times 29/20$$

Therefore

$$\text{Proportion of area needed} = 3.2/110 \times 20/29 \times 1/100\% = 2.0\%$$

Hence

Upflow rate, m/h	1.6	1.95	2.5	3.05	3.65	4.2	4.7	5.15
Proportion of area needed, %	1.9	2.0	2.3	2.6	3.1	3.6	4.5	5.8

For a different aluminum dose, the area will need to be accordingly proportionally greater or less. In practice, a greater area will be required to cope with the short-term need to remove excess floc at a high rate to prevent the blanket from reaching the launders when the upflow rate is increased quickly. ▲

Flat-Bottomed Tanks. It is simpler and cheaper to build a floc blanket tank with a flat bottom, and therefore few, if any, tanks are now built with hoppers. In flat-bottomed tanks, good flow distribution is achieved using either multiple downward, inverted-candelabra feed pipes or laterals across the floor (Figs. 9-1 and 9-2).

An inverted-candelabra system can ensure good distribution for a wide range of flows but may obstruct installation of inclined settling systems. The opposite can apply to a lateral distribution system. In the proprietary Pulsator[®] design, reliability of flow distribution is ensured by periodically pulsing the flow to the laterals.

Inclined Settling with Floc Blankets. Tube modules with the typical spacing of 50 mm (2 in) between inclined surfaces are not cost effective in floc blanket clarifiers (Gregory, 1979). With the blanket surface below the tube modules, the settled water quality is no better than from a stable and efficient tank without modules.

With the blanket surface within the modules, the floc concentration in the blanket increases by about 50 percent, but no commensurate improvement in settled water quality occurs. The failure of closely spaced inclined surfaces to increase hindered settling rates relates to the proximity of the surfaces and a circulatory motion at the blanket surface that counteracts the entrapment mechanism of the blanket (Gregory, 1979).

The problem with closely spaced surfaces diminishes with more widely spaced inclined surfaces. An effective spacing is about 0.3 m (1 ft), but no optimization studies are known to have been published. Large (2.9 m) plates, however, have been shown to be preferable to shorter (1.5 m) plates (Casey et al., 1984). The combined action of suppressing currents and inclined settling with widely spaced surfaces can result in about a 50 percent greater throughput than with a good floc blanket without inclined surfaces. The proprietary Superpulsator[®] tank is the Pulsator[®] design with widely spaced inclined surfaces. A further development is the Ultrapulsator[®] design which although similar to the Superpulsator[®] design, has short inclined hexagonal tube modules in the supernatant zone.

Sludge Recycling. Many proprietary designs of clarifiers purposely incorporate recycling of sludge. This is relevant for precipitation lime softening, and historically this may account for this design feature, which probably was subsequently promoted as beneficial for coagulation-flocculation. The benefits of producing denser floc, for example, pelletization, have been justified by Tambo and Wang (1993) and Bache and Gregory (2007), and sludge recycling is one way of achieving this. However, so far pelletization has not found application for potable water production probably because of undue dependence on the use of polyelectrolyte. The DensaDeg[®] process (Degremont, 1991) combines flocculation, inclined tube settling, and sludge settlement in a raked thickener; it also incorporates sludge recycling. The sludge recycling is considered a core feature of the process to enhance particle density and hence increase settlement rate and enhance sludge settling and thickening. The process has found widespread application for uses other than potable water production.

Ballasted Floc Systems. Floc produced by coagulating mineral-bearing water generally settles faster than floc produced by coagulating water containing little mineral turbidity. Consequently, mineral turbidity added purposely to increase floc density can be useful. Bentonite is the usual choice, and fly ash has been considered in eastern Europe. The advantages of ballasting floc also arise with powdered activated carbon, dosed for taste and odor control or pesticide removal (Standen et al., 1995), and when precipitation softening is carried out in association with iron coagulation. Sometimes fine sand has been used as the ballasting agent.

A process based on fine sand ballasting was developed in Hungary in the 1950s and 1960s. In this process, microsand (<200 μm) is recovered and recycled for economy by pumping the sludge through a bank of small hydrocyclones. The basic process was first introduced in the United Kingdom by the proprietary name of *Simtafier* (Webster et al., 1977) and in France by the name of Cyclofloc[®] (Sibony, 1981). A subsequent development

Actiflo® Turbo

FIGURE 9-21 Actiflo® Turbo: schematic diagram of a typical unit. (Courtesy of Veolia Water Solutions and Technologies, Saint Maurice, France.)

is the Fluorapide® system, which combines floc blanket settling and sand ballasting with inclined settling (Sibony, 1981). Another development is the Actiflo® system (de Dianous et al., 1990), which combines sand ballasting with inclined settling and has become widely applied, with Actiflo® Turbo as the most recent development of the process (Fig. 9-21).

Typically in the Actiflo® process, Fig. 9-21, the raw water is first coagulated. The microsand (about 70–100 μm) is then dosed together with the polymer and about 6 min allowed for maturation prior to lamella settling. Typical microsand doses are 3 g/L (range of 3–5 kg/m^3). It is important to ensure the sand size range is within specification for efficient recovery by the hydrocyclones so that sand loss is typically about 2 mg/L. At some plants, part of the polymer dose is dosed to the recycled sand before entering the flocculation tank. Although this does not improve clarified water quality, it can increase filter run lengths. As with ordinary clarification, it is important not to overdose polymer to avoid filter blinding. Desjardins et al. (2002) studied ballasted flocculation in the laboratory by jar tests. The results showed that coagulant dose and coagulation pH have the greatest effects on settled water quality. By contrast, filterability was more sensitive to coagulant and microsand doses. Filterability was also dependent on the ratio of microsand-to-polymer dose and improved when this increased.

The ballasting agent, whether for example, microsand or bentonite, besides enhancing floc density will act also as a collector (see Eq. 9-36). It follows that the ballasting agent must have an optimum dose for a given water quality and choice of chemical treatment. Al Farisi (1988) (Bache et al., 1995) examined the impact of bentonite dose on the size-density function (e.g., Fig. 9-4). As the bentonite dose increased, it was found that the floc density passed through a maximum located in the interval 3–7 mg/L, that is, similar to the doses used in practice for bentonite.

Powdered magnetite, recovered by magnetic drum filters, also has been suggested as a ballasting agent. A process from Australia (Dixon, 1984), with the proprietary name Sirofloc®, is based on recycling magnetite without coagulation, other than for a small

dose of cationic polymer. The magnetite is chemically conditioned with sodium hydroxide (changing its surface charge) such that a metal-ion coagulant is not needed. Sirofloc® is almost efficient enough for subsequent filtration to be unnecessary. High-rate (20-m/h) filtration may be needed to remove residual magnetite and manganese that Sirofloc® cannot normally remove (Gregory et al., 1988).

Other Factors Influencing Sedimentation Efficiency

Surface Loading. The surface loading of a sedimentation tank is expressed as the flow rate per unit of surface area of that part of the tank in which settling is meant to happen. The performance of all settling processes is influenced by surface loading. Settled water quality deteriorates when surface loading is increased (Fig. 9-8). The reasons for this deterioration are various, but (particularly for discrete particle settling processes) changes in flow rate may affect flocculation performance as well as sedimentation efficiency.

The point at which the performance curve (Fig. 9-8) crosses the limit of acceptable quality defines the maximum reliable surface loading. Cost effectiveness requires the highest surface loadings possible; however, the efficiency will then be more sensitive to major variations in surface loading and water quality.

The reliable surface loading for a given type of settling process depends on a wide range of factors. For example, when treating a highly colored, low-alkalinity water in winter by floc blanket clarification, the loading might be only 1 m/h (3 ft/h), whereas when treating a minerally turbid, high-alkalinity water in summer with a flocculent aid, the loading could be greater than 7 m/h (23 ft/h).

Size and Shape of Tank

Size and Number. The number of tanks can affect the flexibility of plant operation. When operating close to the limit of acceptable quality, isolation of one tank is likely to impose a reduction in total plant production. No fewer than two tanks should be used for reliability, while three will provide greater operational flexibility. See Baruth (2005) for further guidance on water treatment plant design.

The size of tanks might be limited by construction constraints, and consequently this will dictate the minimum number of tanks. Although factors that affect sedimentation efficiency, such as loading, velocity, and various dimension ratios, can be maintained with any size tank, the performance of extra-large tanks may become unacceptable and limit tank size. For example, tanks with large surface area will tend to be more vulnerable to environmental effects, such as wind-induced circulation.

When considering the number of tanks, the performance of a floc blanket is dependent on the upflow velocity, blanket floc concentration, effective blanket depth, and dosing and delay time conditions. Thus, provided that the size and shape of floc blanket tanks do not affect these factors, any such size or shape might not be expected to affect sedimentation efficiency. The efficiency is affected, however, because differences occur between tanks in their hydrodynamic and hydraulic conditions for flocculation and flow distribution.

The length/width ratio is not relevant to floc blanket clarifiers, although baffles have been shown to be useful (Gregory and Hyde, 1975). With inclined settlers the length of the flow path affects the sedimentation efficiency (Yao, 1973). When lengths are short, end effects may limit efficiency. Additionally, problems of flow distribution may mean that inclined plate settlers with narrow plates are more efficient than those with wide plates.

Depth. According to Hazen's law (Eq. 9-23b), for discrete particle settling, the settling efficiency depends on the tank area and is independent of the depth. However, in practice increasing tank depth promotes settling efficiency and is interrelated with width

in horizontal and inclined settlers. A minimum depth may be needed to limit scour as mentioned previously. Depth also defines the spacing between inclined surfaces and, therefore, the number of layers and inclined settler efficiency.

Flow Arrangements

Inlet and Outlet. The purpose of an inlet is to distribute the incoming water uniformly over the cross section of a tank for a wide range of flow rates. The outlet arrangement is as important as the inlet in ensuring good flow distribution. Numerous investigations (Fair and Geyer, 1954; Thirumurthi, 1969) have shown how inlets and outlets in horizontal-flow tanks influence residence time distribution and settling efficiency. Tests with model tanks (Price and Clements, 1974; Kawamura, 1981) have shown that symmetry is desirable and obstacles (such as support walls and piers) can disturb uniformity. Complex arrangements can be as good as simple ones, and a uniformly fed submerged weir can give good results without a baffle. See Baruth (2005) for further guidance on water treatment plant design.

For all types of settlers, flow velocities in approach channels or pipe work that are low enough to allow premature settlement must be avoided. Conversely, flows high enough to disrupt floc must also be avoided.

In floc blanket tanks, the injection velocity from the inlet pipes governs the input energy, which can affect blanket stability and boiling. Boiling causes direct carryover and a reduction in blanket concentration; these result in deterioration of settled water quality.

Outlet weir or launder length and loading affect outlet flow distribution. Therefore, weirs and launders must be kept clean and unobstructed, but the effectiveness of long launders is questionable (Kawamura and Lang, 1986).

Baffling. Baffles are useful in horizontal-flow tanks at the inlet and outlet to assist flow distribution, longitudinally to increase length/width ratio, and as vanes to assist changes in horizontal-flow direction. Kawamura (1981) did numerous model tests with diffuser walls and arrived at a number of design guides relating to the position of walls and the free area in the walls.

In hopper-bottomed floc blanket tanks, baffles might help inlet flow distribution (Gould, 1967; Hale, 1971), but the centering of the inlet should be checked first (Gregory, 1979). A matrix of vertical baffles in the floc blanket is an alternative method for improving tank performance if flow distribution is poor (Gregory and Hyde, 1975).

Vertical baffles have been installed in some solids-contact clarifiers so that the central mixer does not cause the fluid to rotate in the settling zone. Fluid rotation will lift the floc up the outer side of the settling zone. A proprietary tube-module baffle system (Envirotech Corp) has been used to improve flow distribution in radial-flow tanks. Baffles at the water surface can help to counteract wind disturbance.

Particulate and Water Quality

Seasonal Water Quality. Sedimentation efficiency may vary with seasonal changes in temperature, alkalinity, and similar parameters, as well as with changes in the nature of dissolved organic matter (DOM) (e.g., color) and turbidity being coagulated.

Temperature affects efficiency by influencing the rate of chemical reactions, solubilities, viscosity of water, and hence particle settling velocities. Temperature can also be a surrogate for change in other parameters that occur on a similar seasonal basis. Changes in alkalinity, color, turbidity, and orthophosphate concentration for eutrophic waters affect coagulation reactions and the properties and rate of settling of resulting floc particles.

With floc blanket clarification, for example, the reliable upflow velocity in the summer can be more than twice that in the winter (Fig. 9-8) (Gregory, 1979; Setterfield, 1983). This is important when plant size or reliable plant output is defined.

Example 9-5 Floc Blanket Upflow Rate

What will be the floc blanket upflow rate at maximum flux for different temperatures, given the conditions defined in Example 9-1?

Solution The Stokes' settling velocity of particles is inversely proportional to water viscosity, Eq. 9-8.

$$v_{\text{temp } 1} = v_{\text{temp } 2} \times \left(\frac{\mu_{\text{temp } 2}}{\mu_{\text{temp } 1}} \right)$$

The viscosity of water for different temperatures (see App. D) is as follows:

Temperature, °C	5	10	15	20	25
Viscosity, mN-s/m ²	1.52	1.31	1.14	1.00	0.893

If the results given in Example 9-1 were obtained at the temperature of 10°C, then assuming no change in water chemistry and other factors that might affect the floc, the maximum flux upflow rate at 20°C can be estimated, for example, as

$$v_{20^\circ\text{C}} = 3.44 \times 1.31/1.00 = 4.50 \text{ m/h}$$

Hence for the above temperature range,

Maximum flux upflow rate, m/h	2.96	3.44	3.95	4.50	5.05
-------------------------------	------	------	------	------	------

This means that the upflow rate for reliable operation in the summer could be more than 1.5 times that in the winter for this temperature range. ▲

Raw Water Settlement. The turbidity of raw waters is caused by either or both organic and inorganic matter. Bar screens remove large solids and prevent the entry of larger fish while mesh strainers are intended for removing small fish and organic debris, algae, and other planktonic species. Neither is intended for removing high concentrations of organic or inorganic silt that can occur in some directly abstracted river waters. The settlement characteristics of these solids, and their individual and relative concentrations may vary substantially according to season, for example, between wet and dry seasons. Removal of most of these solids before chemical treatment helps to minimize the chemicals needed and protects from blockages in pipes and channels and from damage to pumps. It is not unusual to have either or both grit channels and preliminary settlement tanks (i.e., without coagulation). Such initial removal of solids may also help with managing solids waste costs. The literature does not provide much help on settlement methods for raw waters entering treatment works. Ideas can be gleaned from methods used to control siltation in canals and impounding reservoirs and sewage works inlet grit removal, with a mind to how accumulating solids can be routinely removed. One of the authors has encountered a site where after grit channels, preliminary horizontal-flow settlement was done in conjunction with marginal coagulation (adequate for destabilization) followed by floc blanket clarification with secondary coagulation (adequate to complete coagulation with respect to residual aluminum, turbidity, and dissolved color).

Coagulation. Particle settling velocity is affected by various particle characteristics, principally size, shape, and density. The choice of coagulant, coagulation pH, and application efficiency affect floc particle characteristics. The choice of coagulant should be dictated by chemical considerations (see Chap. 8). Optimum chemical doses for sedimentation

can be predicted reliably by jar tests. Jar tests also reliably predict color and DOC removal and soluble metal-ion concentrations, but not turbidity removal because of the difference in hydrodynamic conditions in the batch jar test and the continuous settling process.

Adequate control of dosing and mixing of the chemicals should be provided. If a change in coagulant dose or pH improves the sedimentation efficiency, the current chemical doses may be incorrect or the mixing or flocculation inadequate. The difference in efficiency between identical tanks supposedly receiving the same water can be because of differences in chemical doses if made separately to each tank, poor chemical mixing before flow splitting, or different flows through the tanks.

Flocculation. The efficiency of horizontal and inclined-flow sedimentation is dependent on prior flocculation if coagulation is carried out. The efficiency of solids-contact units depends on the quality of preliminary mixing. Mixing assists with chemical dispersion, flocculation, solids resuspension, and flow distribution. Because these can conflict with each other, mixing rates should be adjusted when changes are made to the flow-through rate. This is rarely done, however, because it is usually too difficult.

The extent of flocculation is dependent on velocity gradient and time (see Chap. 8). The time delay between chemical dosing and inlet to a floc blanket, to allow preliminary flocculation in connecting pipe work and channels, affects the floc blanket clarification efficiency (Fig. 9-22) (Miller and West, 1968; Yadav and West, 1975). The delay times between dosing the coagulant and dosing a polyelectrolyte and between dosing the polyelectrolyte and the inlet to the tank also affect the efficiency (Fig. 9-23). The reasons for needing such delay times are not entirely understood, but relate to floc development in delivery channels in association with efficiency of mixing, rate of hydrolysis and precipitation, and rate of formation of primary and subsequent floc particles. Useful delay times are likely to be in the range 1/2 to 8 min, similar to those needed for direct filtration. The greatest times tend to be

FIGURE 9-22 Change in settled-water quality with increase in delay time between chemical dosing and inlet to a floc blanket. (Source: Yadav and West, 1975.)

FIGURE 9-23 Change in settled-water quality with increase in delay time between dosing a polyelectrolyte and inlet to a floc blanket. (Source: Yadav and West, 1975.)

needed when coagulating very cold water with aluminum sulfate. High-rate flocculation for inclined settling or dissolved air flotation is similarly affected, such that flocculation times of 5 to 10 min may be effective when water is warm but longer times may be needed when water is very cold, especially with aluminum sulfate. Water temperature has less effect on flocculation with polyaluminum chlorides and ferric salts (see Chap. 8).

Delay time is not a substitute for initial rapid chemical dispersion. Many operators have learned that simple improvements to flow conditions and dispersion arrangements at the point of dosing can produce substantial improvements in chemical utilization and sedimentation efficiency.

Polyelectrolytes and Other Agents. Flocculent aids improve sedimentation efficiency by increasing floc strength and size. Jar tests can be used to select suitable polyelectrolytes and determine a trial dosing range. Optimal doses must be carefully determined by full-scale plant tests. An excessive dose producing good settled water may be detrimental to filters. If the apparent optimal dose of polyelectrolyte on the plant is much greater than that indicated by jar tests, then mixing and flocculation conditions must be checked.

Dosing of flocculent aids increases particle settling velocities in floc blanket clarification and may cause in an increase in the blanket-floc concentration if upflow rate isn't increased to match the improvement. A diminishing return also exists in increasing the dose of flocculent aid and is associated with the blanket-floc concentration increasing with increase in flocculent dose and becoming greater than at maximum flux (Fig. 9-24) (Gregory, 1979).

FIGURE 9-24 Effect of polyelectrolyte type and dose on blanket solids concentration and settled water quality. (Source: Gregory, 1979.)

Thus the polyelectrolyte dose need be only enough to ensure that the floc concentration is greater than at maximum flux and that the blanket surface is distinct and not diffuse and certainly not so great as to take the floc concentration into the thickening regime. Additives that increase floc density and settling velocity, such as floc ballasting with bentonite or fine sand, have an effect on sedimentation similar to flocculent aids.

Climate and Density Currents. Wind can induce undesirable circulation in horizontal-flow tanks, with crossflow winds reducing sedimentation efficiency the most (Price and Clements, 1974). Therefore, wind effects should be minimized by constructing tanks to align with prevailing winds. Strong winds can disrupt floc blanket stability. This can be counteracted by covering tanks with roofs, placing floating covers between the launders, constructing windbreaks around each tank, aligning the launders across the prevailing wind, installing scum-boards or baffles at the water surface across the prevailing wind, or installing fully submerged baffles in the supernatant water. Wind combined with low temperatures can cause severe ice formation and affect outlet flow. Total enclosure may be needed to prevent ice formation.

High solar radiation can cause rapid diurnal changes in water temperature and density. Rapid density changes because of temperature, solids concentration, or salinity can induce density currents that can cause severe short-circuiting in horizontal tanks (Hudson, 1981) and inclined settlers (White et al., 1974). Hudson (1981) has reviewed methods of minimizing or preventing induced currents. He considered the methods to fall into several categories: (1) use of a surface weir or launder takeoff over a large part of the settling basin, (2) improved inlet arrangement, (3) schemes to provide increased basin drag and friction, and (4) slurry recirculation. Substantial diurnal variation in temperature also can result in release of dissolved gases, especially in biologically active waters. The resulting rising columns of bubbles can disrupt floc blankets.

INTRODUCTION TO DISSOLVED AIR FLOTATION

History of Flotation

Over 2000 years ago, the ancient Greeks used a flotation process to separate the desired minerals from the gangue, the waste material (Gaudin, 1957). Crushed ore was dusted onto a water surface, and mineral particles were retained at the surface by surface tension while the gangue settled. In 1860 Haynes patented a process in which oil was used for the separation of the mineral from the gangue (Kitchener, 1984). The mineral floated with the oil when the mixture was stirred in water.

In 1905 Salman, Picard, and Ballot developed the *froth flotation* process by agitating finely divided ore in water with entrained air. A small amount of oil was added sufficient to bestow good floatability to the sulfide grains (Kitchener, 1984). The air bubbles together with the desired mineral collected as foam at the surface while the gangue settled. The first froth flotation equipment was developed by T. Hoover in 1910 (Kitchener, 1984), and except for size, it was not much different than the equipment used today. Later, in 1914, Callow introduced air bubbles through submerged porous diffusers. This process is called *foam flotation*. The two processes, froth and foam flotation, are generally known as *dispersed air flotation* and are widely used in the mineral industry.

Elmore suggested in 1904 the use of electrolysis to produce gas bubbles for flotation. This process, although not commercially used at that time, has been developed into electrolytic flotation (Bratby, 1976). Elmore also invented the dissolved air (vacuum) flotation process in which air bubbles are produced by applying a vacuum to the liquid, which releases the air in the form of minute bubbles (Kitchener, 1984).

The original patent for the dissolved air pressure flotation process was issued in 1924 to Peterson and Sveen for the recovery of fibers and *white water* in the paper industry (Lundgren, 1976). In pressure dissolved air flotation, the air bubbles are produced by releasing the pressure of a water stream saturated with air above atmospheric pressure. Initially, dissolved air flotation (DAF) was used mainly in applications where the material to be removed, such as fat, oil, fibers, and grease, had a density less than that of water. The first reported use of DAF (based on the ADKA vacuum system) for drinking water treatment was in Scandinavia during the 1920s (Haarhoff, 2008). However, it was not until the 1960s the process also became more acceptable for potable water treatment applications (Haarhoff, 2008). Now it has become accepted as an alternative to sedimentation, not only in the Scandinavian countries and the United Kingdom, but also in the United States and many other countries (Haarhoff, 2008). Flotation is employed mainly for the treatment of nutrient-rich reservoir waters that may have heavy algal blooms and for low-turbidity, low-alkalinity colored waters (Zabel and Melbourne, 1980). These types of waters are difficult to treat by sedimentation, because the floc produced by chemical treatment has a low settling velocity. In the United States, some of the DAF plants are for treating relatively high-quality supplies (low turbidity and low color) that were previously unfiltered or had direct filtration, where the addition of DAF provides an extra pathogen barrier.

Types of Flotation Processes

Flotation is described as a gravity separation process in which gas bubbles attach to solid particles to cause the apparent density of the bubble-solid agglomerates to be less than that of the water, thereby allowing the agglomerate to float to the surface. Different methods of producing gas bubbles give rise to different types of flotation processes. These are *electrolytic flotation*, *dispersed air flotation*, and *dissolved air flotation*. The basis of electrolytic or electroflotation is the generation of bubbles of hydrogen and oxygen in a dilute aqueous solution by passing a dc current between two electrodes (Barrett, 1975). The application of electrolytic flotation has been restricted mainly to sludge thickening and small wastewater treatment plants in the range 10 to 20 m³/h (50,000 to 100,000 gpd) and has limited application to drinking water treatment.

Dispersed air flotation involves the formation of bubbles by diffusers, spargers, and other mechanical means. Large bubbles are formed (sizes of a mm) and can be effective in treating suspensions containing large particles such as mineral separation and industrial waste treatment. Dispersed air flotation is generally unsuitable for water treatment as the bubble size is large and because of high turbulence and use of undesirable frothing and surfactant chemicals. However, the French Ozoflot[®] system applies ozone-rich air as a pretreatment oxidation process for waters high in algae using diffusers to achieve dispersion.

In dissolved air flotation, air bubbles are produced by the reduction in pressure of a water stream saturated with air. The three main types of dissolved air flotation are vacuum flotation (Zabel and Melbourne, 1980), microflotation (Hemming et al., 1977), and pressure flotation (Barrett, 1975). In microflotation the entire volume of water is subjected to increased pressure by passing it down and up a shaft approximately 10 m deep. In the down-flow section the water is aerated and the amount of air available for flotation is restricted by the depth of shaft provided. However, pressure flotation in which a proportion of the treated water is recycled under pressure to dissolve the air into the water is the method used in drinking water treatment and is the subject of interest here. A general description is presented next and serves to give the reader a basic description of the DAF process and terminology. This is followed by a section Fundamentals of Dissolved Air Flotation. Then, there is a section Operational and Design Considerations for Flotation. Finally in an applications section we also address emerging technologies.

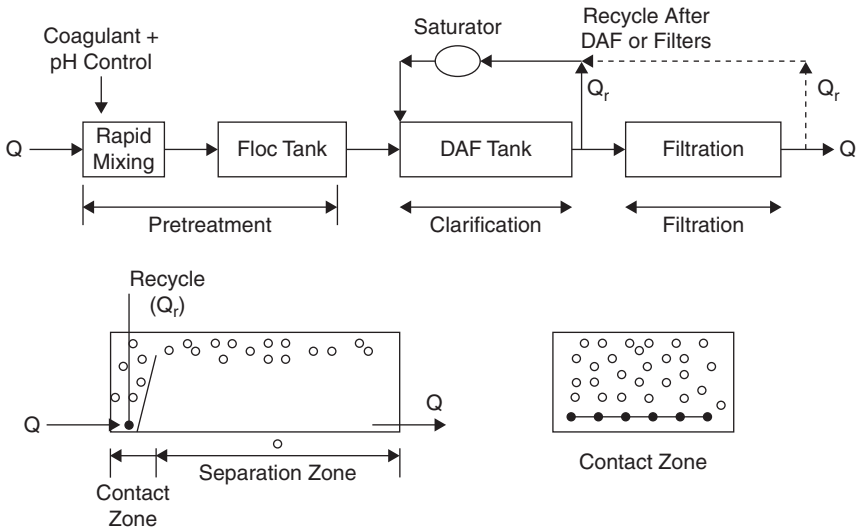

FIGURE 9-25 Top: Process schematic of a DAF in a conventional type water plant; Bottom: DAF tank showing the contact and separation zones.

General Description

Figure 9-25 is a process schematic diagram for DAF in a conventional type drinking water plant in which it has replaced sedimentation as a clarification process. Coagulation and flocculation are required pretreatment processes. Coagulation is a chemical addition step. Metal coagulants such as alum, polyaluminum chlorides, and ferric salts are commonly used. Coagulation has two purposes: to destabilize particles present in the raw water and to convert dissolved natural organic matter into particles. The latter purpose, over the last 25 years, has become an essential part of water treatment used to remove as much dissolved organic carbon (DOC) as feasible through coagulation and subsequent separation of the formed flocs. Good coagulation chemistry is essential for DAF to work efficiently, as it is for sedimentation and filtration. Its fundamental role in DAF is addressed in the next section on fundamentals of DAF, while the section on operational and design considerations for DAF contains some practical material. Principles of coagulation and flocculation are covered in Chap. 8.

The flocculation step involves mixing of the water to induce collisions among particulate contaminants and precipitated particles formed from metal coagulants so as to yield flocs. The size of particles or flocs in the influent to the DAF tank affects greatly the collisions among flocs and bubbles in the DAF contact zone. Flocculation is used in both sedimentation and DAF plants, but their objectives differ. When settling follows flocculation, the goal is to produce large flocs capable of settling at a fairly rapid rate. Flocs with sizes of 100 μm and greater are required to produce reasonable settling rates. Smaller floc sizes are desired for DAF. This is an important feature of DAF that is examined in the sections on fundamentals and operational and design considerations.

The DAF tank is divided into two sections with different functions as illustrated at the bottom of Fig. 9-25. There is a section at the front end that is baffled, called the *contact zone*, where floc particles are introduced and contacted with air bubbles. Here, collisions occur among bubbles and preformed floc particles. If the floc particles are prepared properly via coagulation with respect to their surface chemistry, then bubbles colliding with

the flocs may attach and yield floc-bubble aggregates. This is the principal mechanism for water treatment (Kitchener and Gochin, 1981). Other possible mechanisms for forming floc-bubble aggregates are entrapment of bubbles as flocs form and growth of bubbles from nuclei on flocs.

The water carrying the suspension of bubbles, floc-bubble aggregates, and unattached floc particles flows to the second section of the tank, called the *separation zone*. Here, bubbles not attached to flocs and floc-bubble-aggregates may rise to the surface of the tank. The float layer at the surface of the tank consists of a mixture of bubbles and floc particles attached to bubbles. In drinking water applications, this froth is called the *float*. Over time, this float layer is concentrated producing a sludge that is collected and removed from the tank. Clarified water, often referred to as the *subnatant*, is withdrawn from the bottom of the tank. In a standard type DAF water plant as presented in Fig. 9-25, granular media filtration is placed in a horizontal layout following DAF, and the recycle flow is taken either after DAF or filtration. In some applications of flotation, DAF is placed vertically above the filters and the recycle flow is taken after filtration.

Air bubbles are introduced into the DAF contact zone. First, air is dissolved into the recycle flow by adding air under pressure in a vessel called a *saturator* or *air-dissolving vessel*. The recycle ratio or rate (R) is defined by Eq. 9-52, where Q is the plant throughput flow and Q_r is the recycle flow. Recycle rates are usually in the range of 6 to 12 percent. A rate of 10 percent or a little greater is a typical design value.

$$R = \frac{Q_r}{Q} \quad (9-52)$$

Saturator gauge pressures are usually between 400 and 600 kPa (~60 and 85 psi). The recycle flow is injected through nozzles or special valves at the bottom entrance to the contact zone. Microbubbles are produced with sizes between 10 and 100 μm . These small air bubbles give the water a milky appearance, and so the term *white water* is used to describe the bubble suspension in the DAF tank.

Analogous to sedimentation overflow rates, DAF tank hydraulic loadings are used to describe the rate and size of DAF tanks. There are conventional DAF processes designed at nominal hydraulic loadings of 5 to 15 m/h (2 to 6 gpm/ft²). More recently, high-rate DAF processes have been developed allowing loadings of 15 to 30 m/h (6 to 12 gpm/ft²) and greater. Loading rates and the development of high-rate DAF processes are discussed further in subsequent sections.

FUNDAMENTALS OF DISSOLVED AIR FLOTATION

Principles are presented in this section on the following subjects: (1) solubility of air, (2) bubble suspension in the contact zone, (3) performance model for the contact zone, (4) bubble and floc-bubble aggregate rise velocities, and (5) ideal theory for separation zone performance. The material draws on the paper covering the fundamentals of DAF by Edzwald (2007).

Air Solubility and Bubbles in the Contact Zone

Solubility of Air in Water. Our interest is in determining the equilibrium air concentration in water (i.e., solubility) for normal air composition and normal atmospheric pressure of 101.3 kPa (1 atm). The values obtained are used for the air concentrations ($C_{s,\text{air}}$) in the influent recycle water to the saturator and in the influent flocculated water entering the flotation tank; see Fig. 9-26.

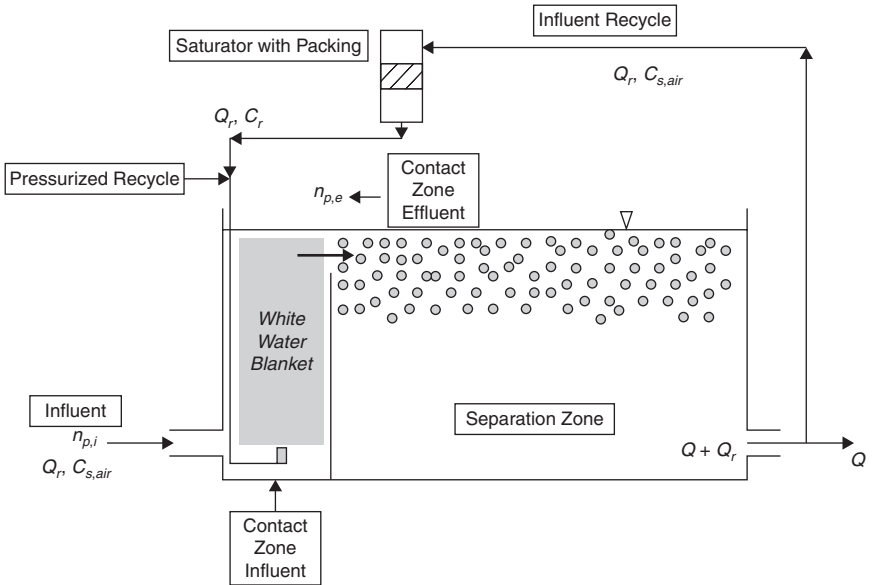

FIGURE 9-26 DAF tank showing the baffled contact zone, the separation zone, the influent recycle flow to the saturator, and the pressurized recycle flow entering the contact zone. (Source: Edzwald, 2007, reprinted with permission from the Journal of the New England Water Works Association, Copyright 2009, Holliston, Mass.)

Henry’s law is used to determine the solubility of a gas in water; Henry’s law is discussed in Chap. 3 under chemical concepts and in Chap. 6 on gas-liquid processes. It is important to note here that Henry’s law applies to individual gases, and so for air, which is a mixture of gases, one has to calculate solubility for each gas and then add them to obtain the solubility of air in water. Nitrogen and oxygen account for over 99 percent of the composition of air. Thus for practical reasons, nitrogen is set at 79.1 percent (slightly higher than actual to account for other minor gases) and oxygen is set at 20.1 percent. The solubility concentrations of nitrogen ($C_{s,N}$), oxygen ($C_{s,O}$), and air ($C_{s,air}$) are given in Table 9-2 for various temperatures. As shown, the solubility of air is a little more than 20 mg/L for warm waters increasing to about 30 mg/L for cold water.

TABLE 9-2 Solubility of Oxygen, Nitrogen, and Air in Water for Atmospheric Air (79.1 percent N_2 [accounts for small amounts of other gases] and 20.9 percent O_2)

Temperature (°C)	$C_{s,O}$ (mg/L)	$C_{s,N}$ (mg/L)	$C_{s,air}$ (mg/L)
5	12.3	19.5	31.8
10	10.9	17.7	28.6
15	9.8	16.1	25.9
20	8.9	14.8	23.7
25	8.1	13.6	21.7
30	7.4	12.6	20.0

Solubility of Air in the Pressurized Recycle Water Exiting the Saturator. The composition of air within the saturator differs from atmospheric air. This is because oxygen is more soluble than nitrogen in water so within the saturator a steady state condition is established with saturator air containing more nitrogen than atmospheric air. This saturator air is called *nitrogen-enriched air*. For example, at a typical saturator design pressure of 500 kPa (72.5 psi) and 20°C and for typical water and air loading rates, the saturator air is composed of 86.7 percent nitrogen. Because nitrogen is less soluble than oxygen, the pressurized recycle water contains less dissolved air than it would if the saturator could be operated under conditions of maintaining atmospheric air. Data from Steinbach and Haarhoff (1997) on the composition of saturator nitrogen-enriched air were used to determine the solubility or equilibrium dissolved air concentration (C_r) in the pressurized recycle flow (Q_r) exiting the saturator; see Fig. 9-26.

Figure 9-27 presents C_r as a function of the saturator gauge pressure for temperatures of 5°C (cold water) and 20°C (warm water). Note that C_r is expressed as a function of saturator pressure, but it is the total dissolved air in the recycle water from pressure applied to the

FIGURE 9-27 Dissolved mass air concentration in the recycle flow as a function of saturator pressure at 5°C and 20°C (C_r is the total dissolved air in the recycle flow from the saturator pressure (gauge pressure) plus atmospheric pressure). (Source: Edzwald, 2007, reprinted with permission from the Journal of the New England Water Works Association, Copyright 2009, Holliston, Mass.)

saturator (gauge pressure) plus atmospheric pressure. More air is dissolved in water at lower temperature, and the theoretical equilibrium dissolved air concentration increases with saturator pressure. The slope of the line is low, so there is a small benefit in varying the saturator pressure to provide more or less delivered air for constant recycle flow. Consequently, the designer and operator should not use the saturator pressure as the primary means to vary the air concentration delivered to the contact zone, but should use the recycle flow.

As pointed out earlier, saturators are designed at gauge pressures in the range of 400 to 600 kPa (~60 to 85 psi). Using a saturator pressure of 500 kPa (72.5 psi) as an example, Fig. 9-27 shows that C_r is about 130 mg/L at 20°C. The theoretical available air concentration that can precipitate in the form of bubbles would be this value (130 mg/L) less the soluble air concentration at atmospheric pressure (24 mg/L), or 106 mg/L. These calculations are for equilibrium conditions, but the actual available air is less than this because

saturators do not achieve equilibrium solubility of air in the recycle water. Transfer of air has kinetic mass transport limitations, which is addressed in the next section.

Bubble Suspension in the Contact Zone. The bubble suspension in the contact zone achieves a steady state bubble concentration arising from the continuous input of pressurized recycle flow (Q_r) mixing with the influent water (Q) from the flocculation tank. This bubble suspension is referred to as a *white water* blanket (see the shaded area of Fig. 9-26). There are three measures of bubble concentrations: mass, volume, and number.

Mass Concentration. Equation 9-53, obtained from a mass balance under steady state conditions for the contact zone, gives the mass concentration of air bubbles (C_b) in the contact zone.

$$C_b = \frac{[e(C_r - C_{s,\text{air}})R - k_a]}{1 + R} \quad (9-53)$$

The difference between C_r and $C_{s,\text{air}}$ represents the amount of air that will precipitate, that is, released as air bubbles. However, as mentioned, the water leaving the saturators does not reach equilibrium solubility conditions because air transfer into water has kinetic limitations; for principles about gas transfer kinetics, see Chap. 6. There may also be a minor loss in air in delivering the recycle water from the saturator to the point of injection. Thus, a saturator efficiency factor (e) is incorporated into the mass balance. The efficiency may vary from 60 to 70 percent for unpacked saturators to 90 to 95 percent for packed saturators; the latter contain plastic packing to increase the rate of air transfer to the water. Practical information about saturators is presented in the section Operational and Design Considerations for Flotation. The parameter k_a accounts for any air deficit in the incoming water (Q). If the flocculated water is at saturation, then k_a is zero. This is the common situation, but not always. Supplies taken from the bottom of reservoirs that are mesotrophic or eutrophic, may have an oxygen deficit, and therefore an air deficit. One should take water for DAF from a supply that is at saturation or nearly saturated with oxygen; otherwise a significant portion of the air provided will not yield air bubbles but rather will be used to satisfy the dissolved oxygen demand. This may require high recycle rates and so make DAF uneconomical.

Volume Concentration. The density of air bubbles is a fundamental property required for calculating bubble volume concentrations and bubble rise velocities. Moist air densities (ρ_b) for conditions of 100 percent humidity and with the dew point temperature equal to the water temperature are used; see App. D of the book for values. The air bubble volume concentration in the contact zone (Φ_b) is calculated from Eq. 9-54.

$$\Phi_b = \frac{C_b}{\rho_b} \quad (9-54)$$

Number Concentration. The air bubble size (d_b) must be known or assumed to calculate the bubble number concentrations (n_b). Small air bubbles are formed instantaneously after injection of the pressurized recycle flow into the contact zone influent at the bottom of the tank. The bubble sizes formed depend mainly on the saturator pressure and the injection device (nozzle type or needle and gate valves). Nozzles are used most often to inject the recycle water into the contact zone, and they produce a more uniform bubble size distribution than gate and needle valves. The pressure difference across the nozzle is the primary factor affecting bubble size. In theory, smaller-size bubbles are produced as the saturator pressure is increased; however, for typical DAF operation at saturator gauge pressures of 400 to 600 kPa (~60 to 85 psi), the bubble sizes are between 10 and 100 μm with most bubbles about 40 to 80 μm . A good estimate of the mean bubble size for the contact zone

is 60 μm (Haarhoff and Edzwald, 2004). For modeling purposes of the contact zone, it is reasonable to assume that the bubble size is maintained throughout the contact zone depth even with the decreasing hydrostatic pressure (Takahashi et al., 1979). However, larger bubbles are found in the separation zone and this is discussed later in the chapter. The number concentration is calculated from Eq. 9-55.

$$n_b = \frac{\Phi_b}{\left(\frac{\pi(d_b)^3}{6}\right)} \quad (9-55)$$

Example 9-6 Bubble Concentrations in the Contact Zone

In this example consider a DAF plant operating at 10 percent recycle with a saturator pressure of 500 kPa (72.5 psi) and 90 percent efficiency. The flocculated water enters the contact zone of the flotation tank with a floc particle concentration ($n_{p,i}$) of 20,000 particles/mL and a floc volume concentration (Φ_p) of 20 ppm. Compute the air mass concentration (C_b), bubble volume concentration (Φ_b), and number concentration (n_b) in the contact zone of the DAF tank, and compare the concentrations of bubbles to floc particles. For these calculations use a water temperature of 20°C; at this temperature ρ_b is 1.19 kg/m³ (see App. D). Assume the flocculated water is saturated with air so k_a is 0.

Solution

- Mass of air in DAF tank.* For this calculation, Fig. 9-27 is used to estimate C_r , the equilibrium air concentration in the pressurized recycle water. The value is approximately 130 mg/L. Equation 9-53 is used to calculate the mass concentration of air bubbles in the contact zone using a value for $C_{s,\text{air}}$ from Table 9-2 of 23.7 mg/L.

$$C_b = \frac{[e(C_r - C_{s,\text{air}})R - k]}{1 + R} = \frac{[0.90(130 - 23.7)0.10]}{1 + 0.10} = 8.7 \text{ mg/L}$$

- Bubble volume concentration.* Now Φ_b is calculated from Eq. 9-54.

$$\Phi_b = \frac{C_b}{\rho_{\text{air}}} = \frac{8.7 \text{ mg/L}}{1.19 \text{ kg/m}^3} = 7.31 \left(\frac{\text{mg}}{\text{kg}}\right) \left(\frac{\text{m}^3}{\text{L}}\right) = 7.31 \left(\frac{\text{mg}}{\text{kg}} \times \frac{\text{kg}}{10^6 \text{ mg}}\right) \left(\frac{\text{m}^3}{\text{L}} \times \frac{10^3 \text{ L}}{\text{m}^3}\right)$$

$$\Phi_b = \frac{7310 \text{ m}^3 \text{ of air}}{10^6 \text{ m}^3 \text{ of water}} = 7310 \text{ parts per million (ppm)}$$

- Bubble number concentration.* n_b is calculated from Eq. 9-55 using a mean bubble diameter of 60 μm ($60 \times 10^{-6} \text{ m}$).

$$\begin{aligned} n_b &= \frac{6\Phi_b}{\pi d_b^3} = \left[\frac{6(7310 \times 10^{-6})}{\pi(60 \times 10^{-6})^3}\right] = 6.47 \times 10^{10} \left(\frac{\text{bubbles}}{\text{m}^3}\right) \times \left(\frac{\text{m}^3}{10^3 \text{ L}}\right) \\ &= 65 \times 10^6 \left(\frac{\text{bubbles}}{\text{L}}\right) \end{aligned}$$

- Ratios of concentrations.*

$$\frac{n_b}{n_{p,i}} = \frac{65 \times 10^6}{20\,000} \left(\frac{\text{bubbles}}{\text{L}}\right) \left(\frac{\text{mL}}{\text{particles}}\right) \times \frac{\text{L}}{10^3 \text{ mL}} = 3.3$$

or about 4 bubbles per floc particle

$$\frac{\Phi_b}{\Phi_p} = \frac{7310 \text{ ppm}}{20 \text{ ppm}} = 365 \text{ bubble volume per floc particle volume} \quad \blacktriangle$$

Discussion of Bubble Concentrations. In Example 9-6 the calculations are instructive, but they were done for specific conditions. A more general analysis is needed to make conclusions regarding bubble concentrations and flotation.

Table 9-3 presents mass, volume, and number concentrations for recycle rates of 6 to 12 percent (typical operating range) at a fixed saturator operating or gauge pressure of 500 kPa

TABLE 9-3 Contact Zone Air Bubble Concentrations Versus Recycle Rate [Conditions: 20°C, saturator pressure of 500 kPa (72.5 psi), C_r for saturator air composition, saturator efficiency of 90 percent, bubble diameter of 60 μm , flocculated water is saturated with air [$k = 0$]].

Recycle rate, R (%)	Mass conc., C_b (mg/L)	Volume conc., Φ_b (ppm)	Number conc., n_b (#/L)
6	5.4	4500	40×10^6
8	7.1	5900	50×10^6
10	8.7	7300	65×10^6
12	10.1	8600	80×10^6

Source: Edzwald, 2007, adapted with permission from the *Journal of the New England Water Works Association*, Copyright 2009, Holliston, Mass.

(72.5 psi). These are of interest because in DAF plant operation, the saturator pressure is usually kept fairly constant and the recycle rate is varied to change the air bubble concentrations in the contact zone. The following comments are made:

- For recycle rates of 6 to 12 percent, the air bubble mass concentrations are 5.4 to 10.1 mg/L, the volume concentrations are 4500 to 8600 ppm, and the number concentrations are 40×10^6 to 80×10^6 bubbles per L.
- The contact zone is designed for collisions to occur between bubbles and floc particles. How do the bubble numbers compare to floc particle number concentrations? Field measurements for floc numbers for floc sizes of 1 μm and greater are in the range of 1×10^6 (low end) to 40×10^6 (high end) floc particles per L. For, say, a design recycle rate of 10 percent, the bubble number is 65×10^6 bubbles per L. Therefore, the bubble number far exceeds the floc number for low floc concentrations—65 to 1. For the high floc particle concentrations, there are 1.5 bubbles per floc so here the recycle rate could be increased to provide additional bubbles if needed. One desires a bubble suspension in the contact zone in which bubble numbers exceed floc numbers to ensure good collision opportunities of bubbles with floc particles. Of course, flotation cannot occur unless at least one bubble is attached to a floc particle, so it is essential to have more bubbles than particles.
- The flocs will not float unless the attached bubble volume lowers the density of the floc-bubble aggregate to less than the density of water. One can gain some insight of the potential for this by comparing bubble volumes to floc volumes. Again, for a design recycle rate of 10 percent, the bubble volume concentration is 7300 ppm (from Table 9-3). The physical meaning of the bubble volume concentration is that for every 10^6 m^3 of water flowing through the contact zone, 7300 m^3 of bubble volume is provided. The floc volumes entering the DAF contact zone for most DAF applications are in the range of 5 to 50 ppm.

Using the high end for the floc volume yields a bubble/floc particle volume ratio of about 146. This large bubble volume provides the means to reduce floc densities to less than that of water so flotation can occur.

Contact Zone Performance Model

Mathematical models describing DAF contact zone performance have been developed over the last 25 years. These models have improved our fundamental understanding of DAF and have been instrumental in advancing the use of the technology around the world. There are two approaches to DAF modeling for drinking water treatment. One approach uses flocculation in which floc particles undergo flocculation with bubbles in the contact zone (see Chap. 8 for flocculation modeling) and has been used by several investigators starting with Tambo and coworkers (Tambo and Matsui, 1986; Fukushi et al., 1995; Matsui et al., 1998). The flocculation-type modeling approach was modified by Leppinen (2000) and by Han (2002) using trajectory analysis to model collisions among bubbles and floc particles. The second modeling approach considers the rising bubble suspension in the contact zone as a blanket of rising bubbles collecting floc particles. The bubbles in the blanket act as collectors and are analogous to a granular media filter where filter grains act as collectors (see Chap. 10 for filter modeling). Edzwald and coworkers (Edzwald et al., 1990; Edzwald, 1995) developed this modeling approach and later the model was reviewed and verified (Haarhoff and Edzwald, 2004). Schers and Van Dijk (1992), Baeyens et al. (1995), and Liers et al. (1996) have also used this approach. Here, the Edzwald modeling approach is presented and the variables that affect design and operating performance are identified and discussed.

Model Framework and Assumptions. The DAF tank is divided into two zones with different functions: the contact zone where bubbles collect particles or flocs and the separation zone where free bubbles and bubble-floc aggregates rise to the surface. Our interest now is the contact zone as shown in Fig. 9-26 and from a design view is depicted to reside on the left-hand side of a baffle, which divides it from the separation zone. Additional collection of flocs by particles can continue in the separation zone, but this is not considered in the model.

The following is a summary of the model development and assumptions. Details are found in Haarhoff and Edzwald (2004):

1. In the model, the term *particle* is used in a general sense and refers to either primary non-flocculated particles or to flocs.
2. The model development considers that a blanket (*white water* suspension) of bubbles exists in the contact zone at a dynamic steady state with a high bubble concentration (between $\sim 40 \times 10^6$ and 80×10^6 bubbles per L; see Table 9-3). This dynamic steady state at a high bubble concentration is maintained by continuous injection of bubbles from the recycle flow and output at the exit of the contact zone plane above the baffle where cross-flow occurs. The bubbles act as collectors of particles analogous to a granular media sand or anthracite filter. In fact, the bubble concentration is so high that the mean separation distance between bubbles is approximately 200 μm , which is about the pore space between filter grains in a filter bed.
3. The basic kinetic equation describing the rate of particle change due to collision and attachment to bubbles is

$$\frac{dn_p}{dt} = -k_c n_p n_b \quad (9-56)$$

where k_c is the rate coefficient and n_p and n_b are the particle and bubble number concentrations, respectively. The rate coefficient depends primarily on how particle collisions occur with bubbles. This is modeled in which the bubbles act as particle collectors using the single collector efficiency (η_T) concept and the particle-bubble attachment efficiency (α_{pb}).

4. A steady state mass balance for particles (n_p) is made across the depth of the contact zone; see Fig. 9-26.
5. Plug flow hydraulic conditions are assumed through the contact zone. This is a reasonable assumption based on tracer studies and the analysis done by Haarhoff and Edzwald (2004), and it is a practical assumption for development of design-based performance models.

Contact Zone Model. The final form of the contact zone performance model is

$$\left(1 - \frac{n_{p,e}}{n_{p,i}}\right) = \left[1 - \left(\exp \frac{-(3/2)\alpha_{pb}\eta_T\Phi_b v_b t_{cz}}{d_b}\right)\right] \tag{9-57}$$

Equation 9-57 gives the fraction of particles that have collided and attached to bubbles in the contact zone. The equation is instructive in that it identifies variables affecting the contact zone performance. These are

- α_{pb} , the attachment efficiency of particles to bubbles
- η_T , the total collision efficiency accounting for all transport mechanisms
- Φ_b , the bubble volume concentration
- v_b , the bubble rise velocity
- t_{cz} , the detention time of the contact zone
- d_b , the bubble size

In this equation the dimensionless particle transport coefficient (η_T) describes the collision efficiency of a single bubble or collector. Particle trajectory analysis was used to determine expressions for η due to gravitational forces, and the convective-diffusion equation was used to determine a η expression for Brownian diffusion. Four individual η expressions are found. They are for Brownian diffusion (η_D), fluid flow or interception (η_I), differential settling of flocs (η_S), and inertia (η_{IN}). For drinking water applications, the inertia term is small and neglected. Equations 9-58 through 9-60 describe the individual single collector collision efficiencies.

$$\eta_D = 6.18 \left[\frac{k_b T}{g(\rho_w - \rho_b)} \right]^{2/3} \left[\frac{1}{d_p} \right]^{2/3} \left[\frac{1}{d_b} \right]^2 \tag{9-58}$$

$$\eta_I = \left(\frac{d_p}{d_b} + 1 \right)^2 - \frac{3}{2} \left(\frac{d_p}{d_b} + 1 \right) + \frac{1}{2} \left(\frac{d_p}{d_b} + 1 \right)^{-1} \tag{9-59}$$

$$\eta_S = \left[\frac{(\rho_p - \rho_w)}{(\rho_w - \rho_b)} \right] \left[\frac{d_p}{d_b} \right]^2 \tag{9-60}$$

The interception expression (Eq. 9-59) is more complicated than the interception equation for granular media filtration (see Chap. 10). This is because in flotation, particles and

bubble sizes are nearly the same size whereas in filtration the filter media collectors are much larger in size than particles applied to the filter yielding a simpler expression for interception. The total single collector collision efficiency (η_T) is the sum of the individual mechanisms.

$$\eta_T = \eta_D + \eta_I + \eta_S \quad (9-61)$$

Discussion of the Contact Zone Model Variables. The contact zone performance model (Eq. 9-57) identifies two types of variables: one type is related to DAF pretreatment; the other type has to do with the design and operation of the DAF tank contact zone. It is instructive to separate the variables as shown in Table 9-4 according to pretreatment variables versus DAF tank variables.

Pretreatment Coagulation Chemistry and Flocculation. The attachment efficiency (α_{pb}) accounts for the fraction of successful collisions between particles and bubbles. If all collisions result in attachment, then α_{pb} is assigned a value of 1. For conditions of

TABLE 9-4 Contact Zone Model Variables

Variable	Dependence	Comments
Pretreatment variables		
α_{pb} (particle-bubble attachment efficiency)	Interaction forces between particles and bubbles from electrical charge, London-van der Waals forces, hydrophobic force, and hydrodynamic retardation.	Coagulation chemistry including dose and pH critical in maximizing particle attachment to bubbles. α_{pb} approaches 1 with optimum coagulation.
η_T (total single collector collision efficiency)	Brownian diffusion: $d_p^{-2/3}$ Settling and interception: d_p^2	Flocculation increases d_p . Desire flocs of 10s of μm .
Flotation tank variables		
d_b (mean bubble diameter)	Controlled mainly by pressure difference across the recycle injection device. Effect also from the nozzle type or injection device.	Desire microbubbles; smaller bubbles better performance. Most 40–80 μm , mean of 60 μm .
η_T (total single collector collision efficiency)	Primarily affected by floc and bubble sizes. Floc size : $d_p^{-2/3}$ and d_p^2 Bubble size: d_b^{-2}	Minimum η_T for floc particles of $\approx 1 \mu\text{m}$. Flocculation should produce floc particles of 10s of μm .
Φ_b (bubble volume concentration)	Affected by recycle rate and saturator pressure.	Controlled mainly by the recycle rate. Increasing Φ_b increases collision opportunities (more bubbles or collectors) and increases bubble volume to reduce particle-bubble aggregate density.
v_b (bubble rise velocity)	Affected mainly by the size of bubbles (d^2). Effect of water temperature: decreases with viscosity for colder waters.	Describes motion of bubbles relative to the water flow in the contact zone.
t_{cz} (contact zone detention time)	Determined by the water velocity and depth of the contact zone.	In practice, detention times are in range of 1–2.5 min. Hydraulic behavior approximately plug flow.

low attachment efficiency, α_{pb} has a value $\ll 1$. From a theoretical view, α_{pb} depends on the interparticle (particle-bubble) forces: electrostatic repulsion; the van der Waals force, which for dissimilar particles (particles and bubbles) in water is repulsive; the major force of attraction, the hydrophobic force; and hydrodynamic retardation (water layer between the bubble and particle). With no coagulant addition, the particles carry a negative charge and have some hydrophilic character so that bubble attachment is poor. Proper coagulant dose and coagulation pH reduce the particle charge and give particles a more hydrophobic character so that attachment to bubbles can occur. A reasonable estimate of α_{pb} for good coagulation is about 0.5 (Schers and Van Dijk, 1992; Shawwa and Smith, 2000; Haarhoff and Edzwald, 2004). Additional discussion of the importance of coagulation in DAF treatment and some practical points are presented in the section Operational and Design Considerations for Flotation.

The contact zone equation (Eq. 9-57) is used to predict performance as a function of particle or floc size for two cases of coagulation conditions: good coagulation ($\alpha_{pb} = 0.5$) and poor coagulation ($\alpha_{pb} = 0.01$). Typical DAF design and operating conditions are set with the contact zone detention time (t_{cz}) at 1.5 min and the bubble volume concentration (Φ_b) at 7300 ppm. The contact zone bubble size is set at 60 μm and the flocs or particles have a density of 1100 kg/m^3 —a reasonable value following coagulation for low-density primary organic particles such as viruses, bacteria, protozoa cysts, and algae or flocculated particles for various water supplies containing the aforementioned primary particles, humic substances, and low mineral turbidities. The predictions are presented in Fig. 9-28. Collection of particles on bubbles occurs primarily by Brownian diffusion for small particles ($<1 \mu\text{m}$) and primarily by interception for large particles ($>1 \mu\text{m}$). For low-density particles, collection by settling is small relative to interception and can be neglected. For poor coagulation and pH adjustment, the contact zone efficiency is low for all particle sizes smaller than about 100 μm . Hence, good coagulation is essential for good DAF performance. The rest of the discussion focuses on good coagulation conditions ($\alpha_{pb} = 0.5$).

There is a minimum in the contact zone efficiency for particles with a size of about 1 μm as shown by Fig. 9-28. This is because the single-collector efficiency is low for both

FIGURE 9-28 Contact zone efficiency as a function of particle or floc size for good ($\alpha_{pb} = 0.5$) and poor ($\alpha_{pb} = 0.01$) coagulation chemistry (Conditions: detention time 1.5 min, floc density 1100 kg/m^3 , bubble size 60 μm , bubble volume 7300 ppm, temp. 20°C).

diffusion and interception; this minimum in collection efficiency also occurs in granular media filtration (see Chap. 10). The contact zone efficiency improves with decreasing particle size ($< 1 \mu\text{m}$) because Brownian diffusion increases as shown by the dependence in Eq. 9-58. However, the addition of coagulant causes flocculation of submicron particles into larger sizes approaching a micron so engineered flocculation is necessary to avoid the minimum in efficiency for $1\text{-}\mu\text{m}$ particles. From Fig. 9-28, we see that as particle or floc size increases, the contact zone efficiency improves greatly through physical interception. In fact, the dependence of η_I (interception) is roughly proportional to the particle size to the second power (d_p^2) (see Table 9-4). If we produce flocs of about $25 \mu\text{m}$, the contact zone efficiency is approximately 99 percent. Larger flocs can be produced and floated, but it is not necessary for good collision opportunities between particles with bubbles. A disadvantage of large flocs is multiple bubble attachment will be required to reduce their density sufficiently to achieve high floc-bubble aggregate rise rates for the separation zone. Plants with long flocculation times can produce flocs with a tendency to settle; this is undesirable.

An important finding from the contact zone model predictions is that the desired and optimum size of floc is about 25 to $50 \mu\text{m}$. This theory has been incorporated into DAF practice so that flocculation tanks in DAF plants are designed and operated at much shorter detention times to produce small pinpoint flocs. Sedimentation plants require flocs with sizes of $100 \mu\text{m}$ or greater and thus longer flocculation times (see the section Sedimentation Theory and Table 9-1). Practical aspects dealing with pretreatment flocculation are addressed in the section Operational and Design Considerations for Flotation.

Flotation Tank Variables. Equation 9-57 contains several variables that affect contact zone performance as summarized in Table 9-4. In terms of design and operation, the four important variables are the bubble size (d_b), the total single-collector efficiency (η_T), the bubble concentration described through the bubble volume concentration (Φ_b), and the hydraulic contact zone detention time (t_{cz}). η_T depends strongly on particle and bubble sizes. Flocculation pretreatment affects floc sizes in the contact zone and this was addressed above. Thus, the discussion here is on bubble size (d_b).

The smaller the bubble size, the better the DAF contact zone performance is. This is a primary reason why dissolved air flotation is a more efficient process than dispersed air flotation, where bubble sizes are much larger at about 1 mm . It was presented above that bubbles in the contact zone are mainly between 40 and $80 \mu\text{m}$ in diameter, with a mean bubble size of about $60 \mu\text{m}$. Although smaller bubbles improve performance just like smaller filter grains improve filtration, the bubble size is fixed mainly by the pressure difference across the recycle injection device and by the injection device. Therefore the designer ensures a good bubble size through the saturator design and selection of nozzle, and the operator has little control over bubble size other than to maintain the saturator pressure at the desired level, such as within the range of 400 to 600 kPa (~ 60 to 85 psi).

Increasing the contact zone detention time (t_{cz}) improves the contact zone performance. The designer sets this time by sizing the contact zone for the design flow. In practice, the contact zone detention time for DAF processes usually exceeds 1 min for design flows. Although the contact zone detention time is not varied directly in plant operation, you can expect shorter (design) times in the summer with greater plant flows and longer times in the winter.

The most important operating and control variable affecting DAF performance is the bubble volume concentration (Φ_b) in the contact zone. The air concentration can be changed by changing the saturator pressure (dissolving more air into the recycle flow) or by changing the recycle rate; see Table 9-3. However, the saturator pressure is not varied very much as explained earlier so the main operational way to change the bubble concentration is to increase or decrease the recycle flow or ratio (R). The plant operator, as needed, can vary the recycle rate from, say, 6 to 12 percent yielding bubble

volumes (Φ_b) from about 4500 to 8600 ppm (see Table 9-3). Haarhoff and Edzwald (2004) have shown with the model that contact zone performance is excellent when the bubble volumes exceed about 6000 ppm for a contact zone detention time of at least 1.5 min. Greater bubble volumes yield excellent performance for detention times as short as 1 min. Poor contact zone performance occurs below 1-min detention time for bubble volumes as high as 9000 ppm.

Bubble and Floc-Bubble Aggregate Rise Velocities

Bubble Rise Velocities. A 100- μm bubble is shown in Fig. 9-29a with no attached particles. Bubbles are larger in the separation zone compared to those in the contact zone of DAF tanks. A bubble of 100 μm is a good estimate of the mean size for bubbles in the separation zone (Leppinen and Dalziel, 2004; Haarhoff and Edzwald, 2004). Three forces act on the bubble: the buoyant force which dominates because the density of the air bubble is far less than water, the gravitation force, and a drag force as the bubble rises. The net result is a rise velocity (v_b) for free bubbles (no particles attached) according to Stokes' law as given in Eq. 9-62. Bubble rise velocity depends greatly on bubble diameter (d_b^2), the density difference between water and air, and the water viscosity. The driving force for the rise velocity is the density difference ($\rho_w - \rho_b$). Since water density is about 1000 kg/m^3 and bubble density is about 1 kg/m^3 , the driving force value is roughly 1000, which is much greater than the driving force for most cases of floc particle settling.

$$v_b = \frac{g(\rho_w - \rho_b)d_b^2}{18\mu_w} \quad (9-62)$$

FIGURE 9-29 Rising of a free bubble and floc-bubble aggregates. (Source: Edzwald, 2007, reprinted with permission from the Journal of the New England Water Works Association, Copyright 2009, Holliston, Mass.)

FIGURE 9-30 Bubble rise velocities at 4 and 20°C.

Figure 9-30 presents bubble rise velocities as a function of bubble diameter for cold water (4°C) and warm water (20°C) conditions. The following observations are made:

- Bubbles rise more slowly in cold water than warm water due to the greater water viscosity.
- Both small and large bubbles occur in the separation zone, but using the mean size of 100 μm as a reference case, the bubble rise rate is about 20 m/h at 20°C. This rise rate is far greater than the settling rate of 100-μm flocs, as shown in Example 9-7.

The classic form of Stokes’ law is used here with a factor of 1/18. Some people model bubble rise velocities with a factor of 1/12 attributing this to less drag (slipping condition) of the bubble as it rises through the water. Our approach of using 1/18 is conservative in that the bubble rise velocities are greater for slipping conditions.

Floc-Bubble Aggregate Rise Velocities. Figure 9-29a, b, and c shows illustrations of one free 100-μm bubble, one 30-μm particle with one attached 100-μm bubble, respectively. To determine the rise velocity of floc-bubble aggregates, one has to determine the aggregate equivalent size and density. For the general case of multiple-bubble attachment, the following three equations are used, where d_{fb} is the aggregate equivalent diameter produced from N bubbles of size d_b attached to a floc particle of size d_f and ρ_{fb} , and v_{fb} are the floc-bubble aggregate density and aggregate rise velocity. K accounts for floc shape and drag force. For spheres, K is 24 (Haarhoff and Edzwald, 2004). Here, it is assumed that K is 24 for flocs smaller than 40 μm and increases gradually to 45 at a floc size at or above 170 μm.

$$d_{fb} = (d_f^3 + Nd_b^3)^{1/3} \tag{9-63}$$

$$\rho_{fb} = \frac{\rho_f d_f^3 + N\rho_b d_b^3}{d_f^3 + Nd_b^3} \tag{9-64}$$

$$v_{fb} = \frac{4g(\rho_w - \rho_{fb})d_{fb}^2}{3K\mu} \tag{9-65}$$

Equation 9-65 is used now to calculate floc-bubble aggregate rise velocities (v_{fb}) for two cases of bubble attachment: 1 bubble attached per floc and half the maximum number of possible bubbles per floc (N_{max}). N_{max} depends on the floc and bubble areas according to Tambo and Matsui (1986), and it is calculated from Eq. 9-66. It is unlikely that the maximum number of bubbles that can possibly attach would do so; thus half that number is assumed for the multiple bubble attachment case. For flocs less than 70 μm , only one bubble is allowed to attach per floc. The number increases gradually to six bubbles per floc for flocs with equivalent sizes of 200 μm .

$$N_{max} = \left(\frac{d_f}{d_b} \right)^2 \tag{9-66}$$

What we learn from the results displayed in Fig. 9-31 (assuming no significant decrease in floc density with increase in size) follows:

FIGURE 9-31 Rise velocity of floc-bubble aggregates versus particle size for 1 bubble attachment and multiple bubble attachment ($1/2 N_{max}$) (Conditions: d_b of 100 μm ; ρ_f of 1100 kg m^{-3} , 20°C). (Source: Edzwald, 2007, reprinted with permission from the Journal of the New England Water Works Association, Copyright 2009, Holliston, Mass.)

- Aggregate rise velocities are near their maximum value (reference case for 100- μm free bubbles) of 20 m/h for flocs with sizes of 50 μm or less with just one bubble attached.
- As flocs increase in size, the rise velocity decreases approaching zero for 200- μm flocs with one bubble attached because the driving force is about zero.
- Multiple-bubble attachment is required for flocs >100 μm to achieve rise velocities of 10 to 20 m/h.

In summary, rise rates of free bubbles of 100 μm are about 20 m/h, and floc-bubble aggregates have about the same rise velocity for flocs < 50 μm with one bubble attached per floc. For larger flocs (100–200 μm), multiple-bubble attachment is required to achieve rise velocities of 10 to 20 m/h. What then is the optimum floc size for DAF? For the contact zone, it was shown that the optimum floc size is about 25–50 μm . For the separation zone, we find that

maximum rise rates of 20 m/h are achieved with one bubble attached to particles $< 50 \mu\text{m}$. Overall then, we can say that optimum floc sizes are about 25 to 50 μm .

Example 9-7 Particle Settling Velocity Versus Floc Bubble Rise Velocity

Calculate:

1. The settling velocity of a floc particle of 100 μm with a particle density of 1100 kg/m^3 for summer (20°C) and winter (4°C) water temperatures
2. The rise velocity of a 50- μm floc particle attached to one air bubble of 100 μm for the same two temperature conditions

Solution

1. *Floc settling velocity.* To solve the problem requires water density and absolute viscosity for the two water temperatures. Values are found in App. D and tabulated next.

Temp. (°C)	Density (kg/m^3)	Absolute viscosity ($\text{N}\cdot\text{s}/\text{m}^2$)
4	998.98	1.570×10^{-3}
20	998.21	1.002×10^{-3}

- a. For 20°C, from Stokes' law for settling of particles, we use Eq. 9-8:

$$v_p = \frac{g(\rho_p - \rho_w)d_p^2}{18\mu} = \frac{9.8(1100 - 998.21)(100 \times 10^{-6})^2}{18 \times 1.002 \times 10^{-3}} \frac{\text{m}}{\text{s}} \times \frac{3600\text{s}}{\text{h}} = 2 \frac{\text{m}}{\text{h}}$$

- b. For 4°C, similar calculations result in $v_p = 1.3 \text{ m/h}$.

2. *Rise velocity of 100- μm air bubble attached to floc particle of 50 μm .* To solve the problem requires water density and viscosity constants (given above) and the density of air: air densities at 4°C and 20°C are 1.27 and 1.19 kg/m^3 , from App. D.

- a. For 20°C, in order to compute the rise velocity, the equivalent diameter of the floc particle-bubble aggregate and density must be calculated. Eqs. 9-63 and 9-64 are used.

$$d_{pb} = [d_f^3 + N_{ab}(d_b)^3]^{1/3} = [50^3 + 1(100)^3]^{1/3} \mu\text{m} = 104 \mu\text{m}$$

$$\rho_{pb} = \left[\frac{\rho_p d_p^3 + N_{ab}(\rho_b d_b^3)}{d_p^3 + N_{ab}(d_b^3)} \right] = \left[\frac{1100(50)^3 + 1(1.19)(100)^3}{50^3 + 100^3} \right] \frac{\text{kg}}{\text{m}^3} = 123.3 \frac{\text{kg}}{\text{m}^3}$$

Note that the equivalent spherical diameter of the floc particle-bubble aggregate is not much larger than the bubble itself of 100 μm . This is because $d_b \gg d_f$. From Eq. 9-65, the particle-bubble agglomerate rise velocity is determined.

$$v_{fb} = \frac{g(\rho_w - \rho_{pb})d_{pb}^2}{18\mu} = \frac{9.8(998.21 - 123.3)(104 \times 10^{-6})^2}{18 \times 1.002 \times 10^{-3}} \frac{\text{m}}{\text{s}} \times \frac{3600\text{s}}{\text{h}} = 18.5 \frac{\text{m}}{\text{h}}$$

- b. For 4°C, the results are

$$\rho_{fb} = 123.4 \text{ kg}/\text{m}^3$$

$$d_{fb} = 104 \mu\text{m}$$

$$v_{fb} = 11.8 \text{ m/h} \quad \blacktriangle$$

Floc bubble aggregate rise velocities are much greater than particle settling velocities and illustrate why DAF tanks can be designed with greater hydraulic loading rates than horizontal-flow settling tanks. The next step is to evaluate these rise velocities with respect to the hydraulics of the separation zone.

Separation Zone Performance

Ideal Separation Zone with Vertical Flow and Conventional Hydraulic Loading Rates. Figure 9-32 depicts a DAF tank with an ideal separation zone analogous to an ideal sedimentation tank; see section Sedimentation Theory. The separation zone is divided into sections: (1) a float layer (sludge) at the top which is periodically withdrawn, (2) a cross-flow section above the baffle dividing the contact and separation zones where flow enters horizontally into the separation zone before moving vertically, (3) the main part of the separation zone with vertical flow and which is considered the clarification section or zone, and (4) an outlet section where water leaves the DAF tank.

FIGURE 9-32 Idealized DAF tank showing separation zone divided into four sections: float or sludge layer, cross-flow section where flows moves horizontally before moving vertically, vertical flow section for clarification, and the outlet.

This idealized clarification zone with vertical flow is considered for evaluation of separation zone performance, in which we compare the hydraulic loading or upward water velocity through the clarification zone to the rise velocities of bubbles and floc bubble aggregates. The theory is similar to the Hazen concept used in sedimentation tank design in which the sedimentation tank overflow rate is used; see section Sedimentation Theory, Eq. 9-23b. For DAF, it is called the hydraulic loading rather than the overflow rate. In addition to the idealized separation zone described, there are several assumptions and conditions used.

- Vertical plug flow through the main part of the separation zone; the horizontal flow near the top of the tank is ignored in evaluating performance.
- This flow structure is assumed for conventional DAF with nominal hydraulic loading rates of 5 to 15 m/h (2 to 6 gpm/sf).

- The area for clarification called the separation zone area (A_{sz}) is the separation zone surface or footprint area, and for the common rectangular DAF tank is the separation zone length (L) times width (W).
- The flow through the separation zone is the sum of the throughput flow (Q) plus the recycle flow (Q_r).
- The hydraulic loading is $(Q + Q_r)$ divided by the separation zone area (A_{sz}), and for vertical flow equals the downward average water velocity (v_w) or v_{sz-hl} .

In evaluating DAF separation zone performance, it is essential to distinguish the separation zone hydraulic loading from the nominal DAF tank hydraulic loading; the latter is defined by Eq. 9-67 as the throughput flow (Q) divided by the gross footprint DAF tank area (A) that includes the contact and separation zones.

$$v_{nom-hl} = \frac{Q}{A} \quad (9-67)$$

To assess the separation zone clarification performance, we must consider the throughput and recycle flows and use the separation zone area. As depicted in Fig. 9-32, free bubbles are removed if their rise velocity is greater than the vertical water velocity or hydraulic loading according to Eq. 9-68. Similarly, floc bubble aggregates are removed if their rise velocity exceeds the hydraulic loading according to Eq. 9-69.

$$v_b \geq v_{sz-hl} = \frac{Q + Q_r}{A_{sz}} \quad (9-68)$$

$$v_{fb} \geq v_{sz-hl} = \frac{Q + Q_r}{A_{sz}} \quad (9-69)$$

In the prior section it was found that free bubbles (reference size of 100 μm for the separation zone) have rise velocities of about 20 m/h, and maximum rise rates of about 20 m/h are achieved for floc-bubble aggregates with one bubble attached to floc particles $< 50 \mu\text{m}$. Therefore, removals of these bubbles and aggregates occur for separation zone hydraulic loadings (see Eqs. 9-68 and 9-69) less than 20 m/h. Example 9-8 shows that DAF processes with nominal conventional loading rates of 5 to 15 m/h have separation zone hydraulic loadings less than 20 m/h and are therefore effective in removing bubbles and floc-bubble aggregates.

Example 9-8 Separation Zone Hydraulic Loading and Area

In this example consider a DAF process with a nominal hydraulic loading of 15 m/h. The recycle rate is 10 percent.

1. Calculate the separation zone hydraulic loading assuming the separation zone footprint area is 90 percent of the gross footprint area, and compare it to bubble and floc bubble aggregate rise velocities.
2. Determine the separation zone area for a design flow of 37,850 m^3/d (10 mgd).

Solution

1. *Separation zone hydraulic loading.* This is calculated simply by recognizing that the flow is 10 percent greater due to the recycle flow and the separation zone area is 90 percent of the gross tank area. Thus, we obtain

$$v_{sz-hl} = v_{nom-hl} \left(\frac{1.1}{0.9} \right) = 15 \left(\frac{1.1}{0.9} \right) = 18.3 \text{ m/h}$$

Good performance is expected because bubbles and floc-bubble aggregates with rise velocities of 20 m/h will be removed.

2. *Separation zone area.* This is obtained using the separation zone hydraulic loading of 18.3 m/h and solving for A_{sz} using either Eq. 9-68 or 9-69.
- 3.

$$v_{sz-hl} = \frac{Q + Q_r}{A_{sz}}$$

Solving for A_{sz} , we get

$$A_{sz} = \frac{Q + Q_r}{v_{sz-hl}} = \frac{(37850 + 3785)}{18.3} \frac{\text{m}^3/\text{d}}{\text{m}^3/\text{m}^2 \text{ h}} \left(\frac{\text{d}}{24\text{h}} \right) = 94.8 \text{ m}^2$$

If we choose a L/W ratio of 1.3, then the separation zone L is 11 m and W is 8.5 m. ▲

High-Rate DAF Systems. High-rate systems are available from several equipment companies with nominal hydraulic loading rates of 15 to 30 m/h (6 to 12 gpm/sf). According to the theory presented above, these systems would not remove bubbles and floc-bubble aggregates with rise velocities of 20 m/h and less, yet high-rate systems have been built and work. The primary reason the high-rate systems work is that the flow pattern is not the simple vertical flow structure depicted in Fig. 9-32. The flow patterns are more complex and contribute to their ability to remove bubbles and aggregates at these high rates. This is addressed in the next section.

OPERATIONAL AND DESIGN CONSIDERATIONS FOR FLOTATION

Conventional and High-Rate DAF Systems

Conventional rate and high-rate DAF systems are classified by the nominal hydraulic loading rate defined as the throughput plant flow divided by the footprint area of both the contact and separation zones; see Eq. 9-67. Conventional rate systems fall within design hydraulic loadings of 5 and 15 m/h (2 and 6 gpm/sf), whereas high-rate DAF is normally in the range of 15 to 30 m/h but can be greater. Table 9-5 shows a summary of the ranges of values for conventional and high rate DAF systems. The values in Table 9-5 serve as guidance and are used below in discussing various design and operating considerations. It is noted at the outset that there is essentially no difference between conventional rate and high-rate DAF with respect to pretreatment flocculation, recycle and saturator systems, and the method of collecting the float or its sludge characteristics. The main differences between the two systems are DAF contact zone and separation zone loading rates. The DAF separation zone is where free bubbles and floc-bubble aggregates rise to the surface. The separation zone efficiencies for removals of free bubbles and aggregates depend on the separation zone hydraulic loading rate. Note from Table 9-5 that the separation zone loadings for high-rate DAF range typically from 20 to 40 m/h (some greater). However, it is not only the separation zone hydraulic loading rate that affects performance (see below); otherwise the systems would not work. Another difference for some high-rate DAF systems pertains to the basin length/width ratio; some systems have a ratio of 1 or less. Some high-rate systems also use a deeper tank as noted in Table 9-5.

TABLE 9-5 Comparison Between Conventional Rate and High-Rate DAF (Common Range of Values*)

Item	Conventional rate	High rate	Comments
Pretreatment flocculation			
Mean detention time (min)	10–20	10–15	Some as low as 5 and some at 20–30 min.
Number of stages	2		Some with 3 stages.
Mixing intensity (G) (sec ⁻¹)	50–100		Some as low as 30 and some as high as 150 sec ⁻¹ . Propeller or Gate Flocculators used. Some use of tapered flocculation. Some use of hydraulic flocculation.
DAF tank			
Hydraulic loading rate (m/h)	5–15	15–30	Some high-rate DAF as high as 40 m/h. Based on the throughput flow only and the combined footprint area of the contact and separation zones. Some high-rate systems have plates or tubes placed at the bottom of the separation zone.
Contact zone loading rate (m/h)	100–200	120–300	With about 10% recycle.
Contact zone detention time (min)	1–2.5	1.0–2.0	Some high-rate DAF < 1 min.
Separation zone loading rate (m/h)	6–18	20–40	Some high rate DAF at 40–50 m/h. Based on the throughput flow and 10% recycle.
Basin length/to width ratio	1.0–2.0		Some high-rate DAF as low as 0.5 and as high as 2.5.
Basin depth (m)	2.0–3.5	2.5–4.5	Some high-rate DAF as deep as 5 m.
Recycle and saturator systems			
Air mass (g/m ³)	6–10	6–11	
Recycle rate %	6–12		10% most typical.
Saturator gauge pressure (kPa)	400–600		Higher pressures for unpacked saturators.
Saturator efficiency (%)	80–95 packed		Higher efficiencies for higher temperatures. Unpacked saturators: 50–70%
Bubble size (µm)	10–100		Depends on saturator pressure and recycle injection device. Common range of 40–80 µm.
Floated sludge			
Hydraulic removal	0.2–1 % solids		
Chain and Flight or reciprocating skimmer	2–3 % solids		Some as high as 5%.
Beach drum	1–3 % solids		Also called star wheel, sludge roller, and flipper.

*Values are a composite obtained from Enpure Ltd. (UK), ITT WWW Leopold (USA), Hazen and Sawyer P.C. (USA), Infilco Degremont, Inc. (USA), Läckeby Water AB, Purac Division (Sweden), and Insinöörtoimisto OY Rictor AB (Finland). In some cases, particular companies design outside the reported values.

During the last 10 years high-rate DAF systems have been developed and introduced into water plant practice at nominal hydraulic loadings of 15 to 30 m/h and greater. Edzwald et al. (1999) demonstrated through pilot studies that DAF can operate at high hydraulic loadings. Their data showed good DAF performance at hydraulic loadings in the range of 20 to 40 m/h with pretreatment flocculation times of only 5 min. Several process equipment companies have developed high-rate DAF systems. These companies include Rictor (Insinööritoimisto OY Rictor AB [Finland]), Purac (Läckeby Water AB, Purac Division, Sweden), Enpure Ltd. (UK) with a system called Enflo-vite® in the United States or DAFRapide® in the United Kingdom, and Leopold with a system called Clari-DAF®. The Rictor Company refers to their process as Turbulent Flotation. The technology is available by license to Infilco Degrémont, and is known by the trade name of AquaDAF®. Figure 9-33 shows a high-rate system available from Enpure.

FIGURE 9-33 Schematic of a proprietary high rate DAF. (Courtesy of Enpure Ltd., UK: Enflo-vite® from Enpure—here fitted with outlet tubes and plate system.)

How is it that high rate DAF processes can perform efficiently at separation zone hydraulic loadings of, say, 40 m/h if free bubble and floc-bubble aggregate rise velocities are about 20 m/h (see theory on rise velocities)? The answer is that it is not just the hydraulic loading in which one assumes simple vertical flow through the separation zone as depicted in Fig. 9-32. This assumes simple plug flow downward through the separation zone so that the clarification area and separation zone area are the same, but this flow pattern does not occur especially for high-rate DAF. DAF tanks, especially those with higher hydraulic loadings exhibit stratified flow (Lundh et al., 2000) in which the flow moves horizontally near the top of the separation zone to the end wall and then returns below this in a horizontal layer, and then may again reverse direction before proceeding to the exit at the tank bottom. A simple and idealized illustration of this stratified flow is presented in Fig. 9-34. In this illustration the flow pattern effectively triples the clarification separation area. Thus, the clarification loading rate is 1/3 the footprint loading rate so a 40 m/h footprint loading rate is a clarification loading rate (as a first estimate) of 13.3 m/h. Therefore, bubbles and floc-bubble aggregates with rise rates greater than 13.3 m/h are removed. In general then, the stratified flow produces hydraulic flow patterns that effectively increase the clarification area for separation of free bubbles and floc-bubble aggregates and is analogous to increasing the clarification area in settling tanks with plates or tubes but without these physical devices. Some companies have provision for

FIGURE 9-34 Idealized stratified flow in the separation zone for high rate DAF.

placing tubes or plates near the bottom of the separation zone (Enflo-vite[®] or DAFRapide[®]) as depicted in Fig. 9-33 for industrial applications, but this is not commonly used for drinking water. The plates or tubes improve the flow patterns in the separation zone and would increase the clarification area if at high rates the bubble blanket reaches the tubes or plates. Several papers were presented on these high-rate DAF systems at the international flotation conferences in Helsinki (2000) and in Seoul (2007).

Types of Flotation Tanks

Circular Tanks. Circular tanks are used mainly in small flotation plants treating wastewater or for sludge thickening applications that require no preflocculation prior to flotation. For potable water treatment, a preflocculation stage is typically required prior to flotation to flocculate the impurities present in water to form agglomerates suitable for removal by flotation. For circular tanks the transfer of the flocs to the flotation tank without breakage creates problems. In larger plants the flocculated water must be introduced close to the bottom of the center section of the flotation tank to achieve even distribution. As a result, most large flotation plants for water treatment use rectangular tanks. However, small and large flotation package plants have been built where flocculation and flotation are contained within the same circular tank.

Rectangular Tanks. Rectangular flotation tanks offer advantages in terms of scale-up, simple design, easy introduction of flocculated water, easy float removal, and a relatively small area requirement. Typical design features are summarized in Table 9-5. Many tanks are equipped at the inlet with an inclined baffle (60° to the horizontal) to direct the bubble-floc agglomerates toward the surface and to reduce velocity extremes in the water entering the separation zone in order to ensure minimum disturbance of the float layer accumulating on the water surface. Some facilities are designed with a baffle at 90°, especially those with flotation over filtration. The gap between the top of the baffle and the water surface should be designed to achieve a horizontal water velocity similar to the velocity in the top section of the baffle area. However, the size and nature of design features such as these will continue to be challenged as investigational tools and computational fluid dynamic (CFD) modeling are developed.

Maximum tank size is determined by hydraulic conditions and the design of the sludge removal system. Tanks with surface areas in excess of 80 m² (860 ft²) are in operation with conventional surface loadings. Detention time in the flotation tank depends on tank depth but generally times are 10–20 min for conventional and high-rate DAF (Table 9-5). The

flotation tank must be covered because both rain and wind can cause breakup of floated solids and because freezing of the float can cause problems. Treated water should be withdrawn, preferably via a full-width weir, to maintain uniform hydraulic conditions and to minimize changes in water level because of variations in flow through the plant.

Countercurrent Flotation. The basic design of dissolved air flotation has some analogy to horizontal-flow sedimentation, with flocculated water entering one end of a tank where it is mixed with dissolved air, followed by separation in a horizontal dimension. One radical reappraisal of the concept of dissolved air flotation concluded that since flotation is mainly in the vertical dimension, then flow through the flotation tank should be the same. This led to the CoCoDAF[®] design (CoCoDAFF[®] when combined with filtration, Fig. 9-35). In this

FIGURE 9-35 Typical arrangement of a CoCoDAFF[®] unit. (Courtesy of Thames Water and Paterson Candy Ltd, Isleworth, UK.)

design, the DAF tank bears more resemblance to an upflow floc blanket clarifier in contrast to a normal DAF tank having similarities with a horizontal-flow sedimentation tank. In the CoCoDAF[®] design, the flocculated water is introduced above the recycle, uniformly across the area of the tank, so that the water flows down through the rising bubble cloud to the treated water outlet, or to the filter bed as in CoCoDAFF[®].

Combined Flotation and Filtration. The combination of flotation and filtration was developed in Sweden (Zabel and Melbourne, 1980) in the 1960s–1970s and now is widely used around the world. The system is sometimes called simply flotation over filtration.

A dual media anthracite-sand filter or sand filter is incorporated in the lower section of the flotation tank. The flotation hydraulic loading rate for the plant is, however, limited by the filtration rate that can be achieved. It is also possible to apply the concept to existing filters, of appropriate dimensions, by retrofitting the dissolved air flotation equipment.

Flotation over filtration has major advantages of a compact water plant (small footprint area) and cost savings. The compactness of the system makes it particularly suitable for package plants and is thus a good application for plants with flows less than 4 ML/d (~1 mgd). However, because of the advantage of a small plant footprint, this system has also been adapted in the last 15 years for large water plants that have land constraints. One example is the water plant in Fairfield, Connecticut in the United States that has been in operation since 1997. It is a 190-ML/d plant with a nominal flotation-filtration loading rate of 15 m/h. The performance of this plant is described in *Performance of Dissolved Air Flotation Plants*, showing that DAF plants with flotation over filtration perform as well as those with separate processes. One of the world's largest DAF plants is being built within the city limits of New York, and this plant is flotation over filtration (DAF/F) (Crossley et al., 2007). The plant is scheduled for commissioning in 2011 or 2012. The flotation and filtration rates will be 12.2 m/h and 15.9 m/h, respectively, treating Croton Reservoir water which has low turbidity (0.6–3.6 ntu), low color (true color of 2–20 cu), low TOC (2.2–4.3 mg/L), and low to moderate alkalinity (40–70 mg/L CaCO₃).

Water plants with flotation over filtration have a smaller plant footprint, thereby reducing the land area, which is a significant advantage for large cities with limited land areas. There is also a construction cost savings of having one structure for flotation and filtration compared to conventional rate plants with separate units. There are two drawbacks for such a system. First, flotation and the filters cannot be independently designed and operated. Thus, the flotation unit is limited to conventional loading rates. A second drawback is that one loses the option of placing an ozonation process between DAF and filtration.

The tank depth of a flotation-filtration unit tends to be deeper compared to a separate flotation unit to accommodate the filter media and underdrains. In addition, the flow to the unit has to be stopped periodically to facilitate cleaning of the filter that is backwashed in the normal way by air scour and water wash. This can be accommodated by having several treatment trains, so that with one out of service, the flow into the plant is reduced to maintain constant loadings on the other trains and the coagulant feed adjusts to the reduced flow. However, as with a bank of filters, providing there are at least four treatment units then when one is isolated for washing, or maintenance, the flow to the others can be ramped up so that there is no change in total flow.

Air Saturation Systems

For an efficient packed-column saturator system, the energy used for air compression is about 5 to 10 percent of that used for recycle water pumping. When efficiency is poor, the air compression can account for a much greater proportion of the power cost of producing the saturated recycle. Therefore, optimization of the recycle system design is important in minimizing operating costs.

Various methods are employed for dissolving air under pressure in the recycle stream. These include sparging the air into the water in a pressure vessel, or saturator; trickling the water over a packed bed; spraying the water into an unpacked saturator; entraining the air with eductors; and injecting the air into the suction pipe of the recycle pump (Fig. 9-36) (Zabel and Melbourne, 1980). The packed column is probably the most widely implemented method.

Introducing the air to the recycled water either on the suction side of the recycle pump or through eductors before entering the saturation vessel leads to substantially higher pumping costs compared with using a separate compressed-air supply, although capital cost and footprint might be smaller. Relatively efficient self-aspirating pumps

FIGURE 9-36 Different air saturation systems.

have been developed to be suitable for DAF without the need for saturator vessels. Although their operating cost (kW-h/kg air) is greater than for a packed saturator system, the capital cost and footprint are smaller. Consequently, the net present cost of self-aspirating pump systems can be less than for a packed-column system and are attractive where space is limited.

A possible disadvantage of using packing is the danger of blockage caused by biological growth or other precipitates. A problem with iron precipitates has been encountered in a few plants treating drinking water. Fouling of packing can be avoided by recycling filtered water rather than clarified water.

Extensive research has been carried out on optimizing the design of packed saturators (Rees et al., 1980b; Casey and Naoum, 1986). It has been shown that saturators can be operated over a range of hydraulic loadings of 12.5 to 104 m/h (36 to 274 ft/h or 5 to 30 gpm/ft²) without any decrease in saturation efficiency. A packing depth of 0.8 m (2.6 ft) with 25 mm (1 in.) polypropylene rings is sufficient to achieve greater than 90 percent saturation (Fig. 9-37) (Rees et al., 1980b). This packing depth, however, was substantially higher than the 0.3 m (1 ft) reported elsewhere (Bratby and Marais, 1977). The theory of saturators for flotation has been examined extensively (Haarhoff and Rykaart, 1995; Haarhoff and Steinbach, 1996; Haarhoff and Steinbach, 1998; Valade et al., 2001).

FIGURE 9-37 Effects of packing depth on air dissolution.

In terms of operating costs, an unpacked saturator must be operated at a pressure of about 200 kPa (30 psi) above that of a packed saturator in order to supply the same amount of air to the flotation tank (Zabel and Hyde, 1977). Water saturated with air under pressure is corrosive. If mild steel is used for construction of the saturation vessel, a corrosion-resistant lining should be provided. Stainless steel or plastic pipes should be used for connecting pipe work between the saturator and flotation tank.

Factors Influencing Dissolved Air Efficiency

The reader is referred to the section Fundamentals of Dissolved Air Flotation for presentation of the principles regarding the variables that affect dissolved air flotation performance or efficiency. For the contact zone efficiency (i.e., the efficiency of collisions and attachment of particles to bubbles), the important variables are coagulation, floc size, bubble size, contact zone detention time, and bubble volume concentration; see Table 9-4 for a summary. For the separation zone efficiency (i.e., removal efficiencies of free bubbles and floc-bubble aggregates by rising to the top of separation zone), the fundamental variables affecting rise

velocities are bubble size, bubble-floc aggregate size, number of bubbles attached to each floc, floc-bubble aggregate density, and water temperature. Practically, the separation zone efficiency relates rise velocities to separation zone hydraulic loading rates. In the following material, some practical factors influencing DAF efficiency are discussed.

Coagulation. Coagulation is a chemical addition step. Metal coagulants such as alum, polyaluminum chlorides, and ferric salts are commonly used. Some water plants in the United States use two primary coagulants: a metal coagulant and a highly charged organic cationic polymer. Coagulation has two purposes: to destabilize particles present in the raw water and to convert dissolved natural organic matter (NOM) into particles. The latter purpose of coagulation is a technology control strategy to remove NOM, thereby reducing TOC and disinfection by-product precursors. This has become an important coagulation objective in water treatment, not only for supplies with moderate to high concentrations of color and TOC but also for supplies with small amounts.

In the contact zone of the flotation tank, collisions occur between bubbles and floc particles. Coagulation is essential to ensure attachment of bubbles to flocs when collisions occur. Without coagulation, the particles carry a negative charge and are often hydrophilic so that bubble attachment is poor. Good coagulation chemistry depends on coagulant dose and pH. Optimum coagulation conditions are those of coagulant dose and pH which produce flocs with charge near zero and with relatively high hydrophobicity. These optimum coagulation conditions cause high bubble attachment efficiency.

The coagulants that are effective for flotation are the same that are used in sedimentation plants. Coagulant selection depends not on flotation per se, but on raw water quality factors of turbidity, NOM concentration (TOC, DOC, UV [254 nm] absorbance, color) and composition, and alkalinity as well as water temperature. Other considerations in coagulant selection are sludge production and overall costs that consider not only the coagulant cost but also costs from dosing of pH control chemicals and sludge handling and disposal. Local water plant preference and availability of coagulants also affect coagulant selection.

Figure 9-38 illustrates the effect of coagulant dose on flotation efficiency for the removals of DOC and turbidity. Electrophoretic mobility (EPM) data are presented as an indicator of floc charge. Figure 9-38 shows clearly that underdosing of coagulant is associated with negative particle charge and poor particle removal as shown by the small difference in turbidities before and after flotation. Minimum turbidity after flotation is associated with a floc charge of about zero and with good removal of organic matter, both DOC and UV (254 nm).

In practice, measurements of particle charge and hydrophobicity are not needed to determine optimum coagulation conditions. Coagulant dosing may be evaluated using standard sedimentation or flotation jar test apparatus (see Chap. 8) in which the optimum dose is that which produces low turbidity and low NOM measured as DOC or UV (254 nm) as a surrogate of NOM. Favorable pH conditions that produce floc charge at the optimum dose and minimize residual soluble coagulant metal depend on the specific coagulant. Guidance on favorable coagulation pH conditions follows for water supplies containing turbidity and DOC of low or moderate (2–6 mg/L) to high (> 6 mg/L) concentrations. For alum, optimum pH is 6 to 7 depending on water temperature (for warm waters, lower pH near 6 is optimum) for low or moderate levels of DOC whereas for high DOC waters, favorable pH conditions are in the mid 5s to low 6s. For PACls of medium to high basicity (see Chap. 8 for PACl characterization), favorable pH conditions are similar to alum but with less dependence on water temperature. For ferric coagulants, favorable pH conditions are in the mid 5s to low 6s for moderate DOC waters whereas for high DOC waters lower pH of low 5 to about 6 is best. Some water plants with very high DOC (say, > 10 mg/L) actually practice coagulation with alum and ferric salts at lower pH values than given above. Water supplies of moderate to high alkalinity that practice coagulation above pH 7 must add additional coagulant or

FIGURE 9-38 Effect of polyaluminum chloride dose on the electrophoretic mobility (EPM: indicator of charge) of flocs and flotation performance for turbidity and natural organic matter (Conditions: high basicity PACI at constant coagulation pH of ~5.5, 4°C, 5 mg/L TOC of fulvic acid, and low initial turbidity). (Source: Edzwald and Malley, 1990.)

acid to reach the desired pH or use higher doses to make up for the unfavorable pH conditions. Water supplies containing turbidity and low DOC, especially low in aquatic humic matter, can achieve optimum coagulation with smaller chemical doses and over a wider pH range than presented here.

Coagulant dosing for turbidity and NOM is fundamentally the same for flotation and sedimentation processes. Optimum coagulant doses and pH conditions are generally the same. An exception is that lower coagulant doses for DAF than for sedimentation processes may be found in treating high-quality waters of low turbidity and low to moderate levels of NOM. This is because in sedimentation the ability to form large-size flocs for settling depends on the floc particle concentrations. To achieve rapid flocculation and aggregation of flocs into large sizes often requires adding additional coagulant to increase precipitated solids (additional sweep floc), thereby increasing the rate of flocculation (see Chap. 8). Large-size flocs are not required for DAF so additional coagulant dosing for these type water supplies is not necessary.

Another important difference is that flotation does not normally require addition of high-molecular-weight polyelectrolyte flocculants. There are some exceptions where water plant operators have found that small amounts of high-molecular-weight polymers improve retention of the floated sludge.

Chemicals must be thoroughly and rapidly mixed with the raw water. If both a coagulant and a pH adjustment chemical are required, good mixing of the first chemical with the source water should be completed before the addition of the second chemical. This is particularly

important when treating soft waters with high DOC. The order of chemical addition can be important if stress conditions of high flow, low water temperature, or poor raw water quality occur. The order of addition can be established through jar tests and plant trials.

Flocculation. Before coagulated particles and NOM can be removed successfully by flotation, flocculation into larger agglomerates (floc) is required. Flocculation time, degree of agitation, and the means of providing agitation affect flotation performance. Flocculation for flotation has a different objective than for sedimentation. Whereas clarification by settling requires flocs with sizes of 100 microns and larger, flotation is effective with smaller floc particles. In DAF, particles with sizes of about 1 μm are not collected efficiently by bubbles so larger flocs are desired but not too large since floc particles larger than about 100 μm require multiple-bubble attachment to achieve high rise rates. Therefore, the theory presented in the section (Fundamentals of Dissolved Air Flotation) predicts optimum floc sizes for DAF are 25 to 50 μm , much smaller flocs than for sedimentation processes.

Flocculation Time. The flocculator usually consists of a tank subdivided by partial baffles into two equal-sized compartments or stages in series each agitated by slow-moving paddles or propeller units; see Table 9-5. Additional compartments can be used, but this is usually not cost effective. The flocculation time required differs with the type of raw water being treated, coagulant being used, and water temperature. Table 9-5 shows common design ranges of flocculation times of 10–20 min for conventional rate DAF and 10–15 min for high-rate DAF systems; however, there has been a dramatic decrease in flocculation times used in practice over the last 20 years, so for new plants flocculation times of about 10 min are often used for both conventional and high-rate DAF systems. Even shorter times such as 5 min may be feasible if demonstrated through pilot studies as was done for the Croton water plant for New York City. In a pilot study done on the Gothenburg (Sweden) water supply, Valade et al. (1996) showed both good DAF and filtration performance with a flocculation time of only 5 min treating water under very cold water temperatures of about 2°C (see Table 9-6).

Degree of Agitation. Besides the flocculation time, the degree of agitation is also important for efficient flocculation. Propeller-type units have become favored since their introduction (Franklin 1997), although gate (paddle) flocculators are still used and were widely used in the past. To avoid excess shear, which prevents adequate floc growth, the tip speed of the paddles should not exceed 0.5 m/s (1.6 ft/s).

The degree of agitation can be expressed by the mean velocity gradient G (see Chap. 8). Tests have indicated that the optimum mean velocity gradient for flotation is about 70 s^{-1} independent of the type of surface water treated (Rees et al., 1979). This compares with

TABLE 9-6 Comparison of the Effect of 5 and 20 min Flocculation on Flotation and Filtered Water Turbidity and Particle Numbers for Cold Water (From work by Valade et al. 1996)

Sample	Flocculation time*			
	5 min		20 min	
	Turbidity (ntu)	Part. #/mL (2–200 μm)	Turbidity (ntu)	Part. #/mL (2–200 μm)
Raw water	1.0	2,040	0.9	4,010
Floc. effl.	6.7	18,480	6.9	14,010
DAF effl.	1.0	1,620	0.8	1,530
Filter effl.	0.01	6	0.04	12

*Conditions: 5 min floc time: ferric sulfate 5.7 mgFe/L, water temp. 2.1°C, recycle 6%; 20 min floc time: ferric sulfate 5.1 mgFe/L, water temp. 5.8°C, recycle 9%. Common conditions: three-stage flocculation G of 70 sec^{-1} , DAF loading 8 m/h (3.3 gpm/ft²), dual-media filters loading, 10 m/h (4.1 gpm/ft²).

an optimum G value for horizontal sedimentation of between 20 and 100 s^{-1} . Valade et al. (1996) found that flotation performance, using either gate or propeller units for flocculation, was affected little by G in the range 30 to 70 s^{-1} . However, there may need to be a minimum degree of agitation in flocculators to prevent settlement of floc in the flocculators or short-circuiting through the tanks. It is also important to produce relatively small and compact flocs to avoid floc breakup when the air is introduced.

Values of Gt between 40,000 and 60,000 are usually considered necessary for efficient flotation. However, the move toward short flocculation times is showing that Gt values less than 20,000 can be effective (Valade et al., 1996).

Hydraulic Flocculation. An alternative approach to mechanical flocculation is the use of hydraulic flocculation in which the energy required for flocculation is provided by the water flowing through the flocculator, which can be a baffled tank. Tests have shown that one-half the flocculation time with a higher G value (150 s^{-1}) was required for hydraulic flocculation compared with mechanical flocculation ($G = 70\text{ s}^{-1}$) (Fig. 9-39) (Rodman, 1982). The difference in G value required is probably due to the more uniform velocity distribution in the hydraulic flocculators, thus avoiding excess shear and floc breakup. However, from these results the Gt value for efficient flotation is independent of whether hydraulic or mechanical flocculation is employed.

FIGURE 9-39 Comparison of hydraulic and mechanical flocculation for flotation. (Source: Rodman, 1982.)

Quantity of Air Required for Flotation. The quantity of air supplied to the flotation tank can be varied by altering the saturator pressure or the amount of recycle or both. Valade and Crossley (1998) concluded that maintaining operating pressure and changing recycle rate is the most energy-efficient way of changing air dose. If a fixed orifice is used for controlling the injection of recycle, an increase in saturator pressure is associated with a small increase in recycle rate. Thus, different nozzle sizes require different combinations of flow and pressure to deliver the same amount of air.

Experiments varying the recycle rate by using different nozzle sizes and saturator pressures have shown that treated water quality is dependent on only the total amount of air supplied, not the pressure and recycle rate employed (Fig. 9-40) (Rees et al., 1979). This confirmed earlier work by Bratby and Marais (1975).

The quantity of air required for treatment of surface waters depends only on the total quantity of water treated and is independent of the suspended solids present, unless the suspended solids concentration is very high ($>1000\text{ mg/L}$). The air/solids ratio required for surface water treatment is approximately 380 mL of air per gram of solids for a

FIGURE 9-40 Effect of quantity of air added and nozzle size on flotation treated water quality. (Source: Rees et al., 1979.)

solids concentration in the raw water of 20 mg/L: this corresponds to a bubble volume concentration of 7600 ppm (see the section Fundamentals of Dissolved Air Flotation and Example 9-6). It is much higher than for activated sludge thickening, where 15 to 30 mL of air per gram of solids is required (Maddock, 1977). The large air/solids ratio required for treatment of surface water with low turbidity is probably necessary to ensure adequate collisions and attachment between floc particles and air bubbles before separation.

With a packed saturator, an operating pressure of between 350 and 420 kPa (50 and 60 psi), and a recycle rate of between 7 and 8 percent corresponding to about 8 to 10 g air/m³ water treated were found adequate for optimum performance (Rees et al., 1979). Subsequent experience has shown this generally to be the case, although with lower efficiency saturators and warm waters the yield of dissolved air may be less.

Fundamentally, volume concentrations of bubbles are more important than mass concentrations. Larger volume concentrations lead to greater collision rates with particles and thereby produce densities of particle-bubble aggregates that are much less than water (see Examples 9-6 and 9-7).

Air-Release Devices. Different types of pressure release devices are employed ranging from proprietary nozzles and needle valves to simple gate valves. To achieve effective air release, the pressure should be reduced suddenly and highly turbulent conditions should exist in the device. The velocity of the recycle stream leaving the pressure-reduction device should be low enough to prevent floc breakup. As water passes through the pressure-release devices at high velocities and as air is released, erosion and cavitation can occur, and so the devices should be made from stainless steel or plastic. For larger plants a number of these devices, usually at a spacing of approximately 0.3 m (1 ft), are used to obtain good mixing and distribution between the flocculated water and the air bubbles. Good mixing of the recycle stream containing the released air bubbles with the flocculated water stream is also essential to facilitate contact between bubbles and floc.

Releasing the pressure of the recycle stream close to the point of injection into the flocculated water is important to minimize coalescence of air bubbles or premature release of air in the recycle prior to injection, which could result in a loss of bubbles available for flotation.

An air injection nozzle was patented and developed (Brit. Pat., 1976) that consists of two orifice plates, to reduce the pressure and to create turbulence, and a shroud section, to decrease the velocity of the stream of recycled water before it is mixed with the flocculated water. The size of the first orifice plate, which is the smaller, controls the amount of recycled water added to the flotation tank. More than 95 percent of the bubbles produced

by the nozzle were in the size range 10 to 120 μm , with a mean size of about 40 μm . A comparison of the proprietary nozzle and a needle valve showed that the nozzle produced smaller air bubbles; however, both devices achieved similar flotation treated water quality (Rees et al., 1979).

Because the production and size of air bubbles are important, considerable attention has been given to understanding and improving nozzle design (Van Craenenbroeck et al., 1993; van Puffelen et al., 1995; Heinänen et al., 1995; Rykaart and Haarhoff, 1995; Offringa, 1995; Franklin, 1997). These investigations have demonstrated that orifice diameter, impingement distance, and other features are important in efficient production of bubbles of the preferred mean size and size range. Franklin (1997) found that small improvements in flotation efficiency could be obtained through changes to nozzle design and bubble size. In general, the size and number of bubbles produced is primarily a function of the energy available, which is not otherwise dissipated in turbulence and friction; the higher the nozzle back-pressure the smaller the bubble size (Jackson, 1994; Rykaart and Haarhoff, 1995).

Float Removal. The sludge that accumulates on the flotation tank surface, called *float*, can be removed either continuously or intermittently by flooding or mechanical scraping. Flooding involves raising the water level in the flotation tank sufficiently by closing the treated water outlet or lowering the sludge beach to allow the float and water to flow into the float collection trough. The flooding method has the advantages of low equipment costs and minimal effect on the treated water quality, but at the expense of high water wastage (up to 2 percent of plant throughput) and low sludge solids concentration (less than 0.2 percent) although concentrations of 0.5–1 percent should be possible. Therefore, with this float removal method, one advantage of flotation—the production of sludge with a high solids concentration—is lost.

The most widely used mechanical float removal devices are of two types: (1) part or full-length scrapers usually with rubber or brush blades that travel over the tank surface and push the float over the beach into the collection channel and (2) beach scrapers that consist of a number of rubber blades rotating over the beach.

As float is removed from the beach, float from the remainder of the flotation tank surface flows toward the beach. The beach scrapers, especially if operated continuously, have the advantage of reducing the danger of float breakup during the removal process because the float is minimally disturbed. Beach scrapers are also of simpler construction compared to full-length scrapers. They have the disadvantage, however, of producing relatively thin sludges (1 to 3 percent; see Table 9-5), because thicker sludge will not flow toward the beach. If a part- or full-length scraper is used, selecting the correct frequency of float removal and travel speed of the scraper is important to minimize deterioration in treated water quality because of float breakup. When optimized they can achieve solids concentrations of 2–3 percent.

Effect of Air/Solids Ratio on Float. In water treatment, the aim is to produce water of good quality, and thickness of the float is of secondary importance. In general, the thicker the float, which means the longer the float is allowed to accumulate on the tank surface, the more severe will be the deterioration in treated water quality during the float removal process. The variations in air/solids ratio, produced by varying the amount of air added to the system, has no influence on the float concentration produced.

Influence of Source Water on Float Characteristics. The characteristics of float obtained from the treatment of different source waters vary considerably (Rees et al., 1979). Therefore, the most appropriate float removal system must be selected for the source water being treated. For example, experience has shown that for cases in which a low-alkalinity, highly colored water was treated, the float started to break up after only 30 min of accumulation. The most appropriate device for such an application is a full-length scraper operating at a removal frequency and blade spacing that does not allow the float to remain on the flotation

tank surface for longer than 30 min. The optimum scraper speed for this application, in terms of treated water quality and float solids concentration, was 30 m/h (0.028 ft/s), producing a sludge of 1 percent solids concentration. An alternative strategy with such quality float might be to strengthen the floc by dosing a high molecular weight polymer.

Conversely, float produced from turbid river water or stored algal-laden water is very stable. Accumulation of float for more than 24 h does not result in float breakup or deterioration in treated water quality. Beach scrapers and part and full-length scrapers have been used successfully for these applications, producing solids concentrations in excess of 3 percent with little deterioration in treated water quality, provided the float is not allowed to accumulate for too long. These floats were suitable for filter pressing, producing cake solids concentration of between 16 and 23 percent without polyelectrolyte addition.

The float stability is independent of the primary coagulant used for optimum coagulant dose and coagulation pH. The addition of flocculant aid has been found useful when using aluminum sulfate in cold waters, with the flocculant aid also helping in weak floc situations to reduce float breakup and increase filter run length.

For optimum operation in terms of treated water quality and float solids concentration, beach scrapers should be operated continuously, the water level in the flotation tank should be adjusted close to the lower edge of the beach, and a thin, continuous float layer of about 10 mm (0.4 in.) should be maintained on the surface of the flotation tank. This operation produces a float concentration, depending on the source water treated, of 1 and 3 percent with minimum deterioration of treated water quality.

Equipment costs for float removal systems can be as much as 10 to 20 percent of the total plant cost. Therefore, selection of the most appropriate and cost-effective removal system for a particular application is important. For example, although a beach scraper might have the lowest cost because of its relative simplicity, it might not be as effective as a flight scraper for the quality and quantity of float produced.

Performance of Dissolved Air Flotation Plants

The several international flotation conferences held periodically (Ives and Bernhardt, 1995; CIWEM, 1997; Helsinki, 2000; and Seoul, 2007) are good sources of information on DAF performance in treating different types of water supplies. The work reported on at these conferences includes the evaluation of pilot and full-scale plants. Some performance data are presented in the following subsections in which the material is arranged according to either the type of source water or the specific source water contaminants.

Treatment of Turbid Lowland (High-Alkalinity) River Water. Under optimum operating conditions (Rees et al., 1979), flotation reduced source water turbidities of up to 100 ntu to levels rarely exceeding 3 ntu at a design loading of 12 m/h (4.9 gpm/sf). When the source water turbidity exceeded 60 ntu, treated water quality was improved greatly by reducing the loading rate through the plant by about 10 to 20 percent. Color was reduced from 70 to less than 5 color units (CU), and residual coagulant concentrations before filtration were in the range 0.25 to 0.75 mg Al/L (total Al).

A floc blanket sedimentation plant operated at an upflow rate of 2 m/h (0.8 gpm/sf) produced similar treated water quality to that of the flotation plant during low-turbidity periods but better quality (by 1 to 2 ntu) when source water turbidity was greater than 100 ntu. Selection of the correct coagulant dosage and coagulation pH was critical during storm events. Because of the short residence time in the flotation plant, changes in source water quality had to be followed closely to maintain optimum coagulation conditions.

Directly abstracted river water can be treated successfully by flotation. However, if the source water turbidity varies rapidly, has high-turbidity peaks (>100 ntu), and large doses

of coagulant are needed, then sedimentation tends to be the more appropriate treatment process. High-turbidity sources are sometimes pumped to bank-side reservoirs or raw water tanks for short-term storage (<3 days); this dampens out short-term quality variation and allows some settlement of solids.

Treatment of Low Turbidity, Low Color Waters. In the United States a large number of DAF plants were built in the 1990s and early 2000s to treat waters of high quality (e.g., New Castle, NY, Fairfield, CT, Greenville, SC, Cambridge, MA, Catskill, NY). In these cases, raw water turbidities are about 1 ntu, color is typically 15 CU or less, and TOC values are 3 mg/L or less. They were designed at DAF loadings of 10–15 m/h (4–6 gpm/ft²) and produce DAF effluent turbidities below 1 ntu and often in the range 0.2 to 0.5 ntu.

Several U.S. cities have limited land and space so the reduced footprint is a considerable advantage. The design of a 1100 ML/d (290 mgd) plant for New York City allows for 1-min flash mixing and 4.8-min flocculation at full capacity prior to flotation over filtration (DAF/F). The DAF loading rate will be 12.2 m/h (5 gpm/sf) and the filtration rate will be 15.9 m/h (6.5 gpm/sf) with four of the 48 DAF/F units out of service (Crossley et al., 2007). This plant is expected to be commissioned in 2011 or 2012.

Treatment of Waters with Natural Color and Humic Substances. Table 9-7 shows a comparison of the water quality achieved by flotation, sedimentation, and filtration treating a stored water of high color and low alkalinity with ferric coagulation (Rees et al., 1979). The flotation plant was operated at 12 m/h (4.9 gpm/sf) loading rate.

The floc blanket sedimentation plant could only be operated at less than 1 m/h (0.4 gpm/sf), even with the addition of polyelectrolyte. The floc produced by coagulation of these waters is very light and has low settling velocities. The quality of the waters treated by the two processes was quite similar. Initially the residual coagulant concentration of the sedimentation plant treated water was usually lower by about 0.2 mg Fe/L. By increasing the flocculation time from 12 to 16 min, however, the residual coagulant concentration in the flotation treated water was reduced to that of the sedimentation treated water.

Another advantage of flotation was that the plant consistently produced good treated water quality even at temperatures below 4°C (39°F), which occurred frequently during the winter months. At these low temperatures the floc blanket in the sedimentation tank tended to become unstable, resulting in deterioration in treated water quality.

TABLE 9-7 Comparison of Qualities Achieved with Flotation,* Sedimentation,† and Filtration (Colored Low-Alkalinity Water) Following Iron Coagulation (Rees et al., 1979; Zabel and Melbourne, 1980)

Type of water	Turbidity, ntu	Dose, mgFe/L	Color, PtCo	pH	Iron, mg/L	Manganese, mg/L	Aluminum, mg/L
Source	3.2	–	45	6.2	0.70	0.11	0.23
Flotation-treated‡	0.72	8.5	2	4.8	0.58	0.16	0.01
Flotation-filtered	0.19	–	0	9.0	0.01	<0.02	0.01
Sedimentation-treated	0.50	6.0§	0	5.05	0.36	0.14	0.10
Sedimentation-filtered	0.29	–	0	10.5	0.01	<0.02	0.10

*Upflow rate 12 m/h (39 ft/h).

†Upflow rate 1 m/h (3.25 ft/h).

‡Improved flotation-treated water quality similar to that achieved with sedimentation was obtained by increasing the flocculation time from 12 to 16 min.

§Plus 0.8 mg polyelectrolyte/L required to maintain the floc blanket.

Treatment of Waters with Algae. Severe algal problems can be experienced in some storage reservoirs containing nutrient-rich waters. Algae tend to float and are, therefore, difficult to remove by sedimentation. Table 9-8 shows the removal efficiency of flotation and sedimentation for different algal species (Rees et al., 1979). At times the algal counts in the flotation treated water were lower than those in the sedimentation and filtered water. (The results in Table 9-8 refer to use of chlorinated ferrous sulfate. This coagulant is no longer used because of its association with THM production. However, the nature of the results still applies to coagulants currently used.) Efficient coagulation and flocculation are essential for effective algal removal. Only 10 to 20 percent algal removal was obtained when the flotation plant was operated without coagulation.

TABLE 9-8 Comparison of Algae Removal Efficiency of Flotation* and Sedimentation[†] Using Chlorinated Ferrous Sulfate as Coagulant (Based on Rees et al., 1979; Zabel and Melbourne, 1980)

Algae type	Source water, cells/mL	Sedimentation-treated water [‡] , cells/mL		Flotation-treated water [‡] , cells/mL	
			% removal		% removal

[†]Upflow rate 2 m/h (6.5 ft/h).

[‡]Before filtration.

[§]Aluminum sulfate used as coagulant.

The greater effectiveness of DAF compared to sedimentation in removing algae is because algae have low densities and so attachment of air bubbles will easily cause separation in DAF plants. Figure 9-41 demonstrates this for removing a green alga (*Chlorella*) and a diatom (*Cyclotella*). Log removals of 2–3 log (99–99.9 percent removal) were found for DAF compared to 1–2-log removal by settling. Other reports on algae removal by DAF support these findings as well as removals of blue-green algae, or cyanobacteria (Teixeria and Rosa, 2006).

The percentage removals given are quite high, but were obtained in well-controlled and optimized treatment conditions with raw water algae at high concentrations. In practice, one should not expect such high removals. For guidance purposes, one should expect 90–99 percent removals of algae by DAF unless the algae are at low concentrations, then lower removals are achieved. Settling processes are not as effective (Table 9-8).

Cryptosporidium and Giardia Removal. Extensive pilot-scale studies (Edzwald et al., 2000; Edzwald et al., 2003) have demonstrated that DAF is very effective in removing *Cryptosporidium* compared to sedimentation. Figure 9-42 illustrates the ability of DAF to produce high-quality clarified water with turbidities of about 0.5 ntu for cold water conditions and at a DAF nominal loading rate of 15 m/h (6 gpm/sf). Plate settling (design hydraulic loading of 0.6 m/h) had higher turbidities of about 1.6 ntu. Likewise as shown in Fig. 9-42, DAF effluent particle counts were much lower than those from sedimentation.

Figure 9-43 presents log removal *Cryptosporidium* data for several pilot runs for summer (17–18°C) and winter conditions (2–5°C), all runs at DAF and dual-media filtration hydraulic loadings of 15 m/h (6 gpm/sf). DAF achieved 2-log removals for summer and

FIGURE 9-41 Bench-scale DAF comparison of log removals of algae by DAF versus sedimentation (4°C, DAF conditions: 5 min flocculation time and 10 min flotation time; sedimentation conditions: 20 min flocculation time and 60 min of settling). (Source: Edzwald and Wiegler, 1990.)

winter. Plate settling performed well for summer temperatures, but only achieved 1-log removal in the winter. These winter results showing better DAF performance than plate settling are in agreement with the turbidity and particle count data presented in Fig. 9-42. Finally, it is noted that overall *Cryptosporidium* log removals by clarification and dual media filtration were 4–5 for both the DAF and plate settling trains.

The filter is the final barrier and ensures high overall log removals of *Cryptosporidium*, but greater particle and *Cryptosporidium* removals can be achieved by DAF compared to sedimentation. An advantage of DAF plants is filtration serves as a polishing step since most of the pathogens are removed by DAF and leave the system in the floated sludge (Edzwald et al., 2003) as opposed to leaving in waste filter backwash water.

FIGURE 9-42 Pilot-scale comparison of DAF to plate sedimentation for turbidity and particle counts under winter conditions (2–5°C). (Source: Edzwald et al., 2003.)

FIGURE 9-43 Pilot-scale comparison of DAF to plate sedimentation for *Cryptosporidium* log removals under summer (17–18°C) and winter conditions (2–5°C). (Adapted from data of Edzwald et al., 2003, *Journal of Water Supply: Research and Technology—AQUA*, 52 (4), 243–248, with permission from the copyright holders, IWA Publishing.)

Edzwald et al. (2000) have also reported on pilot-scale performance for *Giardia* removal. The pilot tests were conducted by spiking *Giardia* into the raw water at high concentrations to represent peak short-term loads for cold-water winter (2–3°C) and spring (13–14°C) water temperatures. It was found that DAF performed better than sedimentation for both seasons. Average log removals for the spring were 2.8 for DAF and 1.5 for sedimentation; for the winter average log removals were lower for DAF with 2.0 but much lower at 0.75 for sedimentation.

Full-Scale Plant Performance for Turbidity, NOM, and Filtration. Tests comparing the performance of rapid gravity sand filters fed with water treated by flotation and by floc blanket clarification showed that these waters have similar turbidities and residual coagulant concentrations. The presence of air bubbles in flotation treated water has no influence on filter performance (Rees et al., 1980a).

An extensive full-scale evaluation of a DAF plant in Fairfield, Connecticut, has been reported by Edzwald and Kaminski (2009). In their study of this 190 ML/d flotation-over-filtration (DAF/F) plant with a nominal design DAF and filter loading of 15 m/h (6 gpm/sf), they evaluated NOM removal [measured by TOC and UV (254 nm) absorbance] and turbidities following DAF and dual-media filtration. The water supply is a reservoir with low turbidities (<3 ntu), low to moderate NOM (UV (254 nm) of 0.065 to 0.12 cm⁻¹ and TOC of 2.2 to 4.0 mg/L. Figure 9-44 presents DAF effluent turbidities and treated water NOM data over a 1-year period. The DAF process performed well with DAF turbidities generally less than 0.4 ntu. The plant performed well in removing NOM producing treated water TOC below 2.0 mg/L and UV (254 nm) generally less than 0.04 cm⁻¹. It was found that over a 5-year period the NOM removals were 44 percent for TOC and 65 percent for UV (254 nm), which are excellent considering the raw water TOC values of 2.2 to 4.0 mg/L. Additional data on filter performance are presented next that were not reported in the paper

FIGURE 9-44 Full-scale performance for DAF effluent turbidity and plant performance for NOM for a reservoir supply. (Source: Edzwald and Kaminski, 2009.)

by Edzwald and Kaminski (2009). For the year, the plant operated at an average filtration rate of 8.1 m/h (3.3 gpm/sf). Excellent performance was achieved with filtered water turbidities not exceeding 0.11 ntu with an average of 0.07 ntu. Good water production was obtained with average unit filter run volume (UFRV) of 640 m³/m²/run (15,700 gal/ft²/run) with values up to 730 m³/m²/run (18,000 gal/ft²/run).

APPLICATIONS

Factors Influencing Choice of Process

A comparison of the various types of dissolved air flotation and sedimentation processes for removing floc prior to normal deep bed filtration is summarized in Table 9-9. The factors influencing choice of process—those principally relating to cost, source water quality, compactness of plant, rapid start-up, and sludge removal—are discussed. Further guidance is provided by Jannssens and Buekens (1993), Valade et al., (2009), and in Chap. 5.

Solids Loading. Solids removal prior to filtration is needed when the solids concentration is too great for filtration to cope with alone. Pretreatment is needed when the coagulant dose required for soft waters exceeds about 1 mg/L Al or Fe or greater than about 2 mg Al/L for hard waters (Gregory, 1991).

The concentration of solids in a floc blanket clarifier using alum coagulation is equivalent to about 100 mg Al/L or 200 mg Fe/L if iron coagulant is used. Floc blanket sedimentation becomes inappropriate for coagulant doses greater than about 7.5 mg Al/L or 15 mg Fe/L because blanket level control requirements become unreasonable (see Example 9-4). Other types of sedimentation then will be more appropriate. In some situations it can be appropriate to have two stages of sedimentation (Chen et al., 2002): first stage with horizontal-flow settlers and primary coagulation to at least achieve particle destabilization, followed by floc blanket sedimentation after a second coagulant dose to achieve sweep floc coagulation.

TABLE 9-9 Comparison of Sedimentation and Dissolved Air Flotation

	Horizontal flow (rectangular)	Radial flow (circular)	Upflow, U.S.- type clarifier	Upflow floc blanket	Floc blanket (widely spaced inclined plates)	Ballasted floc	Inclined plates (unhindered)	Dissolved air flotation
Sedimentation regime	Unhindered	Unhindered	Unhindered or hindered	Hindered	Hindered	Hindered or unhindered	Unhindered	Unhindered (hindered by air)
Theoretical removal of particles with $v_s < v_r^*$	Partial depending on entrance position	Partial depending on entrance position	Partial depending on whether blanket formed	No removal	No removal	No removal	Partial depending on entrance position	Depends on entrance position
Appropriate for heavy silts and lime precipitate as well as light floc	Yes	Yes	Yes if bottom scraped	Flat tanks limited to light floc, hopper tanks can take wider range of settling velocities.		For heavy silts & light floc	Yes	No
Appropriate for eutrophic (algal) waters	No	No	No	No	No	No	No	Yes
Ease of start-up and on/off operation	Easy	Easy	Easy for unhindered	Slow; may take several days to form a new blanket.		Quick but some skill needed	Quick but some skill needed	Quick & easy
Skill level of operation	Low	Low	Medium	Medium	Medium	High	Medium-high	Medium-high
Retention time	High	High	Medium	Medium-low	Low	Low	Low	Low
Short-circuiting	High	High	Medium	Medium-low	Medium-low	Medium-low	Medium-low	Low
Coagulation and flocculation effectiveness	Little difference if adequately designed and properly operated with rapid dispersion of chemicals							
Polymer usage	Low-medium	Low-medium	Low-medium	Low-medium	Low-medium	Medium-high	Medium-high	None-low
Relative capital cost	High-medium	High-medium	Medium	Medium	Medium-low	Medium-low	Medium-low	Medium-low
Relative operating cost	Medium	Medium-low	Medium-low	Low	Low	Medium	Medium	Medium

Floc blanket sedimentation can be used with partial lime softening in conjunction with iron coagulation. For simple precipitation softening, a solids contact clarifier, which is not too complex and is easily maintained, is likely to be the best choice. Consideration should be given to using pellet reactors, however, especially when softening groundwaters. When the raw water bears heavy silts, horizontal and inclined settlers are most appropriate. They will, however, need good arrangements for discharging the sediment with robust sludge scraping equipment. When silt concentrations are very high, sedimentation prior to coagulation may be appropriate. When silt concentrations are low but algae pose a problem, for example, reservoir supplies, and for colored (low alkalinity) waters, flotation is likely to be the best choice for pretreatment. Flotation might also be a better choice for other reasons, as mentioned below.

Costs. The comparison of costs of different sedimentation processes and comparison of sedimentation with flotation must include both capital and operating costs. This is necessary because of the substantial differences in the distribution of costs in the various processes, as summarized in Table 9-9. Floc blanket sedimentation has a relatively high capital cost but low operating cost. In contrast, flotation has a relatively low capital cost but can have a high operating cost because of its energy consumption associated with the saturator; however, smaller flocculation tanks reduce the energy for flocculation mixing.

The chemical cost of basic coagulation should be the same for the various processes. Although generally no advantage occurs from using polyelectrolyte as a flocculation aid with flotation, its use can be cost effective for any form of sedimentation because loading rates can be increased. High loading rates and hence lower capital costs are also possible with ballasted floc sedimentation, but additional operating costs of the ballasting agent, conditioning chemicals, and energy for agent recovery and recirculation are incurred.

The relatively high energy cost of flotation, although still possibly less than the cost of chemicals or labor, is largely incurred in pumping the recycle through the saturator system, to achieve the required level of saturation with air, and through the nozzles, with enough backpressure to prevent premature release of air downstream of the saturators. Most of the remaining energy cost is required for flocculation. The cost of flocculation for discrete-particle settling systems, horizontal flow and inclined sedimentation should be more than for DAF because of the much shorter flocculation times (and smaller flocculator volumes) with DAF. Since a large portion of the operating cost of DAF is in the recycle, it is important that total recycle flow, or pressure, can be reduced for low plant flows. This will need to be done in conjunction with reducing the number of nozzles so as to maintain nozzle backpressure and prevent premature release of air in the recycle. DAF usually produces better clarified water quality than sedimentation; thus filter production will be greater and backwash costs will be lower.

The large differences between processes in fixed and variable costs means that dissolved air flotation is especially attractive for plants with low utilization, less than full flow, or infrequent use, because of its relatively lower capital cost and the reduced variable costs. Other factors besides cost can affect the choice of process, however. Such factors include footprint, rate of start-up, operational flexibility, ease of removing algae or color, coping with high mineral loadings, and producing the best treated water quality.

Low-rate dissolved air flotation (about 8 m/h) is likely to be less expensive than simple floc blanket sedimentation, for a fully utilized plant and if neither or both are covered with a roof or enclosed in a building, only if the sedimentation process cannot be operated at rates greater than about 2 to 3 m/h (0.8 to 1.2 gpm/sf) (Gregory, 1977). For higher-rate, DAF, sedimentation will need to be effective at a greater rate than 2–3 m/h to be financially competitive. As the expected plant utilization decreases, DAF becomes relatively cheaper. The same should apply to ballasted sedimentation also because of its relatively greater operating cost. Whereas, inclined-plate sedimentation (without use of a ballasting agent)

should be similar to the other types of unhindered sedimentation and to coarse-bed filtration in being more appropriate for full-utilization applications.

Sometimes the solids concentration in the water, after initial chemical treatment, is low enough to be within the capacity of filtration to operate without prior sedimentation or flotation and still achieve the desired objective. Just as each form of filtration has a limited capacity to remove solids, so does each form of sedimentation and flotation. This limited ability to remove solids efficiently may limit the surface loading and therefore cost effectiveness of the process. However, some of the big new plants in North America are exploiting DAF costs effectively in treating high-quality raw waters: DAF effluent is so good, even at high rates, that high-rate filtration is also possible. This allows very compact plants to be built.

With the typical applications of flotation, solids loading and air requirements are independent of each other. If the influent solids concentration increases, a greater recycle rate or pressure may be required to achieve efficient flotation, however, and result in a greater operating cost. Additionally, even continuous removal of float might prove inadequate. The greater the solids concentration, the more likely horizontal-flow or lamella sedimentation will be selected. The same applies to floc blanket sedimentation when the extreme situation is equivalent to thickening and then presedimentation before coagulation may be justified. Additionally, the volume of discharged sludge becomes so large that the arrangements for thickening become substantial. At some point, the combination of clarification and thickening has to be rationalized.

For certain types of source waters, flotation does produce better water for filtration and therefore better filtrate quality than sedimentation. This may be because of better use of flocculation (this is applicable also to inclined settling), and the mechanism of flotation that makes it especially effective for algae removal. The aeration in flotation also may be attractive because it might increase dissolved oxygen concentration or even cause some desorption or stripping of volatile contaminants. However, higher than typical recycle rates should not be used to satisfy high dissolved oxygen demand of the water being treated: waters with low DO should have an aeration step before chemical treatment or there should be aeration of the raw water reservoir (probably useful anyway to address stratification and its associated problems).

Compactness. Inclined settling, ballasted floc settlement, dissolved air flotation and coarse-bed filtration are regarded as high-rate processes because of the relatively high surface loadings possible. This label also implies they are compact processes and so occupy less area.

Compactness is important where land is at a premium. These processes are also likely to need shallower and smaller tanks (except coarse-bed filtration), which is important in coping with preparing foundations in difficult sites. Both of these points are relevant where a plant has to be housed in a cold climate or for other environmental or strategic reasons. The compactness of the flotation carried out over the filter (DAF/F) has made it especially attractive for package plants, and in the last 15 years many large DAF plants in locations without much land have adapted this strategy, for example, a 190-ML/d plant in Fairfield, Connecticut, and a 1100-ML/d plant for New York City.

Rapid Start-Up. A floc blanket can take several days to form when starting with an empty tank, especially when the solids concentration is low. In contrast, high-rate inclined settlers and dissolved air flotation can produce good quality water within 45 min from start-up. Such rapid start-up is useful where daily continuous operation is not needed. The disadvantage of high-rate processes is they are more sensitive to failure of chemical dosing and flocculation and changes in inlet water quality. Rapid start-up plants are suitable for unstaffed sites using automatic shut-down and call-out alarms as a means of avoiding relying on difficult automatic quality control.

Sludge Removal. The ability to accumulate sludge, prior to removal, requires space and this depends on the process.

1. In horizontal-flow sedimentation, the whole plan area of the floor of the tank is available for sludge accumulation.
2. In dissolved air flotation, the whole plan area of the surface of the flotation tank is available, but thickness of the floated sludge and ease of its removal are more important.
3. In solids contact clarifiers with scrapers, the whole plan area of the floor is available.
4. Floc blanket clarifiers have only a small area for excess floc removal as sludge. However, when it is designed well, this will be adequate to ensure some thickening before discharge.
5. Some inclined settler systems are combined with thickeners.

Some systems, such as dissolved air flotation and those with combined thickeners can produce sludge concentrated enough for dewatering without additional thickening (see Chap. 22). Although systems that produce the more concentrated sludges are likely to incur greater operating costs for the scraping and pumping, this is likely to be more than offset by a saving in subsequent sludge treatment processes.

Emerging Technology

Developments in sedimentation and dissolved air flotation processes, as currently known, have probably reached the point of diminishing returns. Application lags behind knowledge, including making existing plants work better. Developments will occur in part by paying more attention to the chemical engineering of reagent dosing, mixing, and flocculation rather than the clarification process itself. In the case of flotation, more attention also is likely to be given to the transfer of flocculated water to the flotation tank and mixing with air in the contact zone. The use of CFD (Fawcett, 1997; Eades et al., 1997; Ta and Brignall, 1997; Amato and Wicks, 2009) is leading to radical changes in tank design resulting in confidence with high-rate flotation for treating waters with low to medium solids concentrations. More attention also is likely to be given to selecting the best chemistry and process for a particular application and to the design of the chosen process with regard to materials of construction, control equipment, and compactness. A driver for developments in coagulation chemistry and flocculation is the progress taking place in mathematical modeling that helps to highlight how much process performance may benefit from improvements in such factors as floc size, strength, and density, as has been identified in this chapter and in Chap. 8 and by Bache and Gregory (2007).

No clear benefit has been demonstrated for the aeration that water receives (when the water before treatment does not have a significant oxygen demand) in flotation, but no doubt there is some such as stripping of taste and odor compounds. However, an example of combined ozonation and flotation has been reported as the Flottazone[®] process (Baron et al., 1997). In this process the recycle is saturated with ozone-rich air. This differs from the Ozoflot[®] process in which the flocculated water passes over porous plate diffusers releasing ozone-rich air. More examples of combined ozonation and flotation might occur should it be found appropriate to use ozonation in the treatment of waters for which flotation is also applicable.

Ballasted floc sedimentation systems, recycling fine sand as ballast, have received more attention during the past decade. Use of buoyant ballast has been suggested for flotation to reduce the need for air (Jarvis et al., 2009). Just as flotation has its niche for application, then there will be a niche for ballasted floc sedimentation, plain sedimentation, and other clarification processes. A wide variety of options has emerged and continues to expand

for treatment prior to final filtration. Individual circumstances will dictate the choice. Furthermore, no single process will likely take a major share of new applications because costs of alternatives are generally the same, unless substantial technical advantages exist as has occurred for flotation.

ABBREVIATIONS

CFD	computational fluid dynamics
DAF	dissolved air flotation
DAF/F	dissolved air flotation over filtration
DOC	dissolved organic carbon
DOM	dissolved organic matter
NOM	natural organic matter
PACl	polyaluminum chloride
TOC	total organic carbon
UFRV	unit filter run volume
UV (254 nm)	ultraviolet absorbance at 254 nm

NOTATION FOR EQUATIONS

A	area of particle or tank
A_b	projected area of a bubble
A_H	cross-sectional area of channel to liquid flow
A^*	plan area of tank with horizontal flow for ideal settlement
A_{sz}	separation zone surface area
b	breadth
C	mass concentration
C_b	mass concentration of air or bubbles in contact zone
C_D	drag coefficient
C_{fl}	mass concentration of air or bubbles in flotation tank effluent
C_r	mass concentration of dissolved air in recycle flow
$C_{s,air}$	air mass concentration at saturation in water for atmospheric pressure
C_{sN}	solubility or equilibrium concentration of nitrogen in water for atmospheric pressure
C_{sO}	solubility or equilibrium concentration of oxygen in water for atmospheric pressure
d	diameter
d_b	diameter of bubble
d_f	diameter of floc
d_{fb}	diameter of the floc-bubble aggregate

d_H	hydraulic diameter
d_p	diameter of particle
e	saturator efficiency
E	porosity
E^+	porosity at maximum flux
F	function of
f_b	buoyancy
f_d	drag force
f_g	external force such as gravity
Fr	Froude number
F_M	solids mass flux
F_t	fraction at time t
F_V	solids volume flux
g	gravitational constant (9.806 m/sec ²)
G	velocity gradient
h	vertical distance $\leq H$
H	height or depth
k_a	air deficit concentration
k_B	Boltzmann's constant
$k, k_1, \text{etc.}$	coefficients
K	constant from Yao's inclined settling equation, or factor to account for shape effects on drag
K_H	Henry's law constant
L	horizontal distance or length of tank or DAF separation zone
L_p	length of surface for inclined settlement
L_r	Yao's relative length of settler
L^*	length of tank for ideal settlement
L'	greater than or equal to L^*
m_f	maximum number of attached air bubbles to floc particles
n	power index dependent on Re
n_b	bubble number concentration in the contact zone
n_p, n_j	number concentrations
$n_{p,e}$	floc or particle number concentration in the contact zone effluent
$n_{p,i}$	floc or particle number concentration in the contact zone influent
N	number of channels, compartments or stages, or number concentration e.g. of bubbles attached to a floc
N_{\max}	maximum number of bubbles that can attach to one floc
p	partial pressure
P	perimeter
q	constant

Q	volumetric flow rate
Q_r	recycle flow rate
r	power index
R	recycle ratio
Re	Reynolds number
s	particle specific gravity = ρ_p/ρ_w
S_c	Yao's inclined flow geometry number
t	detention time
t_{cz}	contact zone hydraulic detention time
T°	absolute temperature
v	particle or liquid velocity
v_b	bubble rise velocity
v_d	horizontal velocity in Fig. 7-7
v_{fb}	floc-bubble rise velocity
v_n	velocity relating to h_n and t_n
v_o	settling velocity of suspension for concentration extrapolated to zero
v_p	particle settling velocity
v_s	settling velocity of suspension
v_t	terminal settling velocity
v_θ	velocity at angle θ
v_w	water velocity
$v_{clar-hl}$	clarification area hydraulic loading
v_{nom-hl}	nominal tank hydraulic loading
v_{sz-hl}	separation zone hydraulic loading
v^*	overflow rate of the ideal settling tank
v'	less than or equal to v^*
V	volume
w	perpendicular spacing
W	width, e.g., of separation zone
x	mole or mass fraction
x^*	mass fraction of particles with settling velocity v^*
α	collision attachment factor
α_{pb}	particle-bubble attachment efficiency
ε	mean energy dissipation rate
Φ	particle volume concentration
Φ_b	air or bubble volume concentration
Φ^*	apparent volume concentration
Φ^+	particle volume concentration at maximum flux
N_{ij}	collision frequency between particles of concentrations n_i and n_j
η	collector collision efficiency

η_D	collision efficiency due to Brownian diffusion
η_I	collision efficiency due to fluid flow or interception
η_{IN}	collision efficiency due to inertia
η_S	collision efficiency due to differential settling
η_T	total single-collector efficiency
μ	dynamic viscosity
π	geometric constant $\pi = 3.14$
θ	angle of inclination
Θ	shape factor
ρ	density
ρ_b	density of air or gas bubble
ρ_{fb}	floc-bubble density
ρ_p	density of particle or floc
ρ_w	density of water

OVERVIEW OF PARTICLE FILTRATION PROCESSES

The purpose of this chapter is primarily to present the principles and practice of using porous beds of granular media to remove particulate materials as part of the overall process of drinking water treatment. The precoat filtration process is also discussed. Types and important characteristics of particles in water are described in some detail in Chap. 3 of this book. Particles may be present in the raw water (e.g., clay, silt, microorganisms, detritus) or formed during treatment (e.g., aluminum or iron hydroxide precipitates from coagulation, calcium carbonate precipitates from softening), and their characteristics, such as size, density, and stability, have important effects on the performance of processes used for their removal. Media and precoat filtration are types of solid–liquid separation processes; others include clarification by dissolved air flotation or sedimentation (Chap. 9), processes that are always followed by particle filtration, and low pressure membrane filtration [e.g., microfiltration and ultrafiltration (MF/UF); Chap. 11]. Consistent with this book’s objectives, this chapter introduces and reviews important principles of media filtration; the reader should consult separate sources for more in-depth coverage of filtration practice (Logsdon et al., 2002; Logsdon, 2008) and process design (e.g., Kawamura, 2000; AWWA, 2004; MWH, 2005; Hendricks, 2006).

Types of Particle Filtration

The various types of filters used for particle removal in potable water filtration can be classified by several factors, including (1) the dominant overall mechanism for particle removal, (2) the filtration media and apparatus used, (3) the hydraulic loading rate, and (4) the source of head or energy for filtration.

Overall, particle removal mechanisms can be divided into two or three main classifications. *Depth filtration* occurs when particles deposit within the pore spaces of a filter, usually a bed of granular media, due to transport to and attachment on the surface of the granular media or previously deposited particles; the removed particles generally are much smaller in size than characteristic dimensions of the pore spaces through which they are transported. *Straining* or *sieving filtration* occurs when particles are prevented from passing through a pore space because of size exclusion; that is, the particle is too large to pass through the pore opening; removal by straining is the predominant mechanism in low pressure membrane filtration and for microsieves. Straining is also the dominant mechanism in *cake filtration*, wherein the water to be filtered passes through a cake comprised of previously deposited particles; precoat filtration is an example of particle removal by a cake comprised of previously removed particles and very small media or body feed [e.g., diatomaceous earth (DE)], continuously added to the water to be filtered.

In application, most particle filtration processes involve a dominant mechanism, whereas other mechanisms also can be significant. Granular bed, or media, filters are generally dominated by depth filtration, yet straining by constricted pores and cakes of deposited particles also occurs, depending on various fixed and operational parameters of the process. Cake filtration, along with biological activity, is especially important in the slow sand media filtration process. Low pressure membrane filtration processes rely on the straining mechanism as typical dead-end operation (all water passes through the membrane) causes cake filtration to occur on the membrane surface; depth filtration inside a membrane pore is undesired and is one cause of membrane fouling.

Another useful classification of filtration processes is based on the physical material used for particle removal. Thus *granular bed*, or *media filters* are comprised of specified depths of one or more types and sizes of granular media; rapid sand, dual-media, and slow sand filters are some examples. In contrast, *membrane filters* for particle removal are manufactured from a thin layer of material with pores that allow water passage while straining out particles; synthetic polymer hollow fiber membranes and ceramic membranes are two examples (see Chap. 11).

An important design and operational characteristic of particle filtration processes is the *hydraulic loading rate* (HLR), or water flux, defined as the flow rate Q through the filter divided by the surface area of the filter A , or Q/A ; typical units for media filtration are meters per hour ($m/h = m^3/m^2/h$) or gallons per minute per square foot (gpm/ft^2), whereas for membrane filtration the typical units are liters per square meter per hour ($L/m^2/h$ or lmh) or gallons per square foot per day ($g/ft^2/d$ or gfd). Rapid-rate media filters operate at much higher HLRs than slow sand filters; in turn, these media filter HLRs are much higher than membrane filter HLRs. The HLR has a significant impact on the capital cost of treatment because the required filtration surface area to produce a desired flow decreases as the design HLR increases.

Filtration processes are also classified according to the source of the energy required to force water to flow through the filter. Historically, the most common source for large treatment plants has been *gravity*, relying on an open surface hydraulic grade line (HGL) upstream of the filter that exceeds the downstream HGL; the granular media are contained in a steel or concrete walled open tank. Flow through the filter also may be caused by applying *pressure* in a closed vessel within which the filter media are housed. The pressure vessel typically is steel for media and precoat filters, whereas synthetic polymer housings are often used for low pressure membrane filters. Filtration flow also can be induced by application of a *vacuum* on the downstream side of the filter, such as used for submerged low pressure membrane filters (see Chap. 11) and some precoat filters.

Thus a filter can be fully described by an appropriate choice of adjectives. For example, a rapid, gravity, dual-media filter describes a deep bed comprised of two media (usually anthracite coal on top of sand) operated at high enough rates to encourage depth removal of particulates within the bed and operated by gravity in an open tank.

Particle Filtration within the Treatment Plant: Configurations and Secondary Roles

It can be argued that particle filtration processes are possibly the most critical component in potable water treatment facilities because of their ability to remove microorganisms, especially pathogens that cause acute human health concerns. The selection and performance of particle filtration processes are affected greatly by raw water quality and the configuration of processes prior to filtration. Particle filtration processes also may have important secondary roles in the overall treatment train.

The number and type of prefiltration treatment processes depends mostly on raw water quality but also can be influenced by such factors as land area, cost, and residuals disposal. Relatively pristine sources with low turbidity and natural organic matter (NOM) may be suitable for direct application to slow sand media filtration without chemical coagulant or oxidant addition prior to filtration. The same or similar source water may be suitable for treatment by *direct filtration* with chemical coagulation and flocculation but without a clarification process prior to filtration; *in-line* or *contact filtration* is similar yet with no or minimal engineered flocculation. Less pristine sources with more NOM, turbidity, and algae are better treated by *conventional filtration* involving chemical coagulation, flocculation, and clarification prior to filtration (and usually media filtration is implied). Useful guidance for selection of treatment processes based on raw water quality has been provided by several authors (e.g., Valade et al., 2009; Janssens and Buekens, 1993). While direct or in-line filtration can be cost-effective by eliminating the clarification process, the inherent reliability of the overall treatment facility is improved by provision of two separate methods for particle removal, that is, clarification and filtration. In the United States, a number of direct filtration facilities were constructed in the 1970s and 1980s, whereas selection of such a process train has been less frequent in the last two decades; this issue is discussed further later in this chapter. The significant increase in selection of low pressure membranes for particle filtration in recent years has resulted in increased consideration of conditions that lead to the use of clarification ahead of the membrane filters; compared to media filtration, less generalization is possible because of the range of filter element geometries and operational modes employed.

Clarification processes used prior to filtration include sedimentation (conventional, plate, tube, ballasted, etc.), dissolved air flotation (DAF), upflow sludge blanket clarifiers, and coarse media roughing filters. These processes occur most often in a tank or vessel that is separate from the filtration process (but often attached via a common wall). An important exception is the application of DAF directly above the granular media filter bed in the same process tank; two examples are the 190 ML/d (50 mgd) plant in Fairfield, Conn., operated by the Aquarion Water Company and the soon-to-be-completed 1100 ML/d (290 mgd) Croton Treatment Plant for New York City (see Chap. 9).

It is important to recognize that particle filtration processes are designed most commonly to only remove particulate matter, although there are important exceptions, as described below. Statements of the performance of particle filtration processes for the removal of raw water constituents that are normally dissolved, such as NOM or manganese, require careful consideration; removal of such constituents by many particle filtration processes requires their transformation to particulate form prior to filtration, typically by coagulation and oxidation processes.

Particle filtration processes also may serve important secondary functions for control of water quality, often involving processes occurring at the surface of the filter media. One important example is the promotion of biological activity on filter media surfaces (via biofilm formation)

for the biological transformation of one or more dissolved constituents. A common example is the use of granular activated carbon (GAC) media for particle removal and as support media for biofilms to oxidize biodegradable organic matter (BOM) and/or specific taste- and odor-causing compounds. Prefiltration conditions may be optimized to promote biofiltration; for example use of ozonation to increase BOM levels and no use of chlorine prior to filtration. Another process that can occur at the surface of granular media and be used for treatment is adsorption. GAC media adsorptive capacity most commonly would result in relatively short-term water quality impacts, but long-term continuous impacts may be realized because of combined adsorption and biodegradation (see Chap. 14). An important process used for removal of dissolved (reduced) manganese (Mn^{2+}) is sorption to manganese-oxide coatings on granular filter media (anthracite, sand) with subsequent oxidation and regeneration of the adsorption site by the presence of an oxidant, usually free chlorine, in the water applied to the media filter, sometimes referred to as the *natural greensand effect* or *catalytic oxidation* (see Chap. 7). It can be challenging to design and operate a filtration process for optimal performance with respect to particle removal as well as additional contaminant removal (e.g., Wiesner et al., 1987a); particle removal takes precedence, and sometimes a separate treatment process, often after filtration, is the best option to achieve objectives in addition to particle removal.

Regulatory Requirements

Beginning in 1989, the U.S. Environmental Protection Agency (USEPA) promulgated a number of regulations that require filtration of water sources, set limits on the turbidity of filtered waters, and regulate recycling of certain process residual flows. These regulations have been promulgated in conjunction with requirements for disinfection and for control of disinfection by-products (DBPs). Some pertinent regulations for this chapter are summarized below, and the reader is referred to Chap. 1 for additional coverage of regulations.

Surface Waters. The USEPA 1989 Surface Water Treatment Rule (SWTR), the 1998 Interim Enhanced SWTR (IESWTR), the 2002 Long Term 1 Enhanced SWTR (LT1ESWTR), and the 2006 Long Term 2 Enhanced SWTR (LT2ESWTR) collectively require disinfection of all surface water sources and require filtration of all surface waters unless stringent source water quality criteria are met; these rules also apply to so-called groundwater under the influence (GWUI) of adjacent surface water. In lieu of setting maximum contaminant levels (MCLs) for specific pathogenic microorganisms, the USEPA has used a treatment technique (TT) approach based on required levels of overall removal/inactivation of classes of pathogens (log removals), documented performance of particle separation technologies for pathogen removal, compliance with filtered water turbidity standards, and provision of specified levels of disinfection. As such, certain requirements are technology- and pathogen-specific. Individual states impose regulations that are at least as stringent as the USEPA regulations.

The USEPA regulations require that the combined extent of physical removal and inactivation be at least 3 log (99.9 percent) for *Giardia* cysts and 4 log (99.99 percent) for viruses, independent of raw water quality. Requirements for total removal of *Cryptosporidium* oocysts are 3 log (99.9 percent) unless the results of raw water sampling required by the LT2ESWTR show that greater removal is needed. Guidance documents for the SWTRs indicate assumed pathogen log removal performance for specified treatment technologies that apply when required filtered water turbidity levels are met. The required log inactivation via disinfection is the difference between the total removal/inactivation required and that achieved by particle removal processes.

Assumed log removal credits and required filtered water turbidity for certain specified technologies are shown in Table 10-1. The filtered water turbidity requirement to be met at least 95 percent of the time for conventional and direct filtration processes (both include chemical coagulation; conventional includes clarification and media filtration;

TABLE 10-1 USEPA Log Removal Credits and Turbidity Requirements

Filtration process	Log removal credits			Combined filter effluent turbidity requirement
	<i>Giardia</i>	Virus	<i>Cryptosporidium</i>	
Conventional	2.5	2.0	3.0	≤0.3 ntu in 95% of samples each month; never >5 ntu
Direct	2.0	1.0	2.5	≤0.3 ntu in 95% of samples each month; never >5 ntu
Slow sand	2.0	2.0	3.0	≤1.0 ntu in 95% of samples each month; never >5 ntu
Diatomaceous earth	2.0	1.0	3.0	≤1.0 ntu in 95% of samples each month; never >5 ntu

direct filtration has no clarification process) was decreased to 0.3 ntu by the IESWTR from the 0.5 ntu level specified in the 1989 SWTR. The LT2ESWTR allows for an additional *Cryptosporidium* 0.5 log removal credit if a 0.15 ntu level in the combined filter effluent is achieved; the credit increases to 1.0 log if effluent from individual filters is at the 0.15 ntu level. Criteria for slow sand and diatomaceous earth filtration are also included in Table 10-1. In general, some level of inactivation of *Giardia* and viruses is always required, whereas inactivation or an additional filtration method is required only if raw water *Cryptosporidium* levels exceed 1.0 oocysts/L (bin 3 or 4 of the LT2ESWTR). Log removal credits for physical removal and filtered water turbidity requirements for technologies not specified in the regulations, so-called alternative filtration technologies, must be determined by states, often via demonstration studies; low pressure particle filtration membranes generally fall into this category. Because of the relatively large size (4–12 μm) of protozoan pathogens relative to the typically less than 0.2 μm pore size of MF/UF processes, log removal credits for protozoa are typically high (i.e., >4 log) for MF/UF, whereas in the same context log credits for typically sub-100 nm size viruses may not be allowed or are much less than those for protozoa.

The Safe Drinking Water Act (SDWA) Amendments of 1996 directed the USEPA to regulate the practice of recycling of waste or spent filter backwash within the treatment plant; USEPA thus promulgated the Filter Backwash Recycling Rule (FBRR) in 2001 (USEPA, 2001). This rule regulates the practice of recycle of waste filter backwash water, supernatant from sludge thickeners, and liquids from dewatering processes (e.g., centrifugation, belt press) at conventional and direct filtration facilities. These flows must be recycled to the head of the treatment plant in order to be subjected to all the processes in the plant. Utilities have to notify states that they practice recycle and describe their practices; states have the authority to request changes in practice. Recycle is discussed more later in this chapter as well as in Chap. 22.

Groundwaters. The USEPA promulgated the Ground Water Rule (GWR) in 2006 following the mandate in the 1996 SDWA to address disinfection of all water supplies. The approach of the GWR is to identify groundwater sources at risk of fecal contamination and possibly require treatment to provide 4 log inactivation/removal of viruses (other actions can be taken to mitigate risks). The GWR applies to groundwater sources for mixed surface and groundwater systems unless the groundwater is blended with a surface water prior to treatment of the mixed sources; in such a case, the SWTRs apply. Chemical disinfection and membrane filtration are indicated as acceptable technologies, whereas combinations of other inactivation and removal processes are considered alternative technologies subject to approval. In practice, groundwater sources are often treated for removal of inorganic matter (iron, manganese, calcium) and NOM, often via

oxidation/precipitation followed by media or membrane filtration. Filtered water turbidity and disinfection requirements for such processes are specified by state agencies because no federal regulation exists.

Removal of Microorganisms by Particle Filtration Processes

The ability of particle filtration processes to remove microorganisms is perhaps the most important reason for their use in the production of potable water. In North America, water-borne disease outbreaks caused by *Giardia lamblia* and *Cryptosporidium parvum*, pathogenic protozoa with high resistance to disinfectants, resulted in federal regulations and numerous pilot- and full-scale studies to evaluate removal of microorganisms by treatment processes. In the preamble language in the *Federal Register* for the SWTR, IESWTR, LT1ESWTR, and LT2ESWTR, the USEPA reviews and cites extensive literature documenting filtration performance. Many of these studies were focused on media filtration process trains involving coagulation, whereas some investigations of the efficacy of slow sand filtration and DE filtration also have been carried out. Some pertinent results for media filtration of protozoan pathogens are discussed below.

Pilot-plant studies (Logsdon et al., 1985; Al-Ani et al., 1986) established the need for attaining effective coagulation and filtered water turbidity in the range of 0.1 to 0.2 ntu for effective removal of *Giardia* cysts. Additional research by Nieminski and Ongerth (1995) on *Giardia* and *Cryptosporidium* confirmed the necessity of attaining low filtered water turbidity and the importance of maintaining proper coagulation chemistry. They evaluated a small (4.9 ML/d or 1.3 mgd) plant for removal of protozoan cysts and concluded that a properly operated treatment plant producing finished water turbidity of 0.1 to 0.2 ntu, using either the direct filtration mode or the conventional treatment mode, could achieve 3.7 to 4.0 log removals for *Giardia* and *Cryptosporidium*. The similarity of results for direct filtration and conventional treatment is different from the outcome reported by Patania et al. (1995), who observed 1.4 to 1.8 log additional removal for *Cryptosporidium* and 0.2 to 1.8 log additional removal for *Giardia* when sedimentation was included in the treatment train, in comparison with in-line filtration treatment employing only coagulation and filtration.

LeChevallier et al. (1991) examined raw and filtered water samples from 66 surface water treatment plants in 14 states and 1 Canadian province. Log removals of *Giardia* and *Cryptosporidium* ranged from less than 0.5 to greater than 3.0. Log removals averaged slightly above 2.0 for each organism. Some of these plants were practicing disinfection (usually chlorination) during clarification, so the *Giardia* results may have been influenced by disinfection. They reported that production of water with turbidity less than 0.5 ntu did not ensure that the treated water was free of cysts or oocysts. Treatment plants evaluated by LeChevallier et al. probably would have removed cysts and oocysts more effectively if they had been attaining lower filtered water turbidity. In pilot-plant testing carried out by Patania et al. (1995), when filtered water turbidity was equal to or less than 0.1 ntu, removals of cysts and oocysts were greater by as much as 1.0 log than removals when filtered water turbidity was between 0.1 and 0.3 ntu.

Payment et al. (2001) reported on biweekly monitoring of a conventional water treatment plant (coagulation, flocculation, sedimentation, and filtration) for over 12 months. Clarification through filtration attained the following before any use of disinfectant: (1) 3.0 log or greater removal of human enteric viruses in 20 of 30 samples, (2) 3.0 log or greater removal of coliphage in 20 of 32 samples, (3) 4.0 log or greater removal of *C. perfringens* in 20 of 33 samples, and (4) 3.0 log or greater removal of *Giardia* cysts in 24 of 32 samples. *Giardia* cysts were detected in the filtered water in only 1 of 32 samples. Removals of *Cryptosporidium* oocysts appeared to be lower than those for *Giardia*, but only 2 of 16 raw

water samples contained sufficient densities of *Cryptosporidium* oocysts to permit calculation of 3 log removal based on the detection limit for *Cryptosporidium* in filtered water. During the study, 98 percent of the monthly average turbidity values for individual filters were equal to or less than 0.20 ntu, and 80 percent were equal to or less than 0.10 ntu. These results show that well-run conventional treatment plants present a formidable barrier to the passage of pathogens through effective sedimentation (or other solids separation) followed by media filtration.

In a study of key operational parameters affecting the robustness of media filtration for removal of *Cryptosporidium*, Huck et al. (2002) confirmed the importance of chemical coagulation in maintaining excellent performance; turbidity and particle count breakthrough in the later stages of the filter run also showed concomitant decreases in oocyst removal. Emelko et al. (2005) provide an extensive review of available data for *Cryptosporidium* removal by media filtration.

Slow sand filtration is effective for removal of *Giardia* and *Cryptosporidium*. Pilot-plant studies gave *Giardia* cyst removals of over 3 log at filtration rates up to 0.40 m/h (0.16 gpm/ft²) (Bellamy et al., 1985a, 1985b). Field testing (Pyper, 1985) at a small slow sand filter (area 37 m²) operated at 0.08 m/h (0.03 gpm/ft²) gave 3.7 to 4.0 log *Giardia* removal at temperatures of 7.5 to 21°C, but at temperatures below 1°C, removals ranged from 1.2 to 3 log. Schuler et al. (1988) obtained 3.7 or higher log removals for *Cryptosporidium* in a pilot filter operated at 0.26 m/h (0.11 gpm/ft²) using 0.27 mm effective size (ES) sand.

DE filtration is effective for removal of pathogens in the size range of *Giardia* cysts and *Cryptosporidium* oocysts. The removal mechanism involved is straining, and when an appropriate grade of DE is selected, the pore structure of the filter cake physically blocks the passage of cysts and oocysts into filtered water. Pilot-plant studies (Lange et al., 1986) using a 0.1 m² (1 ft²) test filter have demonstrated *Giardia* cyst removals ranging from 2 to 4 log, typically at filtration rates of 2.4 to 3.7 m/h (1.0–1.5 gpm/ft²). Schuler and Ghosh (1990), using three common grades of DE in pilot filtration studies, reported 100 percent removal of *G. muris* and greater than 3 log removals of *Cryptosporidium* oocysts, all at 4.9 m/h (2 gpm/ft²) and without the use of coagulants. Use of alum or cationic polymer to coat the media did not enhance the cyst removal but aided in the removal of turbidity and coliform bacteria. Principe et al. (1994) reported 3.7 log *Giardia* cyst removals by DE filtration (unspecified grade of DE) at 7.3 m/h (3 gpm/ft²). Ongerth and Hutton (1997, 2001) reported that greater than 6 log removal of seeded *Cryptosporidium* oocysts was achieved at rates of 2.4 and 4.9 m/h (1 and 2 gpm/ft²) in bench/pilot-scale studies using several grades of DE media.

Low pressure membrane filtration (MF/UF) has been found to be effective in removing protozoan cysts and oocysts independent of coagulant addition; this is a logical result based on MF/UF pore sizes of less than 0.2 µm. The extent of virus removal depends on membrane pore size and coagulation pretreatment. See Chap. 11 for more information on membrane filtration.

In summary, filtration options for the removal of pathogenic microorganisms include rapid-rate media filtration, slow sand filtration, DE filtration, and membrane filtration. The most widely used filtration process continues to be coagulation and rapid filtration, and generally the process train includes flocculation and clarification by flotation or sedimentation (conventional treatment). For conventional treatment or for direct or in-line filtration, effective removal of microorganisms requires careful control of coagulation chemistry and operation of filters to consistently attain very low filtered water turbidity. Based on pilot-plant and full-scale studies, removal of microorganisms by these processes can be maximized by the following: (1) filtered water turbidity should be 0.10 ntu or lower, (2) the duration of higher turbidity at the beginning of a filter run should be minimized (<1 hour), and (3) filtered water turbidity above 0.2 ntu should be considered turbidity breakthrough, signaling the need to backwash the filters.

GRANULAR MEDIA FILTRATION PROCESS DESCRIPTION

General

Rapid-rate granular media (or bed) filtration usually consists of passage of pretreated water through a granular bed at rates between 5 to 30 m/h (2–12 gpm/ft²). Flow is typically downward through the bed, although some use of upflow filters is reported in Latin America, Russia, and the Netherlands; upflow roughing filters (very coarse media) are also used. Both gravity and pressure filters are used, although some restrictions are imposed on the use of pressure filters on surface waters or polluted source waters or following lime-soda softening (Great Lakes–Upper Mississippi River Board, 2003).

A schematic of a typical gravity filtration system from one manufacturer is shown in Fig. 10-1, and a generic vertical cross section is shown in Fig. 10-2. One to three layers of specified depths of filter media of selected material and size are supported by an underdrain system that allows for both collection of filter effluent water and application of a reverse-direction water (and often air) backwash. Various methods are used to measure and control filter effluent flow and water level above the filter media. Often piping and valves are placed to provide a filter-to-waste option if filter effluent is not of the desired quality.

Media filtration performance typically is described by measurement of filter effluent quality and head (or pressure) loss as a function of filter operation time; a generic plot is shown in Fig. 10-3. During operation, solids are removed from the filter influent water and accumulate mostly within the voids of the filter bed and to some degree on the surface of the filter bed. Filter effluent turbidity often improves after an initial maximum (the *ripening period*), may be fairly constant for a long period, and then might degrade. The deposition of particles results in an increase in head loss (i.e., clogging head loss) from the initial, or

FIGURE 10-1 Typical gravity rapid-rate filter system. (Courtesy of ITT Leopold.)

FIGURE 10-2 Schematic of a typical gravity filter cross section.

FIGURE 10-3 Generic plot of media filter performance: filtrate quality and head loss.

clean-bed, head loss. If flow remains constant, a linear rate of head loss increase with time often occurs; a decrease in filter flow yields a lower rate of increase in head loss. The total head loss (clean-bed plus clogging) may approach the maximum head loss provided in the plant, sometimes called the *available head loss*.

After a period of operation, the rapid filter is cleaned by backwashing with an upward flow of water, usually assisted by some auxiliary water or air scour system. The operating time between backwashes is referred to as a *filter cycle* or a *filter run*. The head loss at the end of the filter run is called the *terminal head loss*.

The need for backwash is indicated by one of the following three criteria, whichever occurs first: (1) The head loss across the filter increases to the available limit or to a lower established limit, usually 2.4 to 3.0 m (8–10 ft) of water, (2) the filtrate begins to deteriorate in quality or degrades to some allowable limit, or (3) a desired or maximum time limit has been reached (usually 1–4 days).

Filter cycles range from about 12 to 96 hours, although some plants operate with longer cycles; a 24 to 48 hour filter run length is common. Setting an upper time limit for the cycle is desirable because of concern for bacterial growth in the filter and because of concern that compaction of the solids removed in the filter will make backwashing difficult.

In addition to impacts on destabilization of raw water particles to allow aggregation in flocculation and effective clarification and to convert dissolved NOM to particulate NOM, pre-filtration treatment of surface waters by chemical coagulation (see Chap. 8) is essential to achieve effective removal of particles in rapid-rate granular media filters. This is so because of the transport and deposition particle removal mechanism (or depth filtration) predominant in media filtration; particles must be able to attach to the filter media and previously deposited particles. In some cases, filter-aid polymers may be added to the water just ahead of filtration to strengthen the attachment of the particles within the filter media. Groundwaters treated for iron and manganese removal by oxidation, precipitation, and filtration most often do not use other chemical pretreatment.

Filter Media Materials

Types of Media. The most common types of media used in granular bed filters are silica sand and anthracite coal, used alone or in a dual-media combination; an additional layer of garnet or ilmenite sometimes is used in a triple-media configuration. AWWA Standard B100 (AWWA, 2010) provides standard requirements for properties, sampling, testing, placement, and packaging of these filter materials.

Granular activated carbon (GAC) is also used as filter media, sometimes for taste and odor reduction in granular beds that serve both for filtration and adsorption, that is, filter-adsorbers (Graese et al., 1987), as well as for biologically active filters. GAC contactors are also used separately after filtration for adsorption and/or biodegradation of organic compounds (see Chap. 14). AWWA Standard B604 (AWWA, 2006) provides standard requirements for physical properties, sampling, testing, and packaging of GAC.

Garnet and ilmenite are naturally occurring, high-density minerals. Garnet is somewhat of a generic term referring to several different minerals, mostly almandite, andradite, and grossularite, which are silicates of iron, aluminum, and calcium mixtures. Ilmenite is an iron titanium ore that invariably is associated with hematite and magnetite, both iron oxides. Garnet specific gravities range from 3.6 to 4.2 and ilmenite from 4.2 to 4.6.

Other types of granular media include engineered ceramic materials (e.g., Filtralite, Macrolite), naturally occurring and engineered manganese oxide based materials (e.g., greensand), and synthetic polymers (plastic). The engineered ceramic materials include expanded clay aggregates; manufacturing allows for control of both media size and density to produce desired characteristics.

Important Granular Media Properties. A number of properties of filter media are important in affecting filtration performance and also in defining the media. These properties include size, shape, density, and hardness. The porosity of the granular bed formed by the grains is also important.

Grain Size and Size Distribution. Grain size has important effects on particle removal, head loss, and backwashing requirements for a media filter. It is determined by sieve analysis using American Society for Testing and Materials (ASTM) Standard Test Method C136-06, Sieve Analysis of Fine and Coarse Aggregates (ASTM, 2009). A log-probability plot of a typical sieve analysis is presented in Fig. 10-4. Sieve analysis results for most filter materials appear in nearly a linear manner on a log-probability plot.

The size gradation of filter media is commonly described by the effective size (ES) and the uniformity coefficient (UC). The ES is that size for which 10 percent of the grains are smaller by weight. It is read from the sieve analysis curve at the 10 percent passing point on the curve and is often abbreviated by d_{10} . The UC is a measure of the size range of the media. It is the ratio of d_{60} to d_{10} , where d_{60} is the size for which 60 percent of the grains are smaller by weight. In some cases, the lower and upper sizes of the media are specified with some maximum percentage allowance above and below the specified sizes. This can be achieved, for example, by indicating two standard sieves to define the size range; for example, “8 × 20” GAC media are all smaller than the number 8 sieve and larger than the number 20 sieve.

FIGURE 10-4 Typical sieve analysis results for two types of filter media.

Values of d_{10} , d_{60} , and d_{90} can be read from an actual sieve analysis curve such as the one shown in Fig. 10-4. If such a curve is not available, and if a linear log-probability plot is assumed, they can be interrelated by the following equation derived from the geometry of such linear plots for different UCs:

$$d_{90} = d_{10} \times 10^{1.67 \log UC} \quad (10-1)$$

This relationship is useful because the d_{90} size is recommended for calculation of the required backwash rate for a media filter.

Grain Shape and Roundness. The shape and roundness of the filter grains are important because they affect the backwash flow requirements for the filter bed, the fixed bed porosity, the head loss for flow through the filter, the filtration effectiveness, and the ease of sieving.

Different measures of grain shape have evolved in the geologic and chemical engineering literature, leading to considerable confusion in terminology (Krumbein, 1941; McCabe and Smith, 1976). The chemical engineering literature defines the *sphericity* ψ as the ratio of the surface area of an equal-volume sphere (diameter of d_{eq}) to the surface area of the grain (McCabe and Smith, 1976). The equivalent spherical diameter can be determined by a tedious count, weigh, and calculation procedure (Cleasby and Fan, 1981). In the absence of such data, the mean size for any fraction observed from the sieve analysis plot (e.g., Fig. 10-4) can be used as an acceptable approximation of the equivalent spherical diameter.

The chemical engineering definition is used in the following discussion. The sphericity of filter media by this definition can be determined indirectly by measuring pressure drop for flow of water or air through a bed of uniform-sized grains. The Kozeny or Ergun equation for flow through porous media (presented later) is used to calculate ψ after determining all other parameters of the equation (Cleasby and Fan, 1981).

Grain Density or Specific Gravity. Grain density, mass per unit grain volume, is important because it affects the backwash flow requirements for a media filter. Grains of higher density but of the same diameter require higher wash rates to achieve fluidization.

Grain density is determined from the specific gravity following ASTM Standard Test C128-07a, Density, Relative Density (Specific Gravity), and Absorption of Fine Aggregate (ASTM, 2009). This ASTM test uses a displacement technique to determine the specific gravity. Two alternative tests are detailed. The procedure for “bulk specific gravity, saturated surface dry” would be best from a theoretical standpoint for fluidization calculations. However, starting with a reproducible saturated surface dry condition is difficult. Therefore, the “apparent specific gravity” that starts with an oven-dry sample is more reproducible and is an acceptable alternative for fluidization calculations. For porous materials such as anthracite coal or GAC, the sample should be soaked to fill the pores with water before final measurements are made.

Grain Hardness. The hardness of filter grains is important to the durability of the grains during long-term service as a filter. Hardness is usually described by the *MOH hardness number*, which is a scale of hardness based on the ability of various minerals to be scratched by another harder object. A sequence of minerals of specified hardness is listed (Trefethen, 1959).

The two materials of known MOH hardness that can and cannot scratch the filter media are used to estimate the hardness of the filter grain material. This is a rather crude test and difficult to apply to small filter grains. Of the filter media listed earlier, only anthracite coal and GAC have low hardness worthy of concern. Silica sand, garnet, and ilmenite are very hard, and their hardness need not be of concern. A minimum MOH hardness of 2.7 or 3 is often specified for anthracite coal filter media, although measuring fractional values closer than 0.5 is doubtful.

Two standard mechanical abrasion tests are presented in the AWWA Standard B604, Granular Activated Carbon (AWWA, 2006) to evaluate the abrasion resistance of GAC.

TABLE 10-2 Typical Properties of Common Filter Media for Granular-Bed Filters (Cleasby and Woods, 1975; Cleasby and Fan, 1981; Dharmarajah and Cleasby, 1986)

	Silica sand	Anthracite coal	Granular activated		
			carbon	Garnet	Ilmenite
Grain density (ρ_s), kg/m ³	2650	1450–1730	1300–1500 ^a	3600–4200	4200–4600
Loose-bed porosity (ϵ_0)	0.42–0.47	0.50–0.60	0.50	0.45–0.55	b
Sphericity (ψ)	0.7–0.8	0.46–0.60	0.75	0.60	b

^aFor virgin carbon, pores filled with water; density increases when organics are adsorbed.

^bNot available.

Despite its greater friability than anthracite, the reduction in grain size of GAC because of backwashing and regeneration operations is not reported to be a serious problem (Graese et al., 1987), although some loss of GAC occurs with each regeneration.

Fixed Bed Porosity. Fixed bed porosity is the ratio of void volume to total bed volume, expressed as a decimal fraction or as a percentage. It is important because it affects the backwash flow rate required, the fixed bed head loss, and the solids holding capacity of the filter bed. Fixed bed porosity is affected by the grain sphericity; angular grains (i.e., grains with lower sphericity) have higher fixed bed porosity (Cleasby and Fan, 1981), as is evident in Table 10-2. For the low UC commonly specified for filter media, UC has no effect on porosity; however, for natural materials with high UC, the nesting of small grains within the voids of the large grains can reduce the average bed porosity.

Fixed bed porosity is determined by placing a sample of known mass and density in a transparent tube of known internal diameter. The depth of the filter media in the tube is used to calculate the bed volume. The grain volume is the total mass of media in the column divided by the density. The void volume thus is the bed volume minus the grain volume. The fixed bed porosity is substantially affected by the extent of compaction of the media placed in the column and by the column diameter. The loose bed porosity can be measured in a column of water. If the bed is agitated by inversion and then allowed to settle freely in the water with no compaction, the highest porosity will be obtained, that is, the loose bed porosity. It may be as much as 5 percent greater than the porosity measured after gentle compaction of the bed. Materials of lower sphericity show greater change in porosity between the loose and compacted bed conditions.

The porosity of the granular filter bed is higher near the wall of the filter. This can be important in small pilot-scale filter columns because it causes the average bed porosity to be higher than in full-scale filters and affects the particle removal and head loss behaviors during filtration studies. It is common to make the diameter of such filter columns at least 50 times the grain size of the coarser filter grains to be studied (e.g., d_{90}) to minimize such wall effects.

Sieve Analysis Considerations. The standard procedure for conducting sieve analysis of filter media is detailed in ASTM Standard Test C136-06 (ASTM, 2009). This standard does not specify a sieving time or a specific mechanical apparatus for shaking the nest of sieves. Rather, it specifies that sieving should be continued “for a sufficient period and in such manner that, after completion, not more than 1 weight percent of the residue on any individual sieve will pass that sieve during one minute of hand sieving” and conducted in a manner described in the ASTM standard. With softer materials such as anthracite coal or GAC, abrasion of the material may occur when attempting to meet the 1 percent passing test.

When sieving a 100 g sample of hard materials such as sand on 8-in sieves and using a Ro-Tap type of sieving machine, it is common to require three sieving periods of 5 minutes each to satisfy the 1 percent passing test. The Ro-Tap machine imparts both a rotary shaking and a vertical hammering motion to the nest of sieves. With some other sieving machines, the ASTM requirement will not be achieved even after three 5-minute periods of sieving.

When sieving anthracite coal, the sample should be reduced to 50 g because of its lower density. The Ro-Tap machine should be used and the time fixed at 5 minutes. This will not meet the 1 percent passing test, but prolonged sieving may cause continued degradation of the anthracite, yielding a less accurate result.

Because of sieving and sampling difficulties, and because of the tolerance allowed in manufacture of the sieves themselves (ASTM E11-09 Standard Specification for Wire Cloth and Sieves for Testing Purposes, ASTM, 2009), a reasonable tolerance should be allowed in the specified size when specifying filter media. Otherwise, producers of filter material may not be able to meet the specification, or a premium price will be charged. A tolerance of ± 10 percent is suggested. For example, if a sand of 0.5 mm ES is desired, the specification should read "0.45 to 0.55 mm ES." If an anthracite coal of 1.0 mm ES is desired, the specification should read "0.9 to 1.1 mm ES."

Typical Properties of Granular Filter Media. With prior understanding of the importance of various properties of granular filtering materials, Table 10-2 is presented to illustrate typical measured values for some properties. The large difference in grain densities, evident in the table, allows the construction of dual- and triple-media filters with coarse grains of low-density material on top and finer grains of higher-density material beneath; this layering is maintained during fluidized backwashing because of the combination of size and density. Alluvial sands have the highest sphericity, and crushed materials such as anthracite, ilmenite, and some garnet have lower sphericity. Some anthracites contain an excessive amount of flat, elongated, jagged grains resulting in lower sphericity. The loose bed porosity is inversely related to the sphericity; that is, the lower the sphericity, the higher is the loose bed porosity. An approximate empirical relationship between sphericity and loose bed porosity was used in developing a predictive model for fluidization presented later in this chapter (Cleasby and Fan, 1981).

Filter Media Configurations

Some typical configurations of filter media are shown in Fig. 10-5. The most commonly used of these configurations are the conventional sand filter and the dual-media filter, but a substantial number of triple-media filters have been installed. GAC can be used to replace anthracite (or sand), sometimes referred to as *filter-adsorbers*. GAC can be used alone or in dual- or triple-media configurations. The first three configurations in Fig. 10-5 are backwashed with full fluidization and expansion of the bed. Fluidization results in stratification of the finer grains of each media near the top of that layer of media.

The single-media, deep-bed filter using coarse sand, anthracite coal, or GAC (Fig. 10-5, bed 4) differs from the conventional sand filter in two ways. First, because the media in such filters are coarser, a deeper bed is required to achieve comparable removal of particles. Second, because excessive wash rates would be required to fluidize the coarse media, it is often washed without fluidization by the concurrent upflow of air and water. The air-water wash causes mixing of the media, and little or no stratification by size occurs.

The upflow filter is used in some wastewater filtration plants and in a few potable water treatment plants in other countries. It may include a restraining grid to resist uplift, as shown in Fig. 10-5 (bed 5), or it may be operated with a deeper sand layer and to a limited terminal head loss so that the mass of the sand itself acts to resist uplift. The upflow

FIGURE 10-5 Schematic diagrams of some typical filter bed configurations. Beds 1, 2, and 3 are washed with fluidization, whereas beds 4 and 5 are washed with air plus water without fluidization.

filter is washed using a forward flow employing air and water together. Adoption of the upflow filter as the only filtration step in potable water treatment is doubtful because of the potential for contamination of the filtered water by both the dirty wash water and the filtered water exiting above the filter bed. Upflow roughing filtration is being used in potable water treatment plants in the United States, where it is used in the pretreatment process in place of sedimentation or other solids separation processes, ahead of downflow filtration. A buoyant crushed plastic media (2-4 mm size) used in upflow mode ahead of a downflow triple-media bed (Benjes et al., 1985) is one common configuration.

Typical grain sizes used in rapid-rate filters are presented in Table 10-3 for various potable water applications. The UC of the filter media is usually specified to be less than 1.65 or 1.7. Use of a lower UC is beneficial for coarser filter media sizes that are to be backwashed with fluidization because this will minimize the d_{90} size and thereby reduce the required backwash flow rate. The lower the specified UC, the more costly will be the

TABLE 10-3 Typical Media Grain Sizes and Bed Depths for Different Applications

	Effective size, mm	Total depth, m
A. Common U.S. Practice after Coagulation and Clarification		
1. Sand alone	0.45–0.55	0.6–0.7
2. Dual media: Add top-layer anthracite, 0.3–0.6 m deep (bottom sand layer, 0.15–0.3 m deep)	0.9–1.1	0.6–0.9
3. Triple media: Add bottom garnet, 0.1 m, to dual media	0.2–0.3	0.7–1.0
4. GAC: Use in place of anthracite in dual media		
5. For direct filtration: dual media as in A(2)		
B. Coarse Single-Media Filters, Simultaneous Air/Water Wash		
1. For coagulated and clarified water	0.9–1.1	0.9–1.2
2. For direct filtration: May add 0.15–0.3 m bottom sand layer	1.4–1.6	1–2
C. U.S. Practice for Fe and Mn Filtration		
1. Dual media similar to A(2) above		
2. Single media, standard	<0.8	0.6–0.9
3. Single media, coarse	1–2	1.5–3

filter media because a greater portion of the raw material falls outside the specified size range. Therefore, the lowest practical UC is about 1.4. Anthracite coal that will meet this UC is available commercially.

There is growing interest in and use of deeper beds of filtering materials, either single- or dual-media, especially for high-rate direct filtration applications. These filter media configurations typically involve 1.0 to 3.0 m (3.2–9.8 ft) of coarse (1.2 to 1.5 mm ES) anthracite alone or above a 0.15 to 0.3 m (0.5 to 1.0 ft) layer of 0.6 to 1.0 mm ES sand and HLRs as high as 33 m/h (13.5 gpm/ft²). More details and specific examples are described under “Direct Filtration” later in this chapter. One reason for consideration of deep beds is the possibility of having relatively long contact times, which can be advantageous for biologically active filtration, perhaps with GAC media.

For example, Patania et al. (1995) used deep beds (2.0 m or 6.7 ft) of 1.25 mm ES anthracite over 0.25 m (0.83 ft) of 0.6 mm ES sand for in-line filtration pilot studies of cyst removal in Seattle. In 2000, the 454 ML/d (120 mgd) capacity Seattle Tolt plant went into operation, incorporating preozonation, coagulation, and hydraulic flocculation prior to single-media filtration with 1.8 m (6.0 ft) of 1.3 mm ES anthracite with a UC of less than 1.4, which is approved for an HLR of 29 m/h (12 gpm/ft²) (Tarbuck et al., 2002). In late 2009, the new 1800 ML/d (475 mgd) Seymour–Capilano direct filtration plant began operation for the metropolitan Vancouver, BC, water supply. The configuration for the dual-media filters (24) is 1.7 m (5.6 ft) of 1.4 mm ES anthracite (UC < 1.5) over 0.3 m (1.0 ft) of 0.7 mm ES sand (UC < 1.5) (Phelan, 2010). Pilot studies for proposed plants for Sydney, Australia, included deep-bed single-media and dual-media configurations (Murray and Roddy, 1993). The dual-media filters studied included anthracite 1.0 to 3.0 m (3.2–9.8 ft) in depth with 1.7 to 2.5 mm ES over 0.15 to 0.30 m (0.5–1.0 ft) of crushed sand with 0.65 to 1.0 mm ES. The coarser dual media performed best in water production per cycle and in filtrate quality. One reason expressed for the interest in the deep beds was the possible future conversion of the filters to GAC with empty-bed contact times of at least 7.5 minutes.

In addition to the configurations of filtering materials shown in Fig. 10-5, other approaches are used in some applications. For traveling-bridge, continuous-backwash downflow filters (e.g., the ABW Automatic Backwash Filter), the filter is divided horizontally into lateral cells and uses a shallow layer of fine sand, usually of about 0.3 m (12 in) depth (Medlar, 1974). Another approach involves continuous downward movement of the sand bed while water to be treated flows up through the media; the lowest media

is continuously directed to an uplift backwashing system and reapplied to the top of the downflowing media bed (e.g., the DynaSand process). Beds of engineered ceramic media have been used in downflow mode for direct filtration (Saltnes et al., 2002), with special attention to the role of surface roughness for biofilm support (Melin et al., 2000) and particle retention (Emelko et al., 2007).

The Relationship Between Bed Depth and Media Size: The (L/d) Ratio. When considering the use of coarser media, deeper bed depth results when the ratio of bed depth to grain diameter, L/d , is held constant or is increased; the goal is to maintain equal filtrate quality when filtering the same influent suspension at the same filtration rate. The concept is supported by the experiments of Ives and Sholji (1965). However, these authors also analyzed the work of other investigators that suggested that the relationship should be L/d^β , with β values from 1.5 to 1.67. Fundamental theory (see below) supports higher values of β , and the consideration of a characteristic filter bed depth presented by Lawler and Nason (2006) shows the need for increasing the L/d ratio to maintain similar particle removal performance as media size and filtration rate increase.

Nevertheless, the L/d ratio is used in practice. For graded beds, the effective size (d_{10}) has been suggested for the diameter term; the MWH (2005) text indicates a range of 1000 to 2000 for the ratio. For dual- and multi-media filters, the sum of the L/d_{10} values for each layer is calculated for the bed. Some typical values for L/d_{10} for common bed configurations from Kawamura (2000) follow: (1) $L/d_{10} \geq 1000$ for ordinary fine-sand and dual-media beds, (2) $L/d_{10} \geq 1250$ for triple-media (anthracite, sand, garnet) beds, (3) $L/d_{10} \geq 1250$ for a deep, single-media bed ($1.5 \text{ mm} > d_{10} > 1.0 \text{ mm}$), and (4) $L/d_{10} = 1250$ to 1500 for very coarse, deep, single-media beds ($2.0 \text{ mm} > d_e > 1.5 \text{ mm}$).

For a common dual-media filter with 0.6 m (2.0 ft) of anthracite of 1.0 mm ES over 0.3 m (1.0 ft) of sand of 0.5 mm ES, the total L/d_{10} would be $600/1.0$ plus $300/0.5 = 1200$, meeting Kawamura's criteria. Of course, this is a simplistic concept for a complex process, but it does assist in selecting alternative filter media for pilot-scale evaluations. Kawamura (2000) also notes that for media size greater than 1.5 mm, it is advisable to include a shallow (0.3 m or 1 ft) layer of finer sand below the deep coarse-media bed.

Single-Media Versus Multi-Media Filters. The media used in rapid filters evolved from fine-sand single-media filters about 0.5 to 0.9 m (2–3 ft) deep to dual-media and later to triple-media (mixed) filters of about the same depth. Still later, led by the successful use at Los Angeles, there has been a strong interest in deep-bed [1.2–1.8 m (4–6 ft)], coarse, single-media filters. The rationale for this evolution is discussed in this section.

Early research on rapid sand filters with sand about 0.4 to 0.5 mm ES demonstrated that most of the solids were removed in the top several centimeters (few inches) of the sand, and thus the full bed depth was not well used. The dual-media filter bed, consisting of a layer of coarser anthracite coal on top of a layer of finer silica sand, was developed to encourage better penetration of solids into the bed and thus better use of the filter bed.

The use of dual-media filters is widespread in the United States. Camp (1961) reported using dual-media swimming pool filters beginning about 1940 and later in municipal treatment plant filters. Baylis (1960) described early work in the mid-1930s at the Chicago Experimental Filtration Plant, where a 7.5 cm (3-in) layer of 1.5 mm ES anthracite over a layer of 0.5 mm ES sand greatly reduced the rate of head loss development in treatment of Lake Michigan water.

The benefit of dual-media filters in reducing the rate of head loss development, thus lengthening the filter run, is well proven by a number of later studies (Conley and Pitman, 1960a; Conley, 1961; Tuepker and Buescher, 1968); however, the presumed benefit to the quality of the filtrate is not well demonstrated.

Based on their experiences, Conley and Pitman (1960b) concluded that the alum dosage should be adjusted to achieve low levels of uncoagulated matter in the filtrate (low turbidity) early in the filter run (after 1 hour) and that the filter-aid polymer should be adjusted to the minimum level required to prevent terminal breakthrough of alum floc near the end of the run. The dosage of polymer should not be higher than necessary, however, to prevent excessive head loss development.

Further research comparing dual media with fine-sand media was reported by Robeck et al. (1964). They compared three filter bed designs during filtration of alum-coagulated surface water. These comparisons were made by running filters in parallel so that the benefits of dual media were demonstrated more conclusively. The rate of head loss development for the dual-media filter was about half that of the sand media, but the effluent turbidity was essentially the same prior to breakthrough, which was observed under some weak flocculation conditions.

The evidence clearly demonstrated the lower head loss expected for a dual-media filter compared with a traditional fine-sand filter. For a typical dual-media filter with an anthracite ES that is about double the sand ES, the head loss development rate should be about half the rate of the fine-sand filter when both are operated at the same filtration rate on the same influent water.

The benefits gained by the use of dual-media filters led to the development of the triple-media filter, in which an even finer layer of high-density media (garnet or ilmenite) is added as a bottom layer (Conley, 1965, 1972). The bottom layer of finer material should improve the filtrate quality in some cases, especially at higher filtration rates.

The triple-media filter is sometimes referred to as a *mixed-media* filter because in the original development, the sizes and uniformity coefficients of the three layers were selected to encourage substantial intermixing between the adjacent layers. This was done to come closer to the presumed ideal configuration of “coarse to fine” filtration. The original patents have expired, and other specifications for triple-media filters are being used with various degrees of intermixing.

The initial clean bed head loss will be higher for the triple-media filter because of the added layer of fine garnet or ilmenite. Thus, for a plant with a particular total available filter system head loss, the clogging head loss available to sustain the run is reduced, which may shorten the run compared with the run obtained with a dual-media filter (Robeck, 1966).

Some comparisons of triple-media versus dual-media filters have demonstrated triple-media filters to be superior in filtered water quality. On Lake Superior water at Duluth, a mixed-media (triple-media) filter was superior to a dual-media filter in amphibole fiber removal (Logsdon and Symons, 1977; Peterson et al., 1980). Twenty-nine of 32 samples of filtrate were below or near detection level for the dual-media filter and 18 of 18 for the mixed-media filter. Mixed-media filters were recommended for the plant. Mixed-media filters also were reported to be superior in resisting the detrimental effects of flow disturbances on filtrate quality (Logsdon, 1979).

In contrast, Kirmeyer (1979) reported pilot studies for the Seattle water supply in which two mixed-media and two dual-media filters were compared. No difference in filtrate quality was observed in either turbidity or asbestos fiber content with filtration rates of 13.4 to 24.4 m/h (5.5–10 gpm/ft²). Some differences in production per unit head loss were observed favoring dual-media filters at lower rates and mixed-media filters at higher rates.

A number of laboratory studies have compared triple-media versus single-media (fine-sand) filters (Diaper and Ives, 1965; Rimer, 1968; Oeben et al., 1968; Mohanka, 1969). All these studies have shown clearly the head loss benefit gained by filtering in the direction of coarse to fine grains. Three of the studies also clearly showed benefits to the filtrate quality for the triple-media filters (Diaper and Ives, 1965; Rimer, 1968; Oeben et al., 1968).

Cleasby et al. (1992) summarized 12 unpublished pilot- and plant-scale studies conducted for utilities comparing dual- and triple-media filters and deep single-media filters in

high-rate filtration of surface waters. The studies supported the superiority of triple-media filters over dual-media filters (with comparable depths of anthracite and sand) in producing the best-quality filtered water; however, higher initial head losses and better solids capture resulted in shorter filter cycles for triple-media filters, other factors being the same. The studies comparing deep bed, coarse, single-media filters with dual- or triple-media filters were inconclusive with regard to quality of filtrate; however, the deep-bed, coarse, single-media filters achieved longer filter cycles and greater water production per cycle than traditionally sized dual- or triple-media filters.

Use of GAC in Rapid Filtration. GAC media are used for both particle removal and adsorption of organic compounds, that is, as a filter-adsorber, as well as in biologically active filters and post-filtration contactors (see Chap. 14 for more details). The principal application of filter-adsorbers to date is to remove taste- and odor-causing compounds where full-scale experience shows successful removal for periods from 1 to 5 years before the GAC must be replaced/regenerated (Graese et al., 1987). High concentrations of competing organic compounds, however, can reduce this duration. Many GAC filter-adsorbers are retrofitted rapid filters in which GAC has replaced part or all of the sand in rapid sand filters or replaced anthracite in dual- or triple-media filters. In addition, selection of GAC media for new filters is not uncommon.

GAC used in retrofitted filters typically is 0.38 to 0.76 m (15–30 in) of 12 × 40 mesh GAC (ES 0.55–0.65 mm) or 8 × 30 mesh GAC (ES 0.80–1.0 mm) placed over 0.15 to 0.30 m (6–12 in) of sand (ES 0.35–0.60 mm) in a dual-media configuration. These GAC materials often have a higher UC (≤ 2.4) than traditionally used filter materials (≤ 1.6). The high UC can contribute to more fine grains in the upper layers and shorter filter cycles but results in less size intermixing during backwashing, which is beneficial to the adsorption function. A lower UC can be realized by specifying a narrower mesh range, that is, 8 × 20 or 8 × 16 mesh. Some filters designed for GAC media initially use up to 0.9 to 1.8 m (3–6 ft) of coarser GAC (ES 1.3 mm or greater) with a lower uniformity coefficient (1.4). This provision should result in longer filter cycles and longer periods between the need for GAC replacement/regeneration based on adsorption objectives.

GAC has been used successfully in both single-media and dual-media filters. It is as effective in its filtration function as conventional filter media, either sand or dual-media, provided that an appropriate size media has been selected (Graese et al., 1987; Emelko et al., 2006). Particles removed by the GAC filter and the need for frequent backwashing do, however, impede the adsorption function somewhat compared with postfilter GAC contactors with the same contact time (see Chap. 14).

The layer of fine sand in a dual-media GAC–sand filter may be essential where low filtered water turbidity is the goal. The use of sand and GAC in dual-media beds, however, causes difficulties during replacement/regeneration because it is difficult to remove the GAC media from the filter free of sand or to separate the sand after removal. Sand causes difficulties in regeneration furnaces (Graese et al., 1987).

GAC media are often selected for filters that are designed to be biologically active, that is, where removal of biodegradable organic matter (BOM) is expected; often particle and BOM removal are expected to occur in a single filtration process. Urfer et al. (1997), Liu et al. (2001), and Emelko et al. (2006) review and report on factors such as temperature, media type, and chlorination/chloramination of backwash water that can affect the performance of such filters. Media other than GAC (sand, anthracite) can be effective for BOM removal, although GAC appears to perform better for challenging conditions of lower temperature and oxidants in backwash water. Accumulation of biomass in biofiltration necessitates periodic backwashing, which can, in turn, affect BOM removal. Chlorine residual in filter influent is quickly destroyed by the GAC media and may negatively affect the media (see Chap. 14). In general, chlorination of filter influent does not completely prevent

bacterial growth. Since microorganisms detach from biologically active filters, post-filter disinfection is needed.

Because of the adsorption capacity of unused or regenerated activated carbon, there can be rapidly changing impacts of GAC media particle removal filters on certain measures of water quality following filter startup. This is especially true for sorption of NOM, as measured by removal of total organic carbon (TOC) or UV_{254} ; short-term (weeks to months) high removal efficiency is not at all representative of long-term (years) performance. Care must be taken in conducting pilot-scale studies with GAC media to recognize this and either use media that has already had its short-term NOM uptake capacity exhausted or operate the pilot study long enough for this to occur. It is also difficult to measure the expected lower-level long-term removal of NOM by biodegradation on GAC filter media during the duration of a typical pilot study.

GAC is softer than anthracite, but the attrition of GAC media in full-scale plants has not been excessive. GAC losses from 1 to 6 percent per year have been reported (Graese et al., 1987), which is not higher than typical losses of anthracite. A modest reduction in grain size of GAC has been measured at some plants. GAC has a lower density than anthracite, posing some concerns about losses during backwashing, a topic discussed later in this chapter.

Rates of Filtration

Fuller (1898) is commonly credited with establishing a rate of filtration of 5 m/h (2 gpm/ft²) for chemically pretreated surface waters. This filtration rate was considered practically inviolable for the first half of the twentieth century in the United States. Fuller observed that with properly pretreated water, however, higher rates gave practically the same water quality. Of more importance, Fuller acknowledged that without adequate chemical pretreatment, no assurance of acceptable filtered water existed even at filtration rates of 5 m/h (2 gpm/ft²); much more recently, Bellamy et al. (1993) emphasized that optimal coagulation is the most important factor in achieving excellent performance of granular media filtration.

In the 1950s and 1960s, many plant-scale studies were conducted comparing filter performance at different filtration rates (Brown, 1955; Baylis, 1956; Hudson, 1962). These studies generally were conducted as utilities were considering upgrading existing filters or building new plants with filtration rates that were higher than the traditional 5 m/h (2 gpm/ft²). The results of these and similar studies (Cleasby and Baumann, 1962; Conley and Hsuang, 1969) demonstrated that higher filtration rates resulted in somewhat poorer filtrate quality, as both theory and intuition would predict. However, at the time, the turbidity standard was 1 Jackson turbidity unit, and it was presumed that chlorine disinfection would inactivate pathogens that passed through the filters. Nevertheless, there was a gradual acceptance of filtration rates up to 9.8 m/h (4 gpm/ft²) with conventional pretreatment and without the use of filter-aid polymers to increase particle retention (King et al., 1975).

Pioneering work at higher filtration rates, assisted by filter-aid polymer, included the following studies: Robeck et al. (1964) compared performance of pilot filters at 5 to 15 m/h (2–6 gpm/ft²) filtering alum-coagulated surface waters through single-media and dual-media filters. They concluded that with proper coagulation ahead of the filters, the effluent turbidity, coliform bacteria, poliovirus, and powdered carbon removal was as good at 15 m/h (6 gpm/ft²) as at 10 or 5 m/h (4 or 2 gpm/ft²). Pretreatment included activated silica when necessary to aid flocculation and a polyelectrolyte as a filter aid (referred to as a “coagulant aid” in the original article); the filter-aid polymer retarded turbidity breakthrough, causing the filter run time to increase from 16 to 22 hours.

Conley and Pitman (1960a) showed the detrimental effect of high filtration rates up to 37 m/h (15 gpm/ft²) in the treatment of Columbia River water by alum coagulation followed by short-detention flocculation and sedimentation before filtration. A proper dose of

nonionic polymer added to the water as it entered the filters, however, resulted in the same filtrate quality from 5 to 85 m/h (2–35 gpm/ft²).

Over the last 30 years, concerns about *Giardia* and *Cryptosporidium* have emphasized the need to achieve filtered water turbidities at or below 0.10 ntu and have emphasized log reduction of cysts or cyst-sized particles to ensure the absence of protozoan pathogens. Some results of such studies were presented earlier in this chapter, and some are presented below.

When chemical pretreatment was optimized for turbidity and particle removal resulting in filtered water turbidity below 0.10 ntu, Patania et al. (1995) found no difference in *Giardia* cyst and *Cryptosporidium* oocyst removal in pilot studies at Contra Costa at filtration rates of 7 to 15 m/h (3–6 gpm/ft²) and at Seattle at 12 to 20 m/h (5–8 gpm/ft²). Conventional pretreatment preceded filtration at Contra Costa, whereas in-line filtration was used at Seattle. Both used deep-bed dual-media filters and dual coagulants (alum plus cationic polymer). Filter-aid polymer also was used in the Seattle pilot plant.

Design and operation guidelines for optimization of high-rate filtration plants were reported by Cleasby et al. (1989, 1992). The reports were based on a survey of 21 surface water treatment plants with consistent operational success in producing filtered water turbidity below 0.2 ntu at filtration rates at or above 10 m/h (4 gpm/ft²). These plants were characterized by management support of a low turbidity goal, optimal chemical pretreatment, the use of polymeric flocculation and/or filter-aid chemicals, the use of dual- or triple-media filters, continuous monitoring of effluent turbidity for each filter, and good operator training.

The use of unusually high filtration rates was reported at the Contra Costa County Water District plant in California. By precoating the dual-media filters with a small dose of polymer during the backwash operation, Harris (1970) reported successful operation at 24 m/h (10 gpm/ft²). Harris also reported that the initial period of poorer water quality was eliminated by this precoating operation. The Contra Costa County Water District plant was authorized by the State of California to operate at 24 m/h (10 gpm/ft²).

Another example of an unusually high design filtration rate is the 33 m/h (13.5 gpm/ft²) selected for the Los Angeles direct filtration plant. This filtration rate was selected and approved by the state after more than 5 years of extensive pilot-scale studies (Trussell et al., 1980; McBride and Stolarik, 1987). The plant uses ozone, ferric chloride, and cationic polymer in pretreatment and deep-bed (1.8 m or 6 ft) coarse anthracite (1.5 mm ES, 1.4 UC) single-media filters. It has operated successfully at the design rate, producing filtered water below 0.1 ntu on a consistent basis.

Both these treatment plants are large, treating high-quality surface water with skilled management and operation. Thus filtration rates of these magnitudes probably will not become common. With poorer source waters and in smaller plants with less careful surveillance or operation, filtration rates at or below 10 m/h (4 gpm/ft²) are likely to continue to be the prudent choice. Nevertheless, the success at Los Angeles has stimulated great interest in deep-bed single-media filtration. Other similar plants are now in service, but not at such high filtration rates. For example, the Modesto, Calif, plant (Short et al. 1996) uses the same filter media as in the Los Angeles plant, but the design filtration rate is 15 m/h (6 gpm/ft²).

Acceptance of filtration rates above 5 m/h (2 gpm/ft²) varies among state regulatory agencies, however, and plant- or pilot-scale demonstrations are required by some state agencies before acceptance.

The use of higher filtration rates shortens the filter cycle roughly inversely with the rate. This problem is minimized by the use of dual- or triple-media filters or deep beds of coarser media with or without an underlying shallow layer of finer-sand media. As noted earlier, filters with coarser media provide for better penetration of solids into the filter bed and thus better use of the bed pores for solids storage during the filter cycle.

Acceptable Filter Run Length and Production per Run

Higher filtration rates have two conflicting impacts on plant production. First, the clean bed head loss is increased. Thus, for a given amount of available head loss in the plant hydraulic profile, less clogging head loss is available to sustain the filter cycle. This will shorten the filter cycle length if it is terminated based on reaching maximum available head loss. Second, for a given media, the head loss increases at a faster rate per hour at higher filtration rates because solids are captured at a faster rate. However, the water production per unit time also increases so that production per day is increased substantially unless the filter cycles get too short. Therefore, the common importance attached to the length of filter run can be misleading. Rather than emphasizing the effect of filtration rate on length of run, one should emphasize the effect of filtration rate on filtrate quality, net plant production, and production efficiency.

Figure 10-6 illustrates the effect of unit filter run volume on net water production at three filtration rates (Trussell et al., 1980). *Unit filter run volume* (UFRV) is the actual throughput of a filter per unit area during one filter run; it also can be called *gross production per filter run*. Figure 10-6 is based on the assumption that 4 m³/m² (100 gal/ft²) is used for each backwash operation, and 30 minutes of downtime is required per backwash. Similar figures can be constructed with other assumptions. The following example illustrates preparation of the figure.

- Assume four cycles per day per filter.
- Run time per cycle = 6 hours/cycle – 0.5 hour/wash = 5.5 hours/cycle.
- Assume desired maximum filtration rate = 12.2 m³/m²/h (5 gpm/ft²).
- Unit filter run volume 12.2 × 5.5 = 67.1 m³/m²/cycle (1,650 gal/ft²/cycle).
- Gross volume filtered/m²/day = 67.1 × 4 cycles/day = 268.4 m³/m²/day (6600 gal/ft²/day).

FIGURE 10-6 Net (gross) production versus unit filter run volume assuming 30 minutes of downtime per backwash and a backwash volume of 100 gal/ft² per backwash—1 gal equals 3.785 liters. (Source: Trussell et al., 1980.)

- Net water production/ $\text{m}^3/\text{m}^2/\text{day} = 268.4 - \text{backwash volume} = 268.4 - 4.1 \times 4 \text{ cycles/day} = 252 \text{ m}^3/\text{m}^2/\text{day}$ (6200 gal/ ft^2/day).
- Production efficiency expressed as percent of gross volume filtered = $(252/268.4) \times 100 = 94$ percent.

In general, allowing for backwash volumes of 4 to 8 $\text{m}^3/\text{m}^2/\text{wash}$ (100–200 gal/ ft^2/wash) and a downtime of 30 min/wash, production efficiency will remain high if the UFRV exceeds about 200 $\text{m}^3/\text{m}^2/\text{run}$ (5000 gal/ ft^2/run). The calculations just presented are the same whether the backwash water is recovered by recycling through the plant or not recovered. Above 200 $\text{m}^3/\text{m}^2/\text{run}$ (5000 gal/ ft^2/run) UFRV, the net production increases almost linearly with rate. Thus the key issue when considering the impact of high filtration rates on production is not run length alone but rather the gross production per run (run length \times filtration rate) and the filtrate quality. A unit filter run volume of 200 $\text{m}^3/\text{m}^2/\text{run}$ (5000 gal/ ft^2/run) means a run length of 41 h at 4.9 m/h (2 gpm/ ft^2) or 16.7 h at 12 m/h (5 gpm/ ft^2); both rates yield a 98 percent production efficiency, so one is not better than the other by this measure.

In summary, high-rate filtration does have a definite effect on development of head loss and length of filter run that must be anticipated. The benefits of greater net production/ m^2/day at higher filtration rates, however, more than justify that consideration because of lower capital cost for new plants or increased production from existing plants.

Underdrain and Support Gravel

The underdrain system serves to support the filter media, collect filtered water (in down-flow filters), and distribute backwash water and air scour if air is used. A wide variety of underdrain systems are in use; three major types are described below.

The first and oldest type is the manifold-lateral system, in which perforated pipe laterals are located at frequent intervals along a manifold (Fig. 10-7). Perforations in the laterals are 6 to 13 mm ($\frac{1}{4}$ – $\frac{1}{2}$ in), located on 8 to 30 cm (3–12 in) spacing.

FIGURE 10-7 Rapid gravity filter with manifold and lateral underdrain system. (Source: After C. P. Hoover, *Water Supply and Treatment*, National Lime Association.)

The second is the fabricated self-supporting underdrain system that is attached (grouted) to the filter floor, as in Fig. 10-1. The older example of this type is a vitrified clay block underdrain; more recently, plastic block underdrains have been used. The plastic block underdrains are capable of delivering backwash air or water or air and water simultaneously. Top openings on these types of underdrains are about 6 mm ($\frac{1}{4}$ in) when a gravel support layer is used. The plastic block underdrains may have a smaller-opening porous cap installed (plastic bead or stainless steel) to eliminate the gravel support layer.

A third type of underdrain is the false-floor underdrain with nozzles (Fig. 10-8). A false-floor slab or a steel plate is located 0.3 to 0.6 m (1–2 ft) above the bottom of the filter, thus providing an underdrain plenum below the false floor. Nozzles to collect the filtrate and distribute the backwash water are located at 13 to 20 cm (5–8 in) centers. Nozzles may have coarse openings of about 6 mm (¼ in), or they may have fine openings, sufficiently small to retain the filter media. The nozzles may be equipped with a stem protruding about 15 to 23 cm (6–9 in) into the underdrain plenum. One or two small holes or slots in the stem serve to distribute air, either alone or in combination with water.

FIGURE 10-8 Nozzle underdrain system consisting of a monolithic cast-in-place concrete slab on a permanent plastic underdrain with nozzles capable of air and water distribution. (Source: *Multicrete II*, Courtesy of General Filter Co., Ames, Io.)

Many filters use underdrain systems with openings larger than the filter media to be supported. As a result, using several layers of graded gravel between the underdrain openings and the filter media is necessary to prevent the media from passing downward into the underdrain system. Details of gravel sizing and layering are available in design texts (e.g., Kawamura, 2000), in standards (AWWA, 2001), and from manufacturers. The conventional gravel system begins with coarse-sized gravel at the bottom with progressively finer-sized gravel layers above up to the filter media. Typical rules of thumb for the gradations of adjacent layers reported by Huisman (1974) in Europe are as follows:

1. Each gravel layer should be as uniform as possible, preferably with the 10 and 90 percent passing diameters not more than a factor of $\sqrt{2}$ apart. In the United States, a sieve size ratio of 2 for the passing and retaining sieves is commonly accepted (AWWA, 2001).
2. Bottom-layer lower grain size limit should be 2 to 3 times the orifice diameter of the underdrain system.
3. Top-layer lower grain size limit should be 4 to 4.5 times the ES of the media to be retained.
4. From layer to layer, the upper grain size limit of the coarser layer should be 4 times the lower grain size limit of the adjacent finer layer.
5. Each layer should be at least 7 cm (3 in) thick or 3 times the upper grain size limit of the layer, whichever is greater.

The U.S. interpretation of these guidelines is that the upper and lower grain size limits refer to the sieve sizes that pass and retain the gravel. No more than 8 percent by dry weight shall be finer than the lower grain size limit, and a minimum of 92 percent shall be finer than the upper grain size limit (AWWA, 2010).

When air scour is to be delivered through the supporting gravel, great danger exists that the gravel will be disrupted during the backwash cycle, especially if air and water are used simultaneously. Two solutions are being used. One is to use a nozzle or capped-block underdrain with small enough openings so that gravel is not required. The other is to use a double-reverse-graded gravel system graded from coarse on the bottom to fine in the middle and back up to coarse on the top. This concept—originally used by Baylis to solve gravel migration problems in large filters in Chicago (AWWA, 1971)—is being used in air and water backwash filters supplied by several companies.

In addition to the systems just described, various proprietary underdrain systems that eliminate the need for supporting graded gravel layers are available. The long-term success of these new systems remains to be demonstrated. Since filter failures are often attributed to underdrain deficiencies, adoption of unproven systems is a matter of concern.

MEDIA FILTRATION THEORY AND MODELING

The earliest recorded instance of the filtration of impure water through sand is found in *Susruta Sanhita*, a medical treatise of the Hindus in India (Baker, 1948). In a more recent era, slow sand filters were introduced in England in 1829, and rapid-rate sand filters came into existence in the latter part of the nineteenth century. Slow sand filters were introduced into the United States in 1872, with the first plant built in Poughkeepsie, NY (Fuller, 1933). Municipal rapid-rate sand filters followed with the construction of a plant at Somerville, NJ, in 1885.

After the introduction of sand filters into the United States, a long period then followed during which attention was focused on refining the filter apparatus. A period of refinement

in filter operation followed, after which attention was directed toward proper conditioning of the water prior to the filtration step. Only in the past 50 years or so have significant efforts been made toward determination of the mechanisms of particle removal during packed-bed filtration.

Overview

Much can be learned about filtration of particles in water (aquasols) from past work on filtration of particles in air (aerosols). Observations made by Billings (1966) are particularly helpful (Fig. 10-9). Air filters are often made up of mats of cylindrical fibers. In the experimental results shown in Fig. 10-9, a single cylindrical glass fiber represents an aerosol filter. It receives an airflow of 13.8 cm/s containing polystyrene latex particles at a concentration of approximately 1000/cm³. As filtration proceeds, latex particles are removed from suspension. At and near the start of the run, the glass fiber dominates particle removal and is the primary filter media. However, by 135 minutes, previously retained latex particles begin to control the removal of latex particles and accumulation of the filter deposit. By the end of the run (420 minutes), most particles removed from suspension have been removed by filter media that are actually previously retained particles; the contribution of the glass fiber to removal is negligible. The fact that the media operative in much of a filtration run are actually particles removed from the fluid and not the media installed initially in the filter is helpful in understanding how packed-bed filtration functions in water (aquasol) as well as air (aerosol) filtration.

Packed-bed filters remove particles from the suspensions that flow through them. As noted previously, these particles may have been present in the raw water supply or have been formed in pretreatment. Particles in raw water supplies vary widely in origin, composition, concentration, and size. Some are constituents of land-based or atmospheric inputs (clays, microorganisms including pathogens, asbestos fibers, etc.), and others are produced

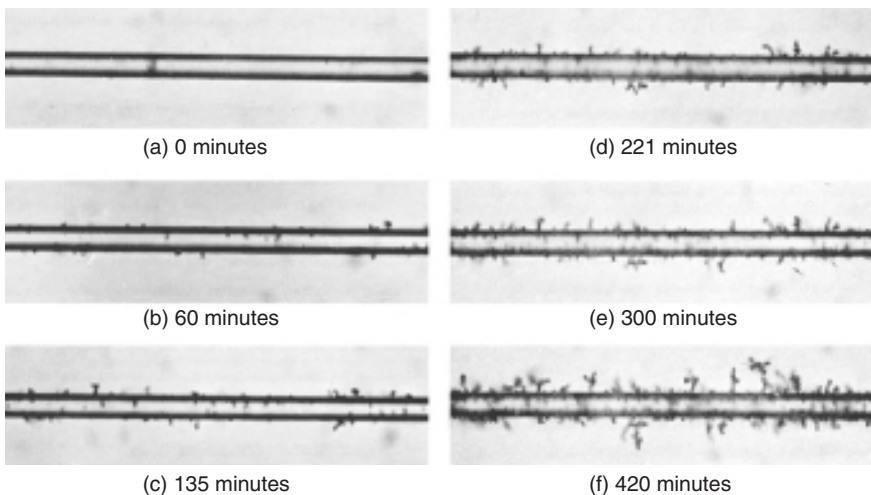

FIGURE 10-9 Deposition of spherical latex particles (1.3 μm diameter) on a cylindrical glass fiber (8.7 μm diameter) from a flowing aerosol suspension. (Source: Billings, 1966.)

by chemical or biological processes in the water source (algae, organic detritus, inorganic precipitates of CaCO_3 , FeOOH , etc.). Soluble natural organic substances (e.g., humic substances) are present in all surface water supplies; these can originate on the land or in the water. Synthetic organic substances and many trace and toxic metals are particle reactive and are associated with particulate materials in the water source. The addition of chemical coagulants aggregates particles present in the water supply, adsorbs and precipitates humic substances, and forms new solid particles [$\text{Al}(\text{OH})_3(s)$, etc.]. The particles reaching a filter in a water treatment system reflect all these inputs and processes (O'Melia 1988).

Pretreatment chemistry is a dominant factor affecting particle removal in packed-bed filters. If the solution chemistry of the water to be treated, the surface chemistry of the particles to be removed, and the surface chemistry of the media used to accomplish removal are not properly controlled, effective particle removal will not occur regardless of the bed depth, filtration rate, and media size installed in the filter system. In practice, this is accomplished by proper selection of the types and dosages of pretreatment chemicals. These may include aluminum or iron(III) salts, polymeric inorganic coagulants such as polyaluminum chloride (PACl), polyiron chloride (PICl) and activated silica, synthetic organic polymers and polyelectrolytes, and even ozone (see Chap. 8).

The principal factors affecting head loss development in packed-bed filters are the concentration and *size* of the particles applied to the filters. Media size, filtration rate, and bed depth have important effects, but the physical properties of the particles applied to filters dominate head loss development after the early stages of filtration in these filters. Small particles can produce large head losses; submicron particles can induce rapid and extensive head loss development when treated by conventional packed-bed filters.

The size of the particles in the water being filtered also affects the removal efficiency of a filter bed when it is clean, such as at the start of a filter run. A critical suspended particle size exists, in the region of $1\ \mu\text{m}$, for which the removal efficiency of clean beds is a minimum. Particles in this size region have the fewest opportunities for contact with the filter media and subsequent removal from suspension. Smaller particles are transported predominately and effectively to the external surfaces of the media by convective diffusion and larger ones by following fluid flow (interception) and by gravity. This $1\ \mu\text{m}$ size is also important in assessing filtrate quality. This is often done by measuring turbidity, a light-scattering property of the particles in the filtrate. As it happens, the turbidity per unit mass of particles in a suspension is a maximum at a size of $1\ \mu\text{m}$ or so; thus the particles that have the smallest chance of removal (based on size) are those that have the largest chance of detection.

It is convenient to describe the removal of a suspended particle in a packed bed of media grains as involving two distinct steps (O'Melia and Stumm, 1967). The first step is transport of the suspended particle from the flowing fluid to the surface of the filter media grain. This is primarily a physical process. The second step is attachment of the particle to the media grain. This is primarily a chemical process.

When filtration is successful in the early stages of a filter run, that is, when the hydrodynamics of particle transport and the chemistry of particle attachment combine to produce effective particle removal in a clean filter bed, these retained particles can serve as filter media during later stages of the run (Fig. 10-9). This produces a ripening of the filter; the efficiency of the removal of particles or turbidity improves with time and can be substantially greater than the "clean" bed in place when the filter run began. Particles removed by the filter become sites (collectors or media) for the deposition of additional material. The important result is that in many and perhaps most of the packed-bed filters used in water and wastewater treatment, the actual filter media operative during most of a filter run are not the sand, coal, or other media installed as specified by the designer. Rather, they are the particles present in the water applied to the filter bed and removed in the filter. Stated another way, the actual filter media active during most of a filter run are formed from

particles present in the water supply and altered during pretreatment processes and from new particles formed by chemical precipitation during pretreatment. Hence the “design” of filter media includes the selection of the raw water source and the design of pretreatment facilities that are installed ahead of the filters. The design of filter media is established “upstream” of the filters by the concentration, size, and surface properties of the particles applied to filters and by the solution chemistry of the aqueous phase.

Particle Removal Theories

Theories or models for particle removal by media filters can be classified into two types of approaches: macroscopic (or phenomenological) and microscopic (or fundamental). The former do not explicitly consider the actual characteristics of the media filter (grain size, shape, etc.) or the particles being removed (i.e., size), whereas the latter focuses explicitly on particle- and pore-scale physics and geometry. Both approaches consider the performance of the “clean” filter media (no significant particle deposit) and how that performance changes as particles are deposited within the filter (“dirty” media). Detailed descriptions of these approaches are available in texts by Tien (1989) and Elimelech et al. (1995).

Macroscopic (Phenomenological) Approach. The contributions of Iwasaki and Ives described next are examples of macroscopic approaches. Based on observations, Iwasaki (1937) published an early mathematical model for slow sand filtration. The equations proposed are as follows:

$$\frac{\partial C}{\partial z} = -\lambda C \tag{10-2}$$

$$\frac{\partial C}{\partial t} + \frac{V}{(1-\epsilon_\sigma)} \frac{\partial C}{\partial z} + \frac{\partial \sigma}{\partial t} = 0 \tag{10-3}$$

$$\lambda = \lambda_0 + k_1 \sigma \tag{10-4}$$

where C is the concentration (mass or volume basis) of suspended material at any bed depth or filtration time, z is the bed depth, λ is an empirical coefficient termed the *impediment modulus* or *filter coefficient*, λ_0 is the initial impediment modulus, t is time, σ is the volume of suspended material retained in the bed per unit of filter volume (termed the *specific deposit*), ϵ_σ is the porosity of the deposited material, V is the approach or superficial filtration velocity, and k_1 is an empirical constant.

Equation 10-2 states that the removal of suspended particles with depth is proportional to the concentration of particles in the water at that depth. A rational basis for this result has been provided by investigators in aerosol filtration (Friedlander, 1958). Equation 10-3 is a volume balance and states (with several assumptions) that the volume of material accumulated within the filter equals the volume removed from suspension. Equation 10-4 expresses Iwasaki’s observations that filtration efficiency improved with time for his slow sand filters.

Based on a mass balance across a filter bed, Ives published an extensive series of results building on Eqs. 10-2 to 10-4 proposed by Iwasaki (e.g., Ives, 1960, 1961, 1963). Ives proposed the following relationship to replace Iwasaki’s Eq. 10-4:

$$\lambda = \lambda_0 + k_2 \sigma - \frac{\phi \sigma^2}{\epsilon - \sigma} \tag{10-5}$$

Here, k_2 and ϕ are empirical coefficients used, respectively, to describe the increase and subsequent decrease in particle removal efficiency with time as the specific deposit increases.

Various other empirical rate expressions have been proposed to relate λ to λ_0 as some function of σ ; 10 such expressions have been summarized by Tien (1989). Two examples illustrate the evolution of such equations. Heertjes and Lerk (1967) proposed the following:

$$\frac{\partial \sigma}{\partial t} = k_1(\epsilon_0 - \sigma)VC \quad (10-6)$$

where ϵ_0 is the clean bed porosity and k_1 is the empirical attachment coefficient (same as λ_0).

This equation states that the rate of particle deposition at a particular depth in a filter at a given time is proportional to the particle flux ($V \times C$) and the volume remaining available for deposition ($\epsilon_0 - \sigma$).

Adin and Rebhun (1977) proposed a rate expression that includes a second term to allow for detachment of already deposited particles:

$$\frac{\partial \sigma}{\partial t} = k_1VC(F - \sigma) - k_2\sigma J \quad (10-7)$$

where k_2 is the empirical detachment coefficient, F is the theoretical filter capacity (i.e., the amount of deposit that would clog the pores such that no more deposition occurred), and J is the hydraulic gradient, with other terms as defined previously.

The first term is almost identical to the preceding expression, but a new filter capacity term F is proposed rather than the clean bed porosity ϵ_0 . The second term states that the probability of detachment depends on the product of the amount of material deposited already, σ , and the hydraulic gradient J .

The mass-balance equation and one rate expression must be solved simultaneously in order to find C and σ as a function of time of filtration in the cycle and depth in the filter. Various numerical or analytical solutions have been used to solve the equations (Heertjes and Lerk, 1967; Adin and Rebhun, 1977; Saatci and Oulman, 1980; Tien, 1989). One of the analytical solutions (Saatci and Oulman, 1980) was developed based on the close similarity between the Langmuir equation for adsorption with the filtration rate expression.

The use of these phenomenological models depends on the collection of pilot- or full-scale filtration data to generate the appropriate attachment and, in some cases, detachment coefficients for the particular suspension being filtered. This need, plus the complex nature of the solutions, has limited the use of such equations in routine filter design. Nevertheless, such models with the appropriate empirical constants can be used to simulate filtrate quality, specific deposit, and head loss as a function time and depth.

The two rate expressions presented (Eqs. 10-6 and 10-7) draw attention to a long-standing question in filtration research, namely, whether detachment of deposited solids occurs in a filter operating at a constant filtration rate or new influent particles merely bypass previously clogged layers. Evidence indicates that detachment does occur, possibly as a result of impingement of newly arriving particles (Clough and Ives, 1986). This evidence was collected using an industrial endoscope inserted into the filter to magnify, observe, and record the deposition process on videotape. The observations were made while filtering kaolin clay on sand filters but without the use of coagulant. Similar unpublished observations (Ives, 1997) were made while filtering a 100 mg/L kaolin suspension that had been coagulated and flocculated with 25 mg/L of alum [$Al_2(SO_4)_3 \cdot 16H_2O$]. Detachment was observed to occur during constant-rate filtration from the impact of arriving particles on unstable deposits and from hydraulic shear stresses without the influence of arriving particles. Further studies of detachment were presented by Ginn et al. (1992), who indicated that detached aggregates in the filter effluent could distort log-removal results for cyst-sized particles obtained by particle counting. Moran et al. (1993) measured particle size distributions as a function of run time and bed depth; the results supported significant detachment that varied with particle size, showing a maximum for particles of several-micron size. In a controlled laboratory

study using several sizes of dyed polystyrene spheres, Kim and Tobiason (2004) provided evidence that for much of a filter run, particles in filter effluents are dominated by detached particles compared with filter influent particles that were never removed.

These types of results, along with rational thinking, make it clear that it is unwise to use measurements of cyst- or oocyst-sized particles in raw water and filter effluent to draw conclusions about the removal of actual protozoan pathogens. Filter influent particles are dominated most often by particles created during treatment, not in the raw water, and filter effluent particles may be detached aggregates of smaller particles. In general, with proper chemical pretreatment, removal performance for actual pathogens is much better than might be inferred erroneously by comparing cyst-sized particles in raw and filtered waters.

Microscopic (Fundamental) Approach. Turning to the microscopic approach, consider a single spherical particle of the filter media. Assume that it is unaffected by its neighbors and fixed in space (Fig. 10-10). This single particle of filter media is termed a *collector*, emphasizing that the ultimate purpose of transporting suspended particles from the bulk flow to the external surfaces of media grains in packed beds is the collection of these particles, thereby accomplishing their removal from the water. The main flow direction is that of gravitational force. A suspended particle following a streamline of the flow may come in contact with the media grain by virtue of its own size (case A in Fig. 10-10); this transport process is termed *interception*. If the density of the suspended particle is greater than that of water, the particle will follow a different trajectory because of the influence of the gravitational force field (case B). The path of the particle is influenced by the combined effects of the buoyant weight of the particle and the fluid drag on the particle. This transport process is called *sedimentation*. Finally, a particle in suspension is subject to random bombardment by molecules of the suspending medium, resulting in the well-known Brownian movement of the particle (case C). The term *convective diffusion* is used to describe mass transport in the flowing fluid by this process.

FIGURE 10-10 Basic transport mechanisms in water filtration.
 (Source: Reprinted with permission from Yao et al., 1971.)

Following after Friedlander (1958) and using the *microscopic approach*, Yao et al. (1971) described the temporal and spatial variation of particle concentration around a single spherical media grain (collector) as follows:

$$\frac{\partial C}{\partial t} + V \cdot \nabla C = D_{hm} \nabla^2 C + \left(1 - \frac{\rho}{\rho_p}\right) \frac{mg}{3\pi\mu d_p} \frac{\partial C}{\partial z} \quad (10-8)$$

Again following Friedlander, the following are defined for a single grain of filter media (Yao et al., 1971):

$$\eta_T = \frac{\text{total rate at which particles strike a media grain}}{\text{total rate at which particles approach a media grain}} \quad (10-9)$$

$$\alpha = \frac{\text{total rate at which particles attach to a mediigrain}}{\text{total rate at which particles strike a media grain}} \quad (10-10)$$

The product $\alpha\eta_T$ is thus the ratio of the flux of particles removed by a single media grain to the flux of particles approaching it. Investigators have had considerably more success describing the transport of particles to media grains (as represented by η_T) than the attachment of these particles to those grains (as described by α , the attachment efficiency factor or sticking probability).

Numerical solutions to Eq. 10-8 have been reported by several authors, notably Yao et al. (1971), Rajagopalan and Tien (1976), and most recently, Tufenkji and Elimelech (2004). The Tufenkji and Elimelech equation follows:

$$\eta_T = 2.4A_s^{1/3} N_R^{-0.081} N_{Pe}^{-0.715} N_{vdW}^{-0.52} + 0.55A_s N_R^{1.675} N_A^{0.125} + 0.22N_R^{-0.24} N_G^{1.11} N_{vdW}^{-0.053} \quad (10-11)$$

The first set of terms on the right-hand side describes transport by convective diffusion, the second by interception, and the third by gravity. The dimensionless groups and parameters in Eq. 10-11 are defined in Table 10-4. Equation 10-11 is based on the Happel sphere-in-cell model of a porous bed and includes the effects of hydrodynamic retardation at small surface separation distances as well as the attractive van der Waals interactions; other repulsive or attractive forces, such as arising from electric double-layer interactions, are not included.

As presented elsewhere (i.e., Yao et al., 1971; Tobiason and O'Melia, 1988), it is instructive to consider the impact of particle size on predicted collision efficiency; Figure 10-11 shows η_T , calculated using Eq. 10-11, as a function of particle size for specified conditions ($d_c = 0.5$ mm, $V = 5$ and 20 m/h, $T = 20^\circ\text{C}$, $\rho_p = 1050$ kg/m³, $\epsilon_0 = 0.4$, $H = 1.0 \times 10^{-20}$ J). The plot shows a characteristic minimum in collection efficiency at approximately $1 \mu\text{m}$, with collection improving as size decreases due to increased particle diffusivity for sub-micron particles and collection improving as size increases above $1 \mu\text{m}$ due to increased interception and sedimentation. Increased velocity decreases collection efficiency, with greater impact for submicron particles. The characteristic minimum in collision efficiency is a universal phenomenon, shown in Chap. 9 of this text for bubble-particle collisions in dissolved air flotation and elsewhere for collisions of aerosols with pine needles and the human nose and lungs. Values of η_T for virus (100 nm), bacteria ($1 \mu\text{m}$), and cyst ($10 \mu\text{m}$) sized particles from Fig. 10-11 are 0.0025 , 0.00056 and 0.0062 , respectively.

The next step in the fundamental approach is to take the results for a single media grain (or collector) as represented by η_T and integrate this over an entire bed of length L . The result is (Yao et al., 1971):

$$\ln \frac{C_L}{C_0} = -\frac{3(1-\epsilon)}{2d_c} \alpha \eta_T L \quad (10-12)$$

TABLE 10-4 Definitions of Parameters in Eq. 10-11 for Single-Collector Efficiency η_T

Parameter	Definition	Parameter	Definition
N_R	$\frac{d_p}{d_c}$	d_p	Particle diameter
N_{Pe}	$\frac{Vd_c}{D_\infty} = \frac{3\pi\mu d_c d_p V}{kT}$	d_c	Collector (grain diameter)
$N_{v,DW}$	$\frac{H}{kT}$	D_∞	Particle diffusivity ($kt/3\pi\mu d_p$)
N_A	$\frac{H}{3\pi\mu d_p^2 V}$	ϵ_0	Clean-bed porosity
N_G	$\frac{d_p^2(\rho_p - \rho)g}{18\mu V}$	g	Gravitational acceleration
A_S	$\frac{2(1-\gamma^5)}{2-3\gamma+3\gamma^5-2\gamma^6}$	H	Hamaker constant
γ	$(1-\epsilon_0)^{(1/3)}$	k	Boltzmann's constant
		T	Temperature
		V	Superficial filtration velocity
		ρ_p, ρ	Density of particle, water
		μ	Viscosity of water

FIGURE 10-11 Calculated clean-bed single-collector removal efficiency as a function of particle size for two filtration velocities according to Eq. 10-11 ($d_c = 0.5$ mm, $V = 5$ and 20 m/h, $T = 20^\circ\text{C}$, $\rho_p = 1050$ kg/m³, $\epsilon_0 = 0.4$, $H = 1.0 \times 10^{-20}\text{J}$).

where C_L and C_0 are the filtrate and influent concentrations of particles, L is the depth of the filter bed, ϵ is the porosity of the clean bed, and d_c is the diameter of the media (collector) grains. Equation 10-12 can be used to examine the impact of several key variables on particle removal. Figures 10-12 and 10-13 show plots of fraction of influent particles removed (or percent removal) and the negative of the log of the fraction remaining in the filter effluent (the log removal) as a function of particle size for specified other conditions. Figure 10-12 has results for a typical single-media sand filter with a 0.60 m (2.4-ft) depth of 0.5 mm diameter sand operated at a filtration rate of 5 m/h (2 gpm/ft²) with a porosity of 0.4. Results for two values of the attachment efficiency are shown: $\alpha = 1$ for complete destabilization (good coagulation) and $\alpha = 0.01$ for somewhat stable particles (poor coagulation). The minimum in removal for the approximately 1 μm particle size is again apparent, as is the very significant detrimental impact of poor coagulation. Laboratory studies have demonstrated experimentally the effects of particle size and chemistry that are consistent with the theory (Yao et al., 1971; Fitzpatrick and Spielman, 1973; Tobiason and O'Melia, 1988; Tobiason et al., 1993). One of the most important points from Fig. 10-12 is that if poor removal of submicron particles, such as viruses, is observed, it is not due to their size; most likely surface and bulk chemistry conditions result in the sticking probability α being low for these particles.

FIGURE 10-12 Effect of particle size on predicted clean-bed removal for typical depth (0.6 m) of typical sand (0.5 mm) media at a low filtration rate (5 m/h) for excellent ($\alpha = 1$) and poor ($\alpha = 0.01$) coagulation (calculated using Eqs. 10-11 and 10-12; other parameters are the same as for Fig. 10-11.)

FIGURE 10-13 Effect of particle size on predicted clean-bed removal for deep bed (1.5 m) of coarse (1.0 mm) media at a high filtration rate (15 m/h) for excellent ($\alpha = 1$) and poor ($\alpha = 0.01$) coagulation (calculated using Eqs. 10-11 and 10-12; other parameters are the same as for Fig. 10-11.)

Figure 10-13 has results for a deeper filter (1.5 m or 5.9 ft) of coarser media (1 mm diameter) operated at a higher filtration rate (15 m/h or 6 gpm/ft²). Predicted particle removal is worse than calculated for the shallower bed of finer-grained media operated at a lower rate despite the L/d_{10} ratio of 1500 for the deeper bed versus 1200 for the shallower bed. This result and the variables on the right-hand side of Eq. 10-12 show that maintaining or even increasing somewhat the L/d ratio for higher-rate filters of coarser media does not provide equal particle removal. According to Eq. 10-12, it is the value of $(\eta_T L)/d_c$ that should remain constant (assuming constant sticking probability). The collision efficiency decreases significantly as HLR (or V) and media diameter, d_c , increase; for the interception mechanism of particle removal η_T is approximately proportional to d_c^{-2} , so the value of L/d_c^3 should be maintained, not L/d_c . Lawler and Nason (2006) present the concept of a characteristic removal length and show the need for increasing the L/d_c ratio as media size and filtration velocity increase. The preceding analysis suggests a risk of less than desired particle removal for high-rate, coarse-media filters, especially if no layer of finer sand media is placed below the deep-bed of coarse media; Kawamura (2001) recommends use of 0.3 m (1 ft) of sand if the media effective size exceeds 1.5 mm. Modeling and laboratory results presented by O'Melia and Shin (2001) demonstrated the importance of the layer of smaller-size media below a layer of coarser media in maintaining desired particle removal.

Combined Microscopic/Macroscopic Models for Dirty Media. The fundamental/microscopic approach to filtration theory has had most success in describing clean-bed or initial particle removal. The changes in particle removal and thus within-media particle deposition over time and bed depth have to date proved too complex to model in a rigorous manner on the scale of particles and pores. Deposited particles alter fluid streamlines and provide greatly increased probability for being contacted by a subsequent suspended particle—hence the observed deposition in Fig. 10-9 for aerosols. Some models that have been developed based on a combination of the fundamental approach and the empirical or phenomenological approach are mentioned here.

O'Melia and Ali (1978) presented a model for filter ripening, or improved particle removal caused by previously retained particles. Removal by the original media was modeled with the Rajagopalan and Tien (1976) equation for single-collector efficiency. Deposited particles were accounted for and allowed to act as collectors for additional particles. Chemical effects were accounted for by attachment efficiency factors, and another empirical factor was used to describe the fraction of the deposit that was able to collect other particles. The model was fit to filter-ripening data from laboratory experiments with suspensions of monodisperse polystyrene particles. The model was subsequently incorporated into particle-based models for combined flocculation, sedimentation, and filtration performance (Lawler et al., 1980) and cost-optimal treatment plant design (Wiesner et al., 1987b). Other researchers subsequently have expanded the hybrid microscopic/macroscopic approach to include limits on maximum deposition (ultimate deposit) as well as particle detachment (e.g., Vigneswaran and Tulachan, 1988; Tobiason and Vigneswaran, 1994). While the modeling work, with a special emphasis on suspended particle size and attachment efficiency, has not resulted in significant advances in design, it has allowed for rational interpretation of filter performance, as measured by turbidity and particle counting. For example, observations of faster ripening based on greater than two micron diameter particle counts than that based on turbidity (which is more affected by 0.5 to 1 μm particles) is expected based on fundamental theory at the particle and pore scale. Additional insight regarding the role of particle size on filtration performance is gained by considering the morphology of deposited particles based on fundamental concepts of fractal geometry (Veerapaneni and Wiesner, 1997; Vigneswaran and Tobiason, 1998).

Head Loss Theories and Models

Theories for the loss of head (or pressure) when water flows through a media filter include fundamental and well-established work for clean media and much more empirical (or phenomenological) approaches for head loss development during the filter run. Both are described below.

Clean Bed Head Loss. The head loss (i.e., pressure drop) that occurs when clean water flows through a bed of clean filter media can be calculated from well-known equations. The flow through a clean filter of ordinary grain size (i.e., 0.5–1.0 mm) at ordinary filtration velocities (5–12 m/h or 2–5 gpm/ft²) would be in the laminar range of flow depicted by the Kozeny equation (Fair et al., 1968) that is dimensionally homogeneous (i.e., any consistent units may be used that are dimensionally homogeneous*):

$$\frac{h}{L} = \frac{k\mu}{\rho g} \frac{(1-\varepsilon)^2}{\varepsilon^3} \left(\frac{a}{v}\right)^2 V \quad (10-13)$$

*Units are not presented for all dimensionally homogeneous equations in this chapter.

where h is the head loss in depth of bed L , g is the acceleration of gravity, a/v is the grain surface area per unit of grain volume (i.e., specific surface $S_v = 6/d$ for spheres and $6/\psi d_{eq}$ for irregular grains), d_{eq} is the grain diameter of a sphere of equal volume, μ is the absolute viscosity of the fluid, ρ is the mass density of the fluid, k is the dimensionless Kozeny constant, commonly found to be close to 5 under most filtration conditions (Fair et al., 1968), with the other variables as previously defined.

The Kozeny equation is generally acceptable for most filtration calculations because the Reynolds number (Re) based on superficial velocity is usually less than 3 under these conditions, and Camp (1964) reported strictly laminar flow up to Re of about 6, where Re is

$$Re = \frac{Vd_{eq}\rho}{\mu} \tag{10-14}$$

The Kozeny equation can be derived from the fundamental Darcy-Weisbach equation for flow through circular pipes:

$$h = \frac{fLU^2}{D(2g)} \tag{10-15}$$

where f is the friction factor, a function of pipe Reynolds number and pipe roughness, D is the pipe diameter, and U is the mean flow velocity in the pipe.

The derivation is achieved by considering flow through porous media analogous to flow through a group of capillary tubes of hydraulic radius, r (Fair et al., 1968). The hydraulic radius is approximated by the ratio of the volume of water in the interstices per unit bed volume divided by the grain surface area per unit bed volume. If N is the number of grains per unit bed volume, v is the volume per grain, and a is the surface area per grain, then the bed volume is $Nv/(1 - \epsilon)$, the interstitial volume is $Nv\epsilon/(1 - \epsilon)$, and the surface area per unit bed volume is the product of N times a , leading to $r = \epsilon v/(1 - \epsilon)a$. The following additional substitutions are made: $D = 4r$, $U =$ interstitial velocity $= V/\epsilon$, $f = 64/Re'$ for laminar flow, and $Re' = 4(V/\epsilon)r\rho/\mu$ is the Reynolds number based on interstitial velocity.

For larger filter media, where higher velocities are used in some applications or for velocities approaching fluidization (as in backwashing considerations), the flow may be in the transitional-flow regime, where the Kozeny equation is no longer adequate. Therefore, the Ergun equation (Ergun, 1952a), Eq. 10-16, should be used because it is adequate for the full range of laminar, transitional, and inertial flow through packed beds (Re from 1–2000). The Ergun equation includes a second term for inertial head loss.

$$\frac{h}{L} = \frac{4.17\mu}{\rho g} \frac{(1-\epsilon)^2}{\epsilon^3} \left(\frac{a}{v}\right)^2 V + k_2 \frac{(1-\epsilon)}{\epsilon^3} \left(\frac{a}{v}\right) \frac{V^2}{g} \tag{10-16}$$

Note that the first term of the Ergun equation is the viscous energy loss that is proportional to V . The second term is the kinetic energy loss that is proportional to V^2 . Comparing the Ergun and Kozeny equations, the first term of the Ergun equation (viscous energy loss) is identical to the Kozeny equation except for the numerical constant. The value of the constant in the second term, k_2 , was reported originally to be 0.29 for solids of known specific surface (Ergun, 1952a). In a later paper, however, Ergun reported a k_2 value of 0.48 for crushed porous solids (Ergun, 1952b), a value supported by later unpublished studies at Iowa State University. The second term in the equation becomes dominant at higher flow velocities because it is a square function of V . The Kozeny equation, however, is more convenient to use and is quite acceptable up to $Re = 6$.

The ability to calculate head loss through a clean fixed bed is important in filter design because provision for this head loss must be made in the head loss provided in the plant;

increased clean-bed head loss for a fixed total available head loss means that there is less available clogging head loss. As is evident from Eqs. 10-13 or 10-16, the head loss for a clean bed depends on the hydraulic loading rate V , grain size, water viscosity, bed porosity, and grain sphericity. Higher HLRs are often accompanied by larger media (and greater bed depth) in part to address head loss issues. In northern climates, water viscosity can change by a factor of 2 from summer to winter, which means that designers must consider the cold water viscosity as a design constraint.

Example 10-1 Head Loss Calculations

Calculate the head loss for the 0.91 m (3 ft) deep bed of the filter sand shown in Fig. 10-4 at a filtration rate of 14.7 m/h (6.0 gpm/ft²) and a water temperature of 20°C using a grain sphericity of 0.75 and a porosity of 0.42 estimated from Table 10-2. Sphericity and porosity can be assumed constant for the full bed depth.

Solution Because the sand covers a range of size and will be stratified during backwashing, divide the bed into five equal segments, and use the middle sieve opening size for the diameter term in the solution. Solving the Kozeny equation in SI units:

$$\frac{h}{L} = \frac{k\mu(1-\epsilon)^2}{\rho g \epsilon^3} \left(\frac{a}{v}\right)^2 V$$

$$\frac{a}{v} = \frac{6}{\psi d} = \frac{6}{0.75d} \tag{10-13}$$

$$\frac{\mu}{\rho} = \nu = 1.004 \times 10^{-6} \text{ m}^2/\text{s at } 20^\circ\text{C}$$

$g = 9.81 \text{ m/s}^2$

$k =$ Kozeny’s constant, which is typically 5 for common filter media

$V = 14.7 \text{ m/h} = 4.08 \times 10^{-3} \text{ m/s (0.0134 ft/s)}$

So

$$\frac{h}{L} = 5 \frac{1.004 \times 10^{-6}}{9.81} \frac{(1-0.42)^2}{0.42^3} \left(\frac{6}{0.75d}\right)^2 4.008 \times 10^{-3} = \frac{6.067 \times 10^{-7}}{d^2}$$

From Fig. 10-4, select mid-diameters and calculate h/L for each selected mid-diameter:

Size	Mid-diameter (mm)	$\frac{h}{L}$	Layer depth (m)	$h(m)$
d_{10}	0.54	2.08	0.18	0.38
d_{30}	0.66	1.39	0.18	0.25
d_{50}	0.73	1.14	0.18	0.21
d_{70}	0.80	0.95	0.18	0.17
d_{90}	0.87	0.80	0.18	0.15
	Average	1.27	Total	1.16

Alternatively, because each layer was the same depth, the average h/L can be used to calculate the head loss for the 0.91 m (3.0 ft) bed of sand, $L = 0.91 \text{ m}$, average $h/L = 1.27$, $h = 1.27 \times 0.91 = 1.16 \text{ m (3.81 ft)}$ of water. ▲

Head Loss Development During Filter Run. As filtration progresses and solids are deposited within the void spaces of the bed, the porosity of the bed decreases, causing a

significant increase in total head loss because of the increasing clogging head loss. Head (or pressure) must be provided in the plant design for both the clean-bed and clogging head loss components. The clogging head loss to be provided is usually based on prior experience for similar waters and treatment processes or on pilot studies because there are no universal fundamental theories or models for clogging head loss. A brief discussion of some empirical modeling work follows.

A general equation for head loss development can be written as

$$h(t, z) = h_0 + fn[\sigma(t, z)] \quad (10-17)$$

where $h(t, z)$ is the total head loss, h_0 is the clean-bed head loss, and the second term is a function of the amount (and character) of specific deposit σ . The amount of specific deposit is directly proportional to the solids loading to the filter (VC) and the particle removal efficiency. The specific deposit varies across the filter depth as well as during run time. In addition, the character of the specific deposit (shape, volume, and strength) is affected by the nature of the deposited particles and physical variables (media size and HLR). Thus fundamental modeling is challenging. Laboratory and field results often show a linear rate of head loss development with time at constant HLR. In such a case, the function in Eq. 10-17 is a constant times run time; the constant is a rate of head loss increase, sometimes expressed in centimeters per hour (inches per hour). Studies show that the value of this constant varies with many factors, including type of raw water, type and dosage of coagulant(s) and filter aid, pretreatment and filtration design, and operating variables.

Results of laboratory studies with model particles have shown dramatic impacts of particle size on head loss development; for the same suspended particle mass concentration, submicron particles cause much greater head loss than larger particles (Habibian and O'Melia, 1975; Tobiasson et al., 1993). Researchers have attempted to describe this impact based on greater exposed surface area for smaller particles (O'Melia and Ali, 1978) and on greater deposit volume (more pore clogging) as a result of the fractal nature of the deposit (Veerapaneni and Wiesner, 1997). Implications for treatment application are that optimal pretreatment for filtration, especially direct filtration, may be based on increasing particle size via flocculation to decrease head loss development; a laboratory study (Westerhoff and Tobiasson, 1991) and pilot results for in-line versus direct filtration (Glaser and Edzwald, 1979; Edzwald et al., 1987) support this concept.

RAPID-RATE FILTER PERFORMANCE

Effluent Quality During a Filter Run

General Pattern. As shown generically in Fig. 10-3, the effluent quality for an individual filter often varies during the run cycle. Quality typically is poorer at the beginning or ripening period of the filtration run cycle, is relatively stable and excellent for a prolonged period, and may deteriorate near the end of the cycle if the cycle is prolonged for a sufficient period of time. The particles removed in the filter are held in equilibrium with the hydraulic shearing forces that tend to tear them away and carry them deeper into or through the filter. Initially, deposited particles acting as collectors cause improved removal performance with time. As deposits increase, the velocities through the more nearly clogged upper layers of the filter increase, and eventually, these layers become less effective in removal. The burden of removal passes deeper and deeper into the filter (Eliassen, 1941; Stanley, 1955; Ling, 1955). Ultimately, adequate bed depth with removal capacity is not available, so filter effluent quality deteriorates (referred to as *breakthrough*), and the filter must be backwashed. As indicated elsewhere, it is important to note that some filter influent particles pass through

the filter throughout the filter cycle and that many filter effluent particles are very likely to be particles that have detached from the media after prior attachment, especially as the filter run progresses (Kim and Tobiasson, 2004). In addition, if the filtration rate of a filter that contains deposited solids is increased, the hydraulic shearing forces also increase, causing some particles to detach, and these may appear in the filter effluent. This aspect of filtration is discussed in detail later.

Initial Performance—Filter Ripening. Cleasby and Baumann (1962) presented detailed data on filtered water quality early in the filter run observed during filtration of precipitated iron (Fig. 10-14). The filtrate was observed to deteriorate for a few minutes and then improve over about 30 minutes before reaching the best level of the entire run. Thereafter, as the 16 to 18 hour filter cycle progressed, steady deterioration of filtrate quality occurred at the highest filtration rate of 15 m/h (6 gpm/ft²) but did not occur at HLRs of 5 and 10 m/h (2 and 4 gpm/ft²), nor in a constant head loss run, where the filtration rate declined from 15 m/h (6 gpm/ft²) at the beginning of the run to about 10 m/h (4 gpm/ft²) at the end of the run.

FIGURE 10-14 Initial effluent improvement on filter startup after backwash. Numbers by curves indicate filtration rate in gallons per minute per square foot. (Source: Cleasby and Bauman, 1962.)

The initial peaks in Fig. 10-14 occurred at approximately the theoretical hydraulic detention time of the filter plus the detention time of the effluent appurtenances to the point of turbidity monitoring. Based on the work of Amirtharajah and Wetstein (1980), it is useful to consider a generic conceptual plot of filter effluent quality versus volume of water filtered per unit area of filter, as shown in Fig. 10-15. After backwash ends, filter effluent is first the clean backwash supply water from the underdrain system, followed by backwash remnant water from within the pores of the filter media, then backwash remnants above the media bed, and finally, new filter influent water. The actual pattern of filter effluent quality for a specific filter is site-specific and depends on many factors, including details of

the backwashing process (i.e., duration, flow rates, and use of air scour), chemistry of the backwash water (i.e., presence of chlorine or phosphate, pH level, and addition of coagulants), method of filter box refilling (i.e., with backwash versus influent), and approach to filter startup (i.e., resting of the filter and initial rate of filtration). It is recommended that operators determine the volume for each component of the filter box (e.g., as in Tobiasson et al., 1996) and analyze initial filter effluent, as shown in Fig. 10-15, in order to understand sources of filter effluent particles and thus inform possible improvement strategies. For example, Amburgey et al. (2003) showed that the initial ripening peak could be eliminated by ending the backwash with a period of subfluidization flow to remove within media remnant particles after the media had returned to their filtration-mode packing. Colton et al. (1996) showed that a no-flow resting period after backwash also could decrease the turbidity ripening peak significantly.

FIGURE 10-15 Filtrate quality during startup after backwash.

The initial filtrate quality degradation period also has been demonstrated based on levels of particles and microorganisms. For example, in a study by Logsdon et al. (1981b), *Giardia muris* (used as a model for the human pathogen *G. lamblia*) was spiked into a low turbidity surface water, coagulated with alum alone or alum and nonionic polymer, flocculated, and filtered through granular media filters. Initial concentrations of cysts in the filtrate were from 10 to 25 times higher than those following the initial improvement period, even though the turbidity improved less than 0.1 ntu during the period. Results from this and other studies were the basis for the USEPA to determine that the poorer initial quality of individual filter effluent was a significant health risk. The 1998 IESWTR established monitoring requirements for individual filter effluent quality during the first 4 hours of operation in addition to the requirement of less than 0.3 ntu in the combined filter effluent for more than 95 percent of measurements; LT1ESWTR and LT2ESWTR maintain these requirements, and the LT2ESWTR identifies the possibility of additional *Cryptosporidium* log removal credit for achieving lower effluent turbidity (see Chap. 1 and earlier in this chapter).

The Practice of Filtering to Waste. In conventional water treatment practice, passage of turbidity during the initial degradation and improvement (i.e., ripening) period is relatively small when averaged over the entire filter run and compared with the total turbidity passed during

the run. For many years, little attention was paid to the effect of the initial period on the average filtrate quality on the assumption that disinfection would control pathogenic microorganisms that passed through the filters. Consequently, based on this assumption, the early-twentieth-century practice of filtering to waste at the beginning of the filter cycle was largely abandoned; many plants were constructed without the valves and piping to allow for filtering to waste. However, interest in filtering to waste increased in the latter part of the twentieth century because of increasing outbreaks of giardiasis and cryptosporidiosis caused by protozoan cysts that are very resistant to chlorine disinfection. Provision of piping to be able to conduct a filter-to-waste period is now strongly encouraged because of the low infective dose for these protozoan pathogens (see Chaps. 2 and 18). Analysis of initial filtrate quality, as shown in Fig. 10-15, can be useful in determining the appropriate filtrate volume to waste based on filtrate quality; selection of an arbitrary filter-to-waste fixed time period without such analysis may compromise the quality improvement objective of this practice or be wasteful of excellent quality filtrate.

Steady State Period and End-of-Run Breakthrough. For conditions of proper pretreatment and constant hydraulic loading, it is common to achieve relatively long periods (e.g., 24–72 hours) of very low and constant effluent turbidity (e.g., <0.1 ntu) in media filter effluent. Early work on surface water treatment by Robeck et al. (1964) showed that for strong floc conditions, the filtrate quality was nearly constant after the initial improvement period, whereas for weak floc conditions, terminal turbidity breakthrough was rather abrupt and occurred at low head loss. In other cases, however, the filtrate quality may improve throughout the run, and no terminal breakthrough is observed (Cleasby, 1969b). Effluent turbidity versus run-time results for four pilot filters are shown in Fig. 10-16; specifications for the filter media are shown in Table 10-5 [see Edzwald et al. (1999) for study details]. These data illustrate how HLR and media configuration may affect effluent turbidity. The typical dual-media filter operated at 10 m/h (4 gpm/ft²) had constant turbidity and no breakthrough over a 24-hour period, whereas three filters of deeper and coarser media operated at 20 m/h (8 gpm/ft²) HLR had similar steady state effluent turbidity and showed breakthrough in an expected sequence based on media size and configuration (largest single-media first, then finer single-media, then dual-media with a finer lower sand layer).

FIGURE 10-16 Turbidity profiles for four pilot filters after alum coagulation; dissolved air flotation prior to filters (see Table 10-5 for filter media descriptions).

TABLE 10-5 Specifications for Pilot Filter Media for Data in Figs. 10-16, 10-20, and 10-21

Filter	Media type(s)	Media depth(s), cm	Effective size, mm	Uniformity coefficient	<i>L/d</i> ratios
1. LR CONV DM Conventional dual media, 10 m/h	Anthracite	60	0.90–1.00	1.4–1.5	630
	Sand	30	0.50–0.55	1.3–1.4	570
2. HR COARSE MM Deep-bed, coarser single media, 20 m/h	Anthracite	200	1.25–1.35	<1.5	1200 (total) 1540
3. HR DM Deep-bed, dual media, 20 m/h	Anthracite	170	1.25–1.35	<1.5	1310
	Sand	30	0.55–0.65	1.3–1.4	500
4. HR FINE MM Deep-bed, finer single media, 20 m/h	Anthracite	200	1.05–1.15	<1.5	1810 (total) 1820
